(a) Generators, motors, electric locomotives, switchboards, light bulbs and the like. (b) Transmission and distribution wire and bus bars, accounting only for the public utility companies. (c) Does not include starter, generator and ignition equipment. (d) Bearings, bushings, lubricators, valves and fittings. (e) Excludes electrical work. (f) Includes air conditioning beginning with 1933. (g) Other than railway. (h) Exclusive of electrical equipment. (i) Includes industrial wire and cable, wire in buildings, railway cars and ships, military, railway and municipal signaling, railway electrification, trolley wire, rod and wire for governmental projects, blasting wire, flexible cord and sundries. (j) Includes condenser tubes, oil-burner tubing, welding rod, screw machine products, nickel silver and phosphor bronze products, rivets and burrs, toilet pins, eyelets and grommets, electrotyping and engraving sheet, spark plugs, inner tube valve stems, jar tops and rouge boxes, flash-light tubes, kerosene lamps, kitchen utensils, kitchen range boilers, linotype matrices, safety razors, blasting caps, asbestos textiles, water meters, thermostats, soldering coppers, yacht fittings, coinage, washing machines, household water heaters, fire extinguishers, pumps, airplanes, engines and sundry machinery, all reckoned in terms of copper content. (k) Computed after deduction of manufactures for export. Exports in 1940 increased because of foreign military demands and similar requirements.

This tabulation is an accounting for final use of refined copper exrefineries and copper content of mill products. Annual discrepancies are ascribable to (1) plus or minus in stocks and (2) statistical error. In this table the production of the ingot manufacturers does not enter except in so far as they used copper from the primary refiners.

Statistics relative to the uses of copper are compiled regularly by the American Bureau of Metal Statistics. These statistics from 1932 to 1940 are given in Table V. Similar data, on a percentage basis, are given in Table VI.

During World War II, copper was used entirely for war material and related essential uses. The normal pattern of use was therefore radically changed. This is clearly shown by Table VII, summarizing the deliveries of copper during two years of the war, under the Controlled Materials Plan, which governed the allocation of steel, copper and aluminum during the war.

As indicated in Fig. 1 and 2, the three prime industries using copper are the brass mills, the wire mills and foundries. A minor fraction of the copper produced is consumed in chemicals and for alloying steel, aluminum and other base metals. However, reliable statistics are not available concerning copper used for these purposes.

In the following sections are outlined briefly the statistics applicable to each of the three prime industries using copper.

Brass Mill Products. Monthly shipment data representing almost 100% of brass mill production are compiled by the American Bureau of Metal Statistics. During World War II, the War Production Board also compiled data on brass mill production. These two series are given in Table VIII. The large difference between the figures of these two series results from the fact that the War Production Board totals include the output of several concerns which, though not brass mills, were rolling substantial quantities of sheet and strip brass for ammunition, in order to meet the greatly increased demand. The data from the War Production Board also include the output of the Defense Plant Corporation plants, which were built specifically for producing mill products for ammunition. Normally also, where the output is in the form of circles or disks, brass mill shipments are stated in terms of net weight of these products. The statistics of the War Production Board, however, give the weight of the strip from which such circles and disks were cut, thus considerably increasing the total, particularly in view of the abnormally large production of ammunition disks.

The output of brass mill products shows some interesting relationships with other features of the national economy. Thus it follows rather faithfully the trend of national income, as shown in Fig. 3. Statistics concerning shipments from brass mills are available only as far back as 1926, while copper production is indicated back to 1918, so there is an overlap from 1926 to 1932 to develop the relationship between the two series. Copper in tons is approximately equivalent to brass mill products in thousands of pounds. The correlation between brass mill shipments and national income is even more obvious in Fig. 4.

A still closer relationship exists between brass mill shipments and industrial production, as indicated by Fig. 5 and 6. It is interesting to note that the rate of change of brass mill shipments is greater than that of industrial

production in general—particularly during times of high activity. Because of the extraordinarily great use of brass mill products in war armament, this effect is, of course, accentuated in time of war, as from 1940 to 1945.

Wire Mill Products. No statistics are available for wire mill products, comparable with those for copper and brass mill products. The War Production Board published data covering wire mill production for several years during World War II, but there are no criteria for comparison with normal production.

Foundry Products. Up to the beginning of 1946, there have been no direct statistics on the quantity of castings made of copper and copper alloys. This has been quite natural, considering the fact that such work is done in a large number of small shops and that the production of many such castings is incidental to other processes.

Beginning with January 1946, the Bureau of the Census has initiated the release of data on shipments and unfilled orders of nonferrous castings, based on reports submitted by the larger foundries on Bureau of the Census Form M24E. These data, applicable to copper and copper alloy castings, are "blown up" to an estimated 100% from foundry reports representing about 90% of the total. Figures for January and February 1946, the only ones now available (June 1946) are given in Table IX.

Recently, fairly complete data have become available concerning deliveries of brass and bronze ingots, which

are the raw material for castings and which, therefore, may be considered an index to activity in that field. Beginning with 1941, the Defense Council of the Ingot Brass and Bronze Industry has been compiling such data for virtually the entire brass and bronze ingot industry and,

Table IX. Shipments of Copper and Copper Alloy Castings
(In Thousands of Pounds)

Type of Casting	January 1946 — For Sale	January 1946 — For Own Use	January 1946 — Total	February 1946 — For Sale	February 1946 — For Own Use	February 1946 — Total
Sand	38,579	26,528	65,107	33,225	23,767	56,992
Permanent mold	748	1,138	1,886	736	977	1,713
Die	466	380	846	389	356	745
All other	899	1,274	2,173	1,084	1,164	2,248
Total	40,692	29,320	70,012	35,434	26,264	61,698

based on these data, the American Bureau of Metal Statistics has presented the following tabulation.

Year	1941	1942	1943	1944	1945
Deliveries of Ingot[a]	299	397	490	512	385

(a) Brass and bronze ingots, in thousands of tons of 2000 lb. Published data from the Bureau of Mines, presumably based on the same source, agree substantially with those given above.

Course of Prices. Several trade papers publish regularly the prices for copper and various copper products. Such information is compiled conveniently in a book called "Metal Statistics", published yearly by American Metal Market, New York. These data, too extensive to include here, cover copper prices, giving the dates of all changes in prices, as well as monthly and annual high, low and average prices; extras for various shapes; prices for brass and wire mill products; brass ingot prices; and scrap prices.

On August 12, 1941, the price of copper was pegged by the government at 12 cents per pound for electrolytic copper delivered in Connecticut (equivalent to 11.87 cents f.o.b. refinery, New York), with cost-plus contracts arranged for all producers unable to meet this price. On February 1, 1942, a premium price plan was inaugurated under which quotas were set for the various producers and 5 cents per pound above the ceiling price of 12 cents per pound was offered for all production exceeding the quota, through the Metals Reserve Company, a government agency. Later a special additional premium up to 15 cents a pound was awarded to small copper mines. The over-all result has been that while the ceiling for copper during the war was maintained at 12 cents per pound, the actual prices paid, according to an OPA report, were as follows, with the government supplying the difference between the ceiling price and the higher prices paid:

Year	1942	1943	1944 (Jan. to June)	1945 (Jan. to June)
Price, ¢ per lb	12.25	13.30	13.54	13.73

During the war, also, the government controlled the procurement of the large quantities of copper obtained from abroad, paying any difference between the ceiling price and the cost. According to an official statement in February 1945, the Foreign Economic Administration, which was purchasing the foreign copper, was obtaining it at a cost of less than 12½ cents per pound.

The Production of Finished and Semifinished Copper Alloy Castings

BY THE SUBCOMMITTEE ON COPPER ALLOY CASTINGS*

THIS ARTICLE describes the production of copper alloy castings in the foundry. The following processes are discussed: melting, sand casting, permanent mold casting, die casting, centrifugal casting, precision investment casting, and plaster molding.

For some statistics concerning copper alloy foundry products the reader may refer to the preceding article. The physical and mechanical properties of 25 cast copper alloys are presented on pages 935 to 942.

Melting

BY H. M. ST. JOHN*

BRASS FOUNDRY PRACTICE is exceedingly variable both as to the kind of melting equipment used and as to procedure. There are sound reasons for much of this variability but some of it is probably unnecessary and uneconomical. The industry has been somewhat slow to take advantage of modern developments, but in recent years there has been an increasing trend toward modernization, strongly influenced by a necessity for reducing costs and improving working conditions.

The term "brass" is widely used to include the high-grade bronzes as well as compositions that consist primarily of copper and zinc. Since this discussion of melting practice deals only with foundry alloys, most of which contain substantial percentages of lead as well as zinc and tin, the word "brass" will be used rather loosely to include all such compositions. The number of alloys in this category is excessively large, in spite of much recent progress toward standardization and the elimination of many meaningless variations. However, with few exceptions, the same melting practice applies to all.

Furnaces. The types and sizes of melting equipment in common use are widely different because of the great differences in size and scope of brass-foundry operations. "Captive" foundries, producing castings only for the manufacturing establishments of which they are a part, may be large or small, may work with many alloys or few. The volume of castings produced may favor highly mechanized production methods, or the diversity of production in kind or size may make such methods unprofitable. The same applies to jobbing foundries, although a large proportion of these are small and thus are not in a position to take full advantage of equipment and practices that have been developed for volume production.

Electric Furnaces. Most large brass foundries make some use of electric furnaces and some foundries employ no other type. The electric furnaces in most common use are: (1) indirect-arc furnaces that oscillate or rock during melting, to ensure a thorough mixing of the charge and a uniform distribution of heat; (2) vertical-ring induction furnaces that also keep the metal in motion during melting, by means of electromechanical forces inherent in the design of the furnace. In less common use are high-frequency induction furnaces—which have a definite place in the melting of brass, but are more widely employed in other fields of the foundry industry—and a type of oscillating furnace that employs an incandescent resistor instead of the electric arc.

The initial investment for electric furnace installations is high, yet when these furnaces are properly operated under suitable conditions, the cost of operation is low. Both the efficiency and the "fixed charges" economy of the furnace depend on steady use with a minimum of interruption and delay. The supply of electric power must be reliable and reasonably cheap. Skilled labor must be

* Wm. Romanoff (H. Kramer & Co.), *Chairman*
Each member of this subcommittee has written on a particular process of casting. The authors of the sections are indicated below each subtitle.
* Superintendent, Brass Foundry, Crane Co., Chicago

available for the installation and maintenance of refractory linings and for electrical and mechanical repairs and adjustments. Supervisors of the melting operation must be fully versed in the requirements of the process, but the melters themselves need not be highly skilled or trained.

When the above requirements can be met, many foundrymen consider electric furnaces to be the most economical type of melting equipment for brass foundries. The utilization of electric energy is efficient if the furnaces are operated steadily for at least five 8-hr days per week. The induction furnace requires some electric current to keep it hot during standby periods and thus benefits greatly from longer hours of operation. It is particularly well adapted for melting high-zinc alloys, such as manganese bronze. In both arc and induction furnaces, losses of metal are low and metal quality and pouring temperatures are easily controlled. The cost of labor is low and working conditions are excellent if adequate ventilation is provided. Mechanical charging and handling of the metal can readily be arranged.

Both arc and induction furnaces are production machines and are less flexible in their use than the crucible. In the arc furnace, successive heats of different alloys can be made if minor contaminations of metal (lead, for example) trapped in the refractory lining are not a serious consideration. If necessary, the body of the furnace can be removed and replaced by a body with a new lining or one that does not carry the undesirable contamination; but this, if done during the working day, involves an interruption of operation. The induction furnace must ordinarily be started with molten metal, melted elsewhere, and carries a considerable heel of metal from one heat to the next, in order to maintain the electrical circuit. For this reason, changes of alloy are made infrequently.

The high-frequency induction furnace is essentially a crucible furnace and, in one of its designs, employs a removable crucible. It is thus as flexible as the older types of crucible furnace and, compared with fuel-heated crucible furnaces, it has the advantage of melting the charge much more rapidly; so it can be used to produce a heat of any metal, ferrous or nonferrous, on short notice. For this reason the high-frequency induction furnace is often employed in large plants that do not operate a production foundry but occasionally need small amounts of various alloys. It is less efficient than arc or low-frequency induction furnaces and is not commonly used for volume production work in red-brass foundries.

The resistor type of oscillating electric furnace has been designed primarily for use with manganese bronze and other high-zinc alloys. It is probably somewhat less economical than the arc furnace in the melting of red brasses and bronzes.

Fuel-Heated Furnaces. The direct-flame furnace, employing either gas or oil, is popular in both production and jobbing foundries of large and medium size. Except for rather high losses of metal, the operating costs are low. The cost of the equipment and installation is much lower than for electric furnaces. Melting is rapid and flexibility of use is about the same as with indirect-arc electric furnaces. More skill is required on the part of the melter to control metal quality and pouring temperatures, and working conditions are only fair. However, irregular operation has no great effect on costs and, in some instances, the supply of gas or oil is cheaper or more reliable than that of electricity. Where the foundry's requirements for metal vary greatly from day to day, direct-flame fuel-heated furnaces are sometimes used to supplement electric melting.

Cupolas* for melting brass use a special quality of coke, high in fixed carbon and low in impurities, to avoid contamination that would otherwise result from direct contact between metal and fuel. The charge is melted rapidly in cupolas and excellent metal can be produced. The unavoidable loss of metal during melting is somewhat high, but other operating costs and the initial investment are low. The principal use for cupolas has been in the volume production of bearing alloys.

* For a more detailed discussion of the use of cupolas in melting brass and bronze, the reader may refer to Chapter XXI of the "Handbook for Cupola Operation", American Foundrymen's Association, 1946.

Crucible furnaces that employ oil or gas as fuel are much used in medium-sized and small foundries. The charge is melted almost as rapidly as in direct-flame furnaces, and with a considerably lower loss of metal. However, crucible furnaces are less economical in their use of labor and fuel, and the cost of replacing crucibles is a considerable item. Furnaces employing a fixed crucible, usually of several hundred pounds capacity, melt brass and bronze more cheaply than the smaller "lift-out" type, but have the disadvantage that failure of the crucible, when it occurs, puts the furnace out of commission for several hours. Working conditions are fairly good, but the melter must have a considerable amount of skill if best results are to be obtained.

Crucible furnaces heated by solid fuel are much less widely used than formerly, although many furnaces of this type are still in operation. With few exceptions they are of the "lift-out" type with crucibles that are employed for pouring as well as melting. Such furnaces are flexible and, properly handled, they produce metal of excellent quality, but they melt the charge slowly and necessarily expose it for a long period to gases and other contaminating elements that may be present.

Most foundries use a few crucible furnaces of one type or another to take care of unusual or odd-lot requirements not so easily handled in larger furnaces or production batteries.

Contamination of the Charge. The melting furnace does not refine or improve the quality of the metal it melts. Instead care must be taken not to impair quality as a result of the melting operation. In best practice, the metal charged into the furnace is carefully selected and known to be of good quality. It is not considered good economy to use miscellaneous scrap, despite the comparatively low cost of such material, nor is it common practice to make extensive use of virgin metals. Aside from foundry returns, such as sprues and gates, and machine-shop turnings from the foundry's own castings, the charge usually consists of "composition ingot" produced by secondary smelters and refiners and made to meet exacting specifications. Small percentages of virgin metals are sometimes used to increase fluidity, which otherwise is likely to be somewhat variable.

During melting, the metal is exposed to gaseous and solid impurities that may contaminate it unless suitable precautions are taken. Possibly the most dangerous of these contaminants is hydrogen or water vapor, which, in the red brasses and tin bronzes, may produce a porous open structure in cast metal, utterly destructive of its quality.

In open-flame gas-heated or oil-heated furnaces care is taken to maintain a slightly oxidizing flame, preferably 0.1 to 0.2% excess oxygen, to ensure the absence of unburned fuel. Although an experienced eye can judge the oxidizing character of the flame quite accurately, the occasional use of an Orsat apparatus is desirable for analyzing the combustion gases. An oxidizing flame is an essential precaution in crucible furnaces also, when liquid or gaseous fuels are employed. On the other hand, an excessively oxidizing condition is not economical and does not yield the highest quality of metal.

In electric furnaces there are no combustion gases and it is both possible and desirable to operate with a truly neutral atmosphere. Care must be taken to avoid introducing water with the charge. Damp charcoal is one potent source of trouble. Unless recently patched furnace linings are dried thoroughly before use, trouble will result. Pouring ladles made with rammed linings are commonly baked for hours before the preheating that immediately precedes use.

The foundry industry has not yet adopted air conditioning, but most foundrymen would probably agree that it is difficult to pour the highest quality of red metal from any type of furnace on a humid day.

Oxidizable impurities, if present as traces only, may be removed in the oxidizing atmosphere of fuel-heated furnaces. Electric furnaces have no such refining action; consequently the presence of such impurities in the charge must be scrupulously avoided. On the other hand, electric furnaces produce excellent metal from charges that consist entirely of borings; in an oxidizing atmosphere, such

a charge would suffer great loss and inferior castings might be produced.

The most important oxidizable impurities are aluminum, silicon and sulfur. Aluminum and silicon are extremely deleterious in the red brasses and bronzes and must be avoided at all costs. In the indirect-arc furnace it is essential that no finely divided carbon or soot should be on the surface of the melt, since when carbon is mixed with sand or other siliceous material and exposed to the intense heat of the arc, this combination will produce metallic silicon, with deleterious effects. Finely divided carbon will result if oil, even in small quantity, is present in the charge. In general, carbonaceous material should be avoided in electric-furnace charges, although dry charcoal is not harmful and even serves a useful purpose in induction-furnace melting. The graphite electrodes employed in the indirect-arc furnace will not be a source of injurious carbon if a clear, free-burning arc is maintained. If the voltage at the arc is insufficient or if the electrodes are damp, a smoky hissing arc will result and the carbon deposited by this smoke is likely to cause reduction of silica to silicon, thus contaminating the charge.

Fluxes. Numerous proprietary fluxes are available and are widely employed. Some of these fluxes are useful when employed in the right way at the right time; however, the indiscriminate application of any flux as a cure-all, is as likely to cause trouble as to cure it. The more powerful fluxes, like powerful drugs, should be administered "by prescription only". Probably without exception, strong fluxes shorten the life of crucibles and furnace linings. For this reason, if for no other, they should be used sparingly.

Pouring. When metal is melted in lift-out crucibles, these crucibles are naturally used for pouring. Crucibles are designed to be good conductors of heat and so lose heat rapidly during pouring. Brass is sensitive to pouring temperature and most brass castings have a short pouring range. If each mold requires only a small quantity of metal, small crucibles should be used. Refractory-lined ladles lose heat less rapidly and can be of larger size economically. It is essential that ladles be preheated thoroughly before use; otherwise they absorb heat rapidly from the metal and thereby chill it.

Pyrometry and Control of Temperature. Effective means are not in common use for measuring the temperature of metal in the furnace. It is desirable not to overheat the metal and particularly desirable not to keep it in the furnace any longer than necessary. As a rule this is subject to the melter's judgment and he must make sure that the metal is hot enough. In fuel-heated furnaces the melter has little to guide his judgment and molten metal temperatures 200 F above the desired pouring temperature are not uncommon. In electric furnaces the switchboard meters are a valuable guide and maximum temperatures 50 to 75 F above the desired temperature can be attained consistently. Pyrometers for measuring temperatures in the ladle are now widely used and are essential to good foundry practice.

Sand Casting

By R. W. Parsons*

SAND CASTING, with the lowest pattern cost and widest tolerances, is the cheapest and most widely used method of producing copper alloy castings in quantities. The process is most flexible in ability to produce various designs and sizes of castings, as well as to handle the variety of alloys that may be cast in this way. Sand casting offers the fewest limitations and castings can be obtained the most rapidly by this method.

In some respects, results do not quite equal those of other methods; the surface obtained is the least desirable, while intermediate density and pressure tightness may be expected in the casting.

Allowances. As with any casting method, sections as uniform and symmetrical as possible are desirable, with proper fillets, draft and machining allowances. The minimum section is about 3/32 in., but a casting should not be so thin over too great a length. For production, about 3 deg of draft should be allowed, though the draft angle is sometimes as small as 1 deg. Finish allowances should be $\frac{1}{16}$ in. for dimensions up to 1 ft; $\frac{1}{8}$ in. from 1 to 2 ft; $\frac{5}{32}$ in. from 2 to 3 ft; and if the equipment is crude, additional finish should be allowed. Shrinkage of $\frac{3}{16}$ in. per ft is usual for most copper alloys, but $\frac{7}{32}$ in. is used in special instances.

A relation should exist between runner and in-gates so that the runner is greater in cross section than the total area of in-gates leading from the runner to the casting or castings. Inadequate runners can cause too great chilling of the metal and may produce misruns. The association of crucible melting with copper alloys has resulted in molds being poured rather generally from one end.

The gating should ensure that the metal enters the mold as quietly as possible in order to minimize the formation of dross from metal agitation. Strainer cores are not used extensively, but either such a core or a choke in the runner is useful for controlling the flow of metal in order to avoid "washing" and dirty castings. Too much choke, especially in heavy castings, may result in such slow pouring that "wormy" surface is produced from alloys that contain zinc. The size of sprue should be related to the runner, so that the sprue can be kept filled by pouring at a fairly uniform rate. Runners should be free from sharp edges and in-gates should be filleted; where possible, in-gates should take metal between the top and bottom of the runner to avoid both dross and spilling of metal into the gates before the runner is filled.

In both design and gating, consideration should be given to directional solidification, so that the portion of the casting farthest from the gate will freeze first, the heaviest section last. The risers must remain fluid the longest so as to supply liquid metal to feed the heavy section of the casting. Passage of metal over the sand will heat the mold so that cooling will be slowest next to the gate, and also in the lower portion (drag) of the casting.

Some designs make it impracticable to employ risers for feeding heavy sections of large castings, and chills are then used to hasten solidification and make cooling more uniform. Chills can be made from cast iron. They should be given a coating of shellac and dipped in sand where the metal comes in contact with them.

Insulating the necks of heavy risers delays solidification and promotes feeding. A cup of insulating material may be used to insulate the entire riser and allow superior feeding from smaller risers.

Much thin-sectioned work is made without the use of risers, and if sections are uniform and the runner is adequate to feed out the shrinkage at the gate, satisfactory results can be obtained. With heavier sections, risers must be provided to ensure sound castings.

The metal in the riser should be hotter than the casting when the metal comes to rest. If open risers are possible, metal may be poured into them to ensure hot risers, and an insulating cover on top will help to maintain temperature. Improperly located risers (as a "dead riser"), which are not hotter than the casting, are often worse than none at all. Open risers also act as vents for the steam and gases generated during pouring. In many production shops the permeability of the sand is expected to permit the escape of steam and mold gases, and vents are not liberally used; but venting of molds wherever practicable is recommended strongly.

Blind risers (not open to the air) are employed more frequently in production foundries. However, if these risers freeze, forming a shell completely surrounding the liquid interior, atmospheric pressure is cut off, rendering the riser less effective than an open riser would be. Gas pressure within the mold may act on the blind riser to force metal into the casting effectively.

Certain alloys, such as the high-strength brasses, have higher liquid shrinkage, or localized shrinkage, and require larger risers than some of the higher-copper alloys.

Results from a given pattern or gating should be checked by some means before a pattern is released for production. In addition to the checking of external dimensions (by the pattern shop), some attention should be directed toward the internal soundness and degree of

* Technical Director, The Ohio Brass Company, Mansfield, Ohio

freedom from shrinkage, and corrective steps should be taken, if necessary, before actual production is begun.

Molding. Natural molding sands are used for the majority of copper alloy sand castings because the requirements are less exacting than where higher temperatures are encountered (for instance in the casting of steel), and such castings are usually produced by smaller concerns that do not have the equipment necessary to produce synthetic sands. Many of the alloys are more "searching" than irons, so finer (tighter) sands are used to give the desired finish.

Cores made from sands prepared as mentioned in the article entitled "Steel Castings", page 523, are usually baked, and are sometimes dipped in graphite, talc, mica, or similar material, to produce a coating that will prevent metal penetration and still allow passage of gas. Molds are sometimes given a wash for the same purpose—to produce superior finish.

Although most copper alloy sand castings are poured into green sand molds, in special instances other methods are used, as with steel (*see* page 523).

Liquid partings (composed chiefly of stearic acid in kerosene) are sprayed on the pattern plates to facilitate drawing the pattern; such partings work well on metal patterns provided no wax fillets or gates are present, and they present no dust hazard. Dry partings may be vegetable or mineral powders treated to make them water repellent. Tripoli works well but creates a silicosis hazard.

Hand molding (as compared with machine molding) requires molders with the greatest skill in order to get results, especially when gates must be cut and loose patterns used. A standardized gating will be found helpful with loose patterns. Split patterns may be mounted on wooden boards to save time and reduce the skill required in molding. At best, hand molding gives least uniformity.

Machine molding gives uniform molds with greater daily production and requires less skill on the part of the molder. It is possible to make temporary mounts of patterns and gating and to derive the benefits of machine molding without the expenditure of a large amount of money for pattern equipment. Unmounted patterns in a hard sand match, make machine molding possible and are useful where parting lines are irregular.

For large quantities and better results, metal patterns should be mounted on metal plates, or cast aluminum match plates should be used.

In machine molding, sand may be rammed by squeezer, jolt machine or slinger. A squeezer may be operated by hand, by air, or hydraulically. Air and hydraulic pressure squeeze more rapidly than hand pressure. A squeezer produces molds that are hardest at the squeezer board and softer next to the pattern; for relatively shallow flasks, this difference is not great. The jolt machine works in just the opposite way; the molds are hardest next to the pattern. As flask depths increase, a combination of jolt-squeeze may be used to produce more uniform molds.

When a double-faced match plate is used, only the drag can be jolted, because after the drag has been jolted, the bottom board placed, and the mold rolled over, a second jolting would undo the work of the first. The cope must be entirely squeezed. For full jolt-squeeze molding, single-faced match plates must be used, and either identical cope and drag halves must be made on the same machine, or the drag on one machine and the cope on another.

Machines that draw the pattern simplify the molding operation and increase production; this feature may be incorporated in squeezers, jolt-squeezers, and slingers.

Sand slingers act to throw "handfuls" of sand, at considerable velocity, on and around the pattern. The slinger head is moved around, back and forth, to obtain a uniform ramming throughout the flask. These machines are adapted to large molds and, equipped with a special head to fit over smaller flasks, are used in production shops for smaller molds on draw machines.

With snap flasks, the cope is usually deeper than the drag in some relationship such as 5 to 3. This is a highly desirable condition, because it provides an extra head of metal during pouring and increased pressure as the metal comes to rest. Since the amount of sand that the molder handles is a basic part of the cost of the mold, the height of the cope is sometimes reduced. On the other hand, where flasks are standardized and cope and drag are made on the same machine, and are the same depth, frequently there is insufficient sand above the top of some of the larger castings. Where such a condition exists, pouring cups may be used for necessary added height.

Pouring. Metal melted in stationary crucible furnaces is usually poured from the crucible directly into the molds; the melting crucible is a fairly good pouring vehicle. For transporting metal from larger furnaces, of whatever type, the best pouring medium is an insulated ladle lined with crucible material. Such ladles have a high initial cost, long life, and cannot damage the metal. Ladles are commonly lined with various ramming mixtures. Crucibles and ladles should be dried thoroughly and preheated before use.

The lip of the pouring ladle should be held as close as possible to the sprue and the metal should be introduced with a minimum of turbulence and agitation. The sprue can be shaped so as to minimize swirling. The first metal should be poured directly into the center of the sprue, not splashed around the rim, and the sprue should be kept filled during the pour. Some molds must be poured "hard" while others will be strained unless the pour is fairly easy. "Uphill" pouring of the mold cavity is recommended and uphill pouring may be followed by tilting of the mold.

It may be advantageous for the molder to pour his own mold, because he is the person most interested in seeing that it is properly done; however, in order that the molder can devote more of his time to molding, pouring crews sometimes do all the pouring. In this way the pouring specialist should become expert.

Pouring Temperature. An extremely important variable in the production of copper alloy castings—particularly those for pressure work—is the matter of pouring temperature. The optimum temperature is the lowest one that will produce sound castings. This is not the same as the lowest temperature at which the job will "run", since feeding is sometimes improved by the use of a slightly higher pouring temperature.

The pouring temperature should be maintained closer than 50 F. This *cannot* be done by eye because the appearance of the metal varies widely with the darkness or brightness of the day and with the time of day. The use of a pyrometer is imperative for good results.

A pyrometer should be used with an immersion type of thermocouple, either bare or enclosed. The bare wire gives faster readings, but the enclosed type lasts longer and can be used with all the alloys. The pyrometer may be of either the millivoltmeter of the potentiometer type. The millivoltmeter type is more common, and may be of either the high-resistance or the low-resistance type. The high-resistance type is more accurate and is affected less by variations in the thermocouple.

The pouring temperature controls the fluidity; temperature also influences the quality and finish.

When castings are made from some of the copper alloys that contain appreciable percentages of lead for ease in machining, such castings can be damaged if shaken from the molds at temperatures where the alloys are "hot short". Several of the alloys can be damaged by cooling in water from an excessively high temperature. Castings of such alloys may develop cracks through the grain boundaries.

Defects. Of great importance is the analysis of defects and the remedial measures required. A committee of the American Foundrymen's Association reported on Analysis of Defects in 1938, and the Nonferrous Ingot Metal Institute rearranged the material in chart form in the Brass and Bronze Manual.

Permanent Mold Casting

By H. G. Schwab*

PERMANENT and semipermanent mold casting may be defined as the art of producing castings in metal molds operated mechanically or by hand, with or without sand cores and without the application of external pressure. The name of the process is something of a misnomer. Although the life of a permanent mold is long and an individual

* Chief Metallurgist, The Bunting Brass & Bronze Co., Toledo

unit may be used repeatedly, the mold can hardly be considered permanent. Mold cost is high and many factors should be considered before choosing the process. In general, however, 500 castings may be regarded as the minimum number for which a permanent mold may be built economically.

Permanent mold castings have numerous advantages over sand castings. A few of these advantages are (1) higher production per unit time per unit of equipment, (2) finer grain size and improved mechanical properties, (3) closer dimensional tolerances, (4) lower costs for machining and (5) greater yield.

The permanent molding process has not been applied extensively to the casting of copper and copper alloys. However, it is gradually gaining favor and today large tonnages of rods and tubes are being produced in this way. The process has been applied successfully in the production of bearing bronzes, with superior bearing properties as a result.

The Mold. In the design of a permanent mold, attention must be focused on the necessity for the control of solidification. Directional solidification is not too difficult to attain in simple castings such as slabs or billets. However, as castings become more intricate in shape, control of solidification becomes more difficult and serious consideration must be given to the location of cores, the relation of light and heavy sections to mold partings, and the position of the gate and feeding risers. The mold cavity should be laid out so that heavy sections of the casting, wherever possible, are at the parting of the mold. If arranged in this way, such sections may be fed directly by the gate or by suitable risers. Permanent molds are costly; therefore, it is advantageous to consider all variables before the design leaves the paper stage.

A permanent mold is generally made of close-grained cast iron. Varying amounts of nickel or chromium may be added to improve the high-temperature properties of the base material. Cores may be machined from the same material or from a heat treated die steel.* After rough machining, mold sections should be stress relieved. It is also good practice to heat the finished mold thoroughly before placing it in production, as an added precaution against warping and cracking.

Painting the Mold. The most important phase of the permanent molding process is the painting of the mold. Basically, mold paints consist of a refractory material, a binder, and a lubricant (such as rouge or graphite) suspended in water and mixed to a consistency suitable for application with a spray gun. There are two general types of mold coatings—those that adhere tightly to the mold surface, giving a number of castings per coat, and those that flake off readily with the casting when it is removed from the mold. The latter type is preferred for copper alloys, especially the tin bronzes containing phosphorus. Generally the coating that flakes readily when the casting is removed, is porous and provides a good means for venting the mold cavity. Also, such a coating permits the metal to lie quietly against the mold surface, thus promoting improved casting finish. Flaking also permits cleaning of the mold cavity simply by using an air jet, and close dimensional tolerance is thus obtained. Careful thought must be given to the selection and application of the mold coating, since the quality of the casting, the surface finish and dimensional tolerance, as well as the life of the mold, depend on it.

Mold Temperature. Control of mold temperature is necessary for the production of sound castings, but at times it is rather difficult to achieve. Such control is usually effected by accurate control of the pouring temperature of the metal being cast, by the thickness of the mold sections, and by the number of molds poured per unit of time. Occasionally, localized areas must be heated or cooled externally. There are probably limiting minimum and maximum temperatures between which a mold will operate successfully and, since each mold has its own temperature range, these temperatures should be determined experimentally and maintained. In general, molds for copper alloys are operated between 250 and 700 F. A good rule for the production of copper alloy castings is this: Operate with as small a differential as possible between the mold temperature and the pouring temperature of the metal being cast.

Pouring. In the pouring of a permanent mold casting, every effort should be made to eliminate the effect of the human element. If the metal to be cast is poured too fast, agitation takes place, causing slag and dross to be trapped in the mold cavity. If the pouring is too slow, freezing takes place in the runners or feeders and misruns occur. Many devices may be used to reduce the variations in the rate of pouring, such as sumps to control turbulence, chokes in the runners, or reduction in the volume of the feeders that act to slow down the flow of metal.

The pouring temperature of a permanent mold casting is determined by the size and shape, by the thickness of section, and by the alloy being cast. The pouring temperatures of the copper alloys cover such a wide range that it is impossible to give any definite information here. However, far better results are obtained by pouring each alloy at the lowest possible temperature. High pouring temperatures lower the rate of solidification and may cause tears, cracks and general porosity. Gas holes are also a direct result of high temperatures.

The permanent mold process has proved rather difficult to apply to copper alloys, primarily because of their long freezing range and their ability to wet the mold surface. To minimize the wetting effect, great care must be taken in the selection and application of the coating material. Nevertheless, compared with sand casting, the advantages to be gained by this process are numerous. Among these advantages are better mechanical properties, finer grain size and better orientation, and lower costs of machining. The complexity of the casting need not rule out the permanent mold process, since sand cores can readily be used in conjunction with metal molds. The control of solidification is of first importance, and every effort must be expended to promote directional solidification by the proper placing of gates and risers, by the use of chills or anti-chills, and by maintenance of the right temperature in both the mold and the metal being cast. Control of the mold temperature is necessary for producing sound castings and for keeping the mold serviceable as long as possible. Close control of pouring temperature is a means for controlling the temperature of the mold and the soundness of the casting. Control of pouring must be considered from every angle for the purpose of reducing the effect of the human element to a minimum.

* See "Composition and Heat Treatment of Die-Casting Dies and Permanent Molds", page 673 in this Handbook.

Die Casting

By J. C. Fox*

AS IN the production of die castings of other alloys, the essential requirements of the die-casting process for brass are (1) a correctly designed die of suitable material, (2) a machine with a means for injecting the molten alloy into the die, and (3) a suitable alloy. A discussion of brass die castings must necessarily start with these three requirements.

Dies. Since about 1930, when the first brass die castings were produced on a commercial scale, attention has been concentrated on seeking out the most suitable die material that will yield a serviceable and economical die.

The fact that such a die material has not yet been found, has been the sole restricting influence in the die-casting of the metals and alloys that have high melting temperatures. Brass die castings can be produced with almost the same facility as those of other alloys now regularly die-cast; but because of the higher casting temperatures necessary for copper alloys, the serviceable life of dies in which copper alloys are cast, is much shorter than the life of dies in which alloys of lower melting temperatures are cast (for example, aluminum or magnesium alloys). The die steels employed for the casting of aluminum or magnesium alloys with casting temperatures up to 1300 F, are definitely unsuited for copper alloys with casting temperatures up to 1700 F.

* Chief Metallurgist, Doehler-Jarvis Corporation, New York

During operation, the extreme surface of a die-casting die for brass, may reach temperatures well above the transformation range of steels. Continued heating of the surface decreases the hardness and strength, lowers the resistance of the steel to the erosive action of the molten alloy, and generally nullifies the effect of any previous heat treatment. While casting is in progress at these high temperatures, the temperature gradients at the die surfaces are very steep, ranging from 1700 to 1750 F down to temperatures from 1100 to 1300 F only 0.050 in. beneath the die surface; and from about 900 to 1000 F at about 0.200 in. beneath the die surface. As a result of these thermal gradients, large stresses are set up that cause early heat checking of the die surfaces.

It is apparent that a suitable die material should resist the effects of these high temperatures. The ideal material should retain its hardness and other mechanical properties in use. In addition, a suitable die material should possess the following characteristics: resistance to thermal checking, resistance to thermal shock or sudden changes in temperature, resistance to erosion or the solvent action of the molten alloy, stability in heat treatment, sufficient hardness to resist deformation, and machinability.

The type of steel most commonly used at present in dies for casting brass, is one of the so-called "hot work" steels that are used for forging, swaging, extrusion and other similar methods for fabricating brass. A typical composition of a steel used in dies for casting brass is 0.30% C, 0.25% Mn, 0.25% Si, 3.5% Cr, 0.50% V, 9.0% W. The heat treatment of this type of steel is discussed in the article on "Composition and Heat Treatment of Die-Casting Dies and Permanent Molds", page 673.

Die Life. In present practice, dies for brass die castings operate from 10,000 to 50,000 cycles before replacement is necessary. The life of the die depends on the size, weight and wall section of the casting. Under similar conditions, dies for thin-walled castings outlast those for heavy-sectioned parts.

For small, thin-walled parts, a life of 50,000 or more cycles may be expected. Some of the die parts require more frequent replacement than the impression parts—particularly the gate block and sprue, which receive the full charge of the molten alloy entering the die and are consequently heated to higher temperatures than more remote parts of the die.

Design of the Dies. Dies for die-casting brass are fabricated in the same manner as dies for other alloys, except that ordinarily the dies for brass are made up in smaller sections to facilitate heat treatment and easy replacement.

The methods of gating and venting dies for brass are similar to those for other alloys.

The minimum for wall sections of brass die castings should be about 0.075 in. with an average of $\frac{1}{16}$ in. for small parts. The wall stock required depends on the size, shape, design and application of the part. Uniformity of wall section and the avoidance of heavy sections wherever possible are important in the control of limits. The walls of brass die castings, as well as the cores, require larger drafts than those used with other alloys of lower melting point. Holes $\frac{3}{16}$ in. in minimum diameter may be die-cast. The necessary taper is $\frac{1}{64}$ in. per in. depth of hole. In general, threads are not die-cast in brass.

Machines.* Brass die castings were first produced on a vertical "cold chamber" type of machine introduced by Polak about 1930. They are now also produced on the horizontal cold chamber machine that is used for the die casting of aluminum and magnesium alloys.

In the Polak process, the molten alloy is held in the furnace as a unit apart from the casting machine. The metal, at a temperature close to the melting point, is ladled into the cold chamber of the machine. Then prompt application of pressure forces the metal into a die.

In the casting cycle of the Polak machine when the die is closed, the brass alloy is ladled into a cup or chamber on top of an ejector plunger. The ejector plunger at this point blocks the gate or inlet into the die. Above the cylinder is a hydraulic ram, controlled by a valve that the casting operator opens immediately after the alloy has been ladled into the chamber. As the ram forces the ejector plunger downward, the metal is forced into the die under ram pressures ranging from 3000 to 10,000 psi. When the pressure is released and the ram withdrawn, the ejector plunger is forced upward by its spring action, which causes it to shear off the gate and sprue and to eject a solid slug of excess metal. The cycle of the casting operation is completed when the die is opened and the gate of castings is ejected.

In the horizontal type of cold chamber machine, a piston, operated by a hydraulic cylinder, applies pressure on the metal, which has been ladled into a chamber held in a horizontal position. The essential difference between the vertical and the horizontal cold chamber machines is that the latter is usually operated more rapidly and is more economical.

The speed of the injection plunger may be varied from 10 to 250 in. per sec. The proper co-ordination and regulation of such factors as speed and pressure of the plunger, temperatures of the dies and metal, gating and venting influence the quality of die castings, especially as related to soundness of structure and surface finish.

Alloys. ASTM Specification B 176-42T covers two brass alloys for pressure die casting. The limits for the composition of these alloys are shown below:

Element	Alloy *A*	Alloy *B*
Copper	57.0 min	63.0 to 67.0
Silicon	0.25 max	0.75 to 1.25
Lead	1.50 max	0.25 max
Tin	1.50 max	0.25 max
Manganese	0.25 max	0.15 max
Aluminum	0.25 max	0.15 max
Iron	0.25 max	0.15 max
Other elements	0.50 max	0.50 max
Zinc	30.00 min	remainder

Alloy *A* is a general-purpose low-cost brass with wide limits for impurities. Alloy *B* is an alloy of higher purity, capable of excellent castability and mechanical properties in the die-cast condition.

The minimum tensile properties of the alloys shown in the above ASTM specification are as follows:

Property	Alloy *A*	Alloy *B*
Tensile strength, psi	45,000	58,000
Yield strength (0.2% offset), psi	25,000	30,000
Elongation, % in 2 in.	10	15

Die-cast test bars of these alloys actually show properties far superior to these minimum figures. For instance, reports from three laboratories, concerning die-cast test bars of these alloys, show an average tensile strength of more than 60,000 psi for alloy *A* and more than 80,000 psi for alloy *B*. The average yield strength reported was more than 37,000 psi for alloy *A* and more than 50,000 psi for alloy *B*. The average Charpy impact strengths were 20 ft-lb for alloy *A* and 30 ft-lb for alloy *B*.

In addition to these brasses, another alloy is being extensively used, particularly for high strength, hardness, and resistance to wear and corrosion. This alloy has the following nominal composition and mechanical properties:

Copper	80 to 81.5
Silicon	3.5 to 4.5
Zinc	remainder
Tensile strength, psi	85,000 to 95,000
Yield strength, psi	45,000 to 50,000
Elongation, % in 2 in.	16 to 18

Die castings of this composition have been found to outwear other hard materials, and in a number of applications this alloy has replaced mild steel.

Die castings can be produced from other copper alloys, but present practice permits the use of only those alloys that have melting points not exceeding 1650 F. Aluminum bronzes, tin bronzes, low brasses and other high-copper alloys can be die-cast readily, but the melting points and casting temperatures are too high to be feasible or economical, considering their effect on the die materials available at present.

* For line drawings of machines used for die casting, see the article "Casting and Production of Zinc Alloys", page 1078.

Applications. The salient properties of brass die castings—high strength, toughness, and resistance to corrosion and wear—make these castings suitable for many varied uses, thus opening to industry a source of engineering parts that have the accuracy, intricacy, stability and economy of the die-casting process. The applications of brass die castings are too widely varied for detailed inclusion in this article, but the following partial list should indicate the potentialities: automotive gears, transmission forks, clutch parts, shock-absorber parts, pumps, bearings, parts for electrical switchboards, contactor parts, brush holders, refrigerator parts, steam-fitting valves, trunnion bearings, oil-burner parts, general engineering fittings, and household hardware.

Centrifugal Casting

By W. W. Edens*

CENTRIFUGAL CASTINGS are of three types: true centrifugal, semicentrifugal and centrifuge castings. A centrifuge casting is not truly a centrifugal casting, but rather a casting in which centrifugal force is used to provide pressure in a mold revolving outside the axis of rotation. Both true centrifugal and semicentrifugal castings can be described as castings that are spun on their own axes during casting.

The axis of rotation may be horizontal or inclined at any angle up to the vertical position. The molten metal is poured into the spinning mold cavity through a suitably sized hole at the top, and the metal is held against the wall of the mold by centrifugal force. The outside surface of the casting or the mold surface proper can be modified from the true circular shape by the introduction of flanges or small bosses but, to secure balance, the shape must be generally symmetrical around the axis. The inside surface of a true centrifugal casting is always cylindrical, although when the axis of rotation is vertical, the gravitational forces, as related to the centrifugal forces, will produce an inside surface that takes the form of a paraboloid, with the smaller inside diameter at the bottom of the casting. In correct operation, using optimum speeds and temperatures, this paraboloid effect can be held to a minimum and, in any event, is readily removed by the rough boring operation.

Semicentrifugal castings are much the same as true centrifugal castings except that, in this type of casting, a central core is used that will allow for shapes other than a true cylinder to be produced on the inside surface of the casting; and the mold is always spun vertically. Not all shapes and sizes can be produced by this method. Successful application depends on the specific size, shape and balance of the particular casting to be produced.

Centrifuge castings are not truly centrifugal castings. In basic principle they employ a static type of mold into which the metal is poured usually through a central sprue on the axis of rotation. Centrifugal force, ordinarily of an extremely low order, is used for helping to feed the castings, which are mounted around the central sprue.

The Production Process. *Equipment.* The equipment for producing centrifugal castings may vary considerably in detail, but basically it consists of a shaft, suitably mounted in bearings and supporting a spider or face plate to which the mold is bolted or otherwise fastened. Individual molds may be bolted to this face plate or, more frequently in small work, a suitable liner is fastened to the face plate, into which the actual molds can be fitted, allowing for easy interchangeability. On the end of the mold opposite the face plate, a suitable cover is placed and fastened by some mechanical means, such as bolting. In the center and on the axis of rotation of the entire mold proper, the cover has a suitably sized hole through which the molten metal can be introduced into the mold. The size of the hole will vary with the inside diameter of the casting, as well as with the size and weight of the casting.

Speed of Rotation. The speed of rotation and the rate of introducing the metal into the mold, vary with the individual casting to be produced. Generally the speed of rotation is governed by either one of two means:

1 Spinning all castings at a speed that will give a fixed amount of centrifugal force expressed by the term G. The centrifugal force will vary anywhere from 50 to 100 G's, using the formula $G = 0.0000142n^2d$, where d is the inside diameter of the casting in inches and n is the number of revolutions per minute. G is then expressed as centrifugal force in pounds per pound.
2 Spinning the molds at a speed that will give a standard velocity of the mold face, where the mold velocity in feet per minute equals πdn, where d is the diameter in feet and n is the number of revolutions per minute.

Common practice seems to favor the first method.

Rate of Pouring. The rate of pouring is usually kept as rapid as possible within the limitations of the diameter of the cover hole, as determined by the inside diameter and weight of the casting. For molds spun on a horizontal axis, the metal is poured at a rate of speed within the ability of the metal to be picked up onto the rotating wall of the mold, so that an excessive pool of metal cannot accumulate in the lower portion of the mold, making it possible for molten metal to run out of the entry hole. The rate of pouring is generally higher than for the same size of castings produced by static methods, primarily sand molding. The rate may vary considerably with the type and size of casting being made.

Molds. The molds used in centrifugal casting are of three general types.

1 Metal molds of cast iron or mild steel are frequently used, particularly when the quantity required will justify the original expense of making the mold. The tin bronzes cause some difficulty in cast-iron molds, but proper washing of the mold with a refractory coating, usually applied by spraying, minimizes this difficulty effectively. Other metals, such as copper, are selected occasionally as mold materials, but are ordinarily limited to extremely small castings. It is normal practice to provide a taper of as much as ⅛ in. per ft on the wall of the mold from top to bottom, as provision for removal of the casting after solidification. In castings 12 in. or more in diam, this taper can be minimized, and in some castings eliminated entirely, since the shrinkage of the casting is usually sufficient to allow reasonably easy removal.
2 Graphite is commonly used as a mold material, giving intermediate service life for jobs that entail medium-length runs. The use of graphite permits some economies, primarily in machining the original mold. Electrode stock is frequently used in making these molds. In such instances the size of the molds is limited primarily by the size of the electrodes available. Since graphite is relatively soft, it is quite easily scratched and marred, requiring fairly frequent dressing. Therefore this type of mold material is usually recommended only for relatively short-run jobs. Graphite does have an advantage, in casting, like that of the metal mold in that it is an effective chill or cooling medium, causing progressive solidification of the casting in a relatively short period of time.
3 Dry sand molds are frequently employed, particularly in the larger sized work, although they have the disadvantage of being usable only once. The low thermal conductivity of the sand mold provides for relatively slow cooling, which, in heavier-walled castings, is frequently less desirable than chill molds. This type of mold material has perhaps the greatest degree of flexibility and is excellent for the larger castings made in limited quantity. The mold is usually covered with a mold wash and baked dry in a core oven, much as dry sand cores are made in ordinary sand foundry production. Dry sand molds are usable for virtually all the copper alloys; but in the heavier sections and in alloys that contain lead, problems of segregation will arise, as well as possible porosity on the inside diameter of the casting. For short-run production, sand is the cheapest material even though the production is limited to one casting per mold.

Preheating. It is desirable to preheat all molds, particularly metal or graphite molds. Dry sand molds do not need to be preheated, although it is better to have their temperature above the dew point. Preheating and operating temperatures for molds will vary from about 150 to 800 F, depending on pouring temperature, size of the casting, frequency of pouring and such considerations. Temperatures above 800 F, as may be achieved in steady frequent pouring, are not recommended because of the serious effect on the durability of metal molds. For cast-iron molds, much lower temperatures are recommended.

Primary Benefits. *Yield.* Because no gates and risers are used in centrifugal casting, the yield or ratio of casting weight to weight of metal poured, is high—usually 90% or higher. The inside diameter of the casting and the top of the casting contain any dirt or dross that might have been present in the molten metal or generated in the casting operation. These inclusions are removed by a simple boring and facing operation. Of course this removed metal is in the form of turnings and borings and may or may not be reworked directly back into castings, depending on equipment available and on the particular alloy.

* Badger Brass and Aluminum Foundry Co., Milwaukee

Uniformity. The uniformity of centrifugal castings approaches that of wrought material, with the added advantage that the mechanical properties are nearly equal in all directions, in contrast with the directional properties of some wrought alloys and shapes. When ordinary sections are cast centrifugally, no noticeable or significant variation in chemical composition exists in alloys of the solid-solution type. This is true of castings made in sand molds as well as of those made in metal or graphite molds. Alloys that contain lead will show some variation in composition from the inside to the outer wall of the casting, depending on the amount of lead, the mold material and the section of the casting. This variation in composition is increased by greater amounts of lead, heavy sections, and mold materials that allow the metal to cool slowly. Table I shows typical results of chemical analysis of samples taken from a gear ring, 36 in. in diam and 8 in. long with a wall 4 in. thick, cast in a metal mold. In general, the usual composition of any specific alloy will not require modification for centrifugal casting.

Mechanical Properties. The mechanical properties of centrifugally cast copper alloys will vary with the alloy composition and will also depend to a large extent on the mold material. Centrifugal castings made in sand molds, where relatively slow cooling prevails, will have lower mechanical properties than castings made in metal or graphite "chill" molds. But even in centrifugal castings made in sand molds, the mechanical properties will average approximately 10% higher than the properties of castings of equivalent section made statically in sand molds. In centrifugal castings made in "chill" molds, these properties are occasionally 30 to 40% better, in some alloys, than the mechanical properties of similar castings made statically in sand molds. Table II lists typical mechanical properties of several alloys, taken from the same gear rings described in Table I.

Table II. Comparison of Mechanical Properties of Gear Rings Cast Centrifugally in Metal Molds and Statically in Sand Molds

See Table I for compositions of alloys

Alloy	Method of Casting	Tensile Strength, psi	Yield Strength, psi	Percentage Elongation in 2 in.	Percentage Reduction in Area
SAE 68	Static	79,200	28,900	39.8	39.5
	Centrifugal	87,600	32,200	40.1	42.5
Navy M	Static	41,460	21,140	39.3	32.5
	Centrifugal	48,775	21,200	60.6	40.1
Navy G	Static	46,675	23,900	24.8	27.8
	Centrifugal	51,500	27,100	55.0	53.5
High Lead	Static	35,680	19,460	24.4	22.7
	Centrifugal	51,250	24,800	42.0	41.0
Mn Bronze	Static	71,700	26,400	30.3	30.1
	Centrifugal	77,500	33,200	37.2	38.0

Centrifugal castings are a high-quality product and, in reasonable quantities, they can be produced economically. For small quantities, the investment in molds and the time required to set up a machine to produce a few specific castings may make the cost of the few castings seem high, but where quality is important, the additional cost is usually justified.

The production of centrifugal castings requires a thorough knowledge of basic foundry practice, plus a thorough knowledge of rotating machinery and mechanical engineering. The combination of molten metal and rotating equipment is extremely dangerous, making high factors of safety on equipment absolutely necessary, as well as experience and the utmost care and caution in the casting operation.

Precision Investment Casting

By Robert Neiman*

PRECISION INVESTMENT MOLDING consists in casting a metal or alloy into a one-piece refractory investment mold from which a pattern or cluster of patterns has been removed, ordinarily by heat, and into which the molten metal is cast, usually under pressure.

The general features of this process are discussed in the article on page 54 in this Handbook. The present article emphasizes points of the process, applications and cost that are peculiar to copper alloys.

Process. *Shrinkages and Methods of Compensation.* The precision caster has four types of dimensional change to consider. Typical values are given below:

Shrinkage of the wax pattern	−1.0%	
Shrinkage of the metal casting	−1.8%	Total −2.8%
Expansion of the investment during setting	0.3%	
Expansion of the investment during heating	1.0%	Total 1.3%
Net shrinkage		−1.5%

To compensate for the net shrinkage of 1.5%, the pattern die must be made 1.5% larger than the desired size.

Shrinkage in any given pattern material and casting alloy will vary directionally, as well as with cross section and with injection practices or casting processes.

The casting shrinkage of copper alloys in investment molds varies from 0.5% to slightly more than 2.0%. Differences in shape and size of casting and nature of investment have a greater effect than variation in the composition of the alloy.

Investments. These are refractory cements made fluid with water and poured around the patterns in a confining metal ring or flask that will set, while standing, to form a hard, heat-resisting mold. For brass, bronze and aluminum the investment is composed principally of a mixture of finely comminuted plaster and silica. In order to avoid roughness and nodules on castings, the investment is usually placed under vacuum to prevent entrapment of air. The investment molds are heated between 1200 and 1400 F to dissipate the patterns. The alloy may be cast into the hot molds or the molds may be cooled to any desired temperature.

Melting of the Alloy. Small batches of 1 to 15 lb are melted in clay-graphite crucibles by gas or by electrical induction. It is practical to use commercial ingots of the desired composition. Beryllium copper is available in convenient small ingots that weigh ½ lb; other standard alloys in similar form would be a great convenience. Fast melting usually prevents contamination and gassing. Commercial fluxes and deoxidizers may be used advantageously with some alloys.

Finish. Once the comparatively soft investment has been broken away, many copper alloy castings emerge with a smooth, clean, and often bright surface of natural color that needs no further treatment. The surface smoothness compares favorably with that produced by usual machining procedures; there is less waviness but no burnished effect. Some alloys require tumbling or blasting with a fine abrasive.

Secondary Machining. When economy or accuracy requires secondary machining, standard machine-shop practice is used for tapping, reaming, or surface grinding.

Applications. *Intricate Shapes.* The outstanding feature of the precision investment casting process is its ability to produce parts of intricate shape. This is possible because a wax pattern can be made in an exactly fitting, multiple-pieced, cored metal die; after the pattern has been invested, it need not be removed from a split mold. This method usually eliminates from 75 to 95% of the

* Director of Research, Whip-Mix Corporation, Chemicast Division, Louisville, Ky.

Table III. Mechanical Properties of Precision-Cast Copper Alloys

Alloy	Composition, % Cu	Zn	Sn	Pb	Others	Tensile Strength, psi	Percentage Elongation	Rockwell Hardness
Leaded red brass	85	5	5	5		42,500	45	B 85
Leaded yellow brass	62	36	0.7	1	0.3 Al	54,000	33.5	B 86

					(reheated)	170,000	3.5	A 71

machining operations that would otherwise be necessary to produce a complicated part. Dies can be made for use in plastic molding, powder metallurgy and precision casting.

Sizes. The most practical sizes are 3-in. maximum dimension and ½-in. maximum cross-sectional thickness. Minimum dimensions range down to 0.005-in. sectional thickness. Larger castings have been made, up to 18 in. long and weighing as much as 100 lb. Investment molds are usually about 5 or 6 in. in diam and of equal length, accommodating from 1 to 60 pieces, depending on size.

Close Tolerances. With careful control it is possible to hold most dimensions within ± 0.005 in. per in. On certain dimensions, limits of ± 0.002 in. per in. can be attained. On small dimensions, such as 0.25 in. or less, tolerances down to ± 0.0005 in. are often attained.

Short Runs. For short runs, ranging from several to a few thousand parts, a master part is made with proper allowance for shrinkage and from this part, a die of low-fusing metal is made. This type of die is comparatively inexpensive and can be produced quickly.

Designing for Precision Castings. *Assemblies and Added Features.* At little or no added cost, this process can often provide such features as slots, keyways, holes, splines, square or odd-shaped blind holes, embossed and debossed numerals, graduations, keystones, cams, stops and bevels. Often an assembly consisting of several to a dozen or more separate parts, can be united into a single precision casting with few conspicuous parting lines, if any.

Dimensioning. A blueprint for a part to be made by standard methods in a machine shop leaves many undecided questions for precision casters. A lathe necessarily turns out work that is truly round, and a surface grinder produces flat surfaces; a precision casting is seldom perfectly round nor is any extensive flat surface truly flat. The precision caster wants to know permissible tolerances on all surfaces; for example, "drill 21 drill" is not explicit enough. Instead, the specification should be given in exact decimals with permissible tolerances added. When all necessary facts are available to him, the precision caster can make a suitable pattern, allowing for the possible desirability of some secondary machining operations where economy and accuracy dictate.

Alloy Specifications. Usual specifications call for leaded yellow brass or 85-5-5-5 for castings that are to be machined. These alloys are not the best for precision casting. For recent information concerning suitable copper alloys for precision casting, the reader may refer to a series of articles by Lipson, Markus and Rosenthal.*

In precision casting, a wide range of mold temperatures is available at the time of casting—from room temperature to 1400 F—and the rate of cooling may vary from slow cooling in air to a rapid quench in water. By making the right choice of conditions it is possible to achieve best combinations of tensile strength, elongation and hardness. Typical mechanical properties are shown in Table III. Rapid quenching immediately after solidification, followed by low-temperature reheating, provides aluminum bronze that will meet ASTM specifications for cast material, and beryllium copper that will meet requirements for wrought material. Most manufacturers prefer alloys that contain at least 0.1% Al, since smoother and cleaner surfaces are obtained. Lead is generally not included because of its opposite effects. If given an indication of the mechanical properties necessary or desirable, the precision caster can usually suggest an acceptable and often superior alloy.

* Iron Age, Nov 1, 1945; Nov 8, 1945; Sept 19, 1946

Cost Factors. Because of the need for making a separate pattern for each casting, this process is in reality a double die-casting process. Articles produced by precision casting cannot compete in price with parts made by automatic screw machines or with sand castings that require only a few finishing operations. The number of castings that can be assembled into one mold, is a controlling factor in the cost, and most manufacturers quote on a piece basis. Standard molds are usually 4, ▮ or 6 in. in diam and of about the same height. Therefore, the smaller the part and the more compactly it can be assembled into the mold, the lower the cost. It costs very little more to cast a mold with 30 small, intricate parts than to cast one with only a few simple, large parts.

For parts weighing a few ounces or less, it is often economical to use better alloys, since the cost of the metal is insignificant compared with better castability and elimination of expensive and difficult machining operations. For these reasons copper alloys may replace ferrous alloys.

Because of shrinkage and many related factors, it is usually necessary to make a preliminary or experimental die, run test pieces, and then make necessary changes in the final die. When the user requests close tolerances throughout the article, additional experimental dies may be necessary. The use of close tolerances where essential, and more lenient ones where permissible, enables die designers to construct a successful die more economically.

Simplicity in the construction of dies, and the need for only a few special tools, jigs, and the like, make quick tooling-up possible and permit lower costs, whether with small runs and experimental parts or large quantities.

Plaster Molding

By H. Hagemeyer*

THE ACCURATE CASTING of metals by the plaster molding method is a refinement of the sand foundry method and employs the match-plate system, cope and drag assembly, separately made cores, and gravity pouring.

The major difference is in the control of all physical factors that are involved in guiding liquid metal into molds made of an investment of calcined gypsum (plaster of Paris) and magnesium silicate (fine-fiber asbestos or long-fiber talc), properly treated with water and baked.

In comparison with other methods for casting metals, this process uses a molding investment that has probably the lowest thermal conductivity of all current commercial processes. The thermal conductivity is approximately 1/10 to 1/15 that of green sand molds.

The plaster of Paris used in this casting process has the following rating of consistency (commercial standard employed by gypsum manufacturers): water, 85 to 95; plaster, 100 (parts by weight).

Typical mixtures used in this process will contain from 70 to 80% plaster of Paris mixed with 20 to 30% magnesium silicate. Depending on the purpose, the water content may be as high as two parts of water to one part of the above mixture. A dried mold will have compressive strength between 8 and 20 psi, depending largely on the ratio of water to solid material.

The wet mold is dried in a continuous radiant-heated oven with minimum circulation of air. The temperature in the initial zone may be as high as 1500 F for the first 10 or 15 min, but it gradually decreases to about 200 F at the

* Castings Patent Corporation, Chicago

discharge end. The complete time cycle for the dehydrating period depends on the height of the mold and requires from 1½ to 2½ hours for mold halves that vary from 1½ to 2¼ in. in height.

Because of its high ratio of water to solid materials in the wet state, the mold material, when dehydrated, has insulative values much higher than those of sand molds. The method employed in controlling the chemical combination, together with the continuous open-faced mold-drying system, produces a mold that results in a smooth casting surface, free from blowholes, run marks, surface pits, and other blemishes.

Some of the principal features inherent in the plaster investment casting method are these:

1 Since the mold material will yield before the contracting alloy when the metal cools to the solidification temperature, the plaster thus prevents cracking and reduces to a minimum the development of stresses in the product.
2 The water content, both free and combined, has been reduced to the point where no bubbling or turbulence develops when the molten metal strikes it. The mold is also free from any volatile materials, since these were eliminated during the drying process.
3 This method makes possible the exact duplication of hydraulic and pneumatic conditions in the mold, and is not critical in regard to the temperature of metal nor the time period of filling. The pouring time can be lengthened from 6 to 10 times that required in sand casting. This is made possible by the use of an orifice inlet to the mold cavity, no greater than 0.0007 sq in. per ounce of metal for any nonferrous alloy. Consequently, riser or shrink bobs can be proportioned accurately to perform their function of supplying metal exactly where required to eliminate microshrinkage.
4 Directional solidification can be controlled, largely for the following reasons: (*a*) Because the molding material has relatively high insulative properties, small orifices can be employed at or near the bottom of cavities, making it possible to control the flow of metal into place over a long period of time, and thus to establish a temperature differential between the feeder and the metal in the farthest section of the mold. (*b*) Because of the small orifices, the sprue can be filled quickly and a column of metal of a definite height can easily be maintained, with a definite hydrostatic head.

The process is largely automatic and is continuous in its operation, resulting in fixed time relations in the various stages and allowing maximum control.

Engineering Characteristics of the Process. *Advantages.* *1 Unit Strip.* The plaster molding process utilizes a standard interchangeable unit-strip match-plate system, which permits assembling as many as 20 different patterns in the same match plate within the dimensional limits of a 12 by 18-in. mold.

2 Patterns. Patterns are made in cope-and-drag match-plate style, with the halves mounted on either side of an accurately machined unit strip. The patterns are not subjected to abrasion, pressure, or shock. Their life is virtually unlimited; consequently very little maintenance is involved. Changes in design that are not too extensive can be made quite readily, since the material used for the patterns is either brass or hard tin base and can be soldered readily.

3 Dimensional Tolerances. The control of dimensions depends on the accuracy of the pattern and on control of the physical factors involved in the process. In most instances an over-all tolerance of ±0.010 in. can be held; and where required, this tolerance can be held to ±0.005, depending on the size and nature of the part to be cast. Outside surfaces normally have ½-deg draft angle; inside surfaces require from ½ to 3-deg draft.

4 Density. Castings made by the plaster molding process are sound in structure and free from porosity.

5 Residual Stresses. Because of slow cooling and the yielding quality of the investment, the product is relatively free from stress.

6 Machining. A primary object in making castings by this process is the reduction of the number of machining operations, and the elimination of machining scrap. Elimination of machining operations is possible, because of the smooth finish and dimensional accuracy of the casting. During machining, castings can be handled easily and the designer can be sure that finished surfaces will always clean up. Roughing operations and roughing scrap are reduced because of lack of porosity and inclusions, a condition that also promotes longer tool life.

Limitations. The process is continuous and involves the handling of a fixed quantity of molding material for a given production unit. This means that there is a definite limitation to the dimensions of articles that can be produced; that is, the dimensions of the molds cannot be varied for this given production unit. One standard molding flask in operation has the dimensions of 12 by 18 in. and an over-all depth, for combined top and bottom halves, of 3½ to 4 in., depending on the volumetric displacement of the pattern on the match plate. Other standard molding flasks in operation are 10 by 18 by 2½ in., 12 by 21 by 6 in., and 24 by 36 by 12 in.

The relatively slow cooling rate in this process produces lower mechanical properties in the leaded bronzes and high properties in tin bronzes, because of segregation of elements; but the average mechanical properties of the product vary less than in castings produced by other methods. To obtain the finest possible surface finish in the copper alloys cast in plaster molds, a small amount of aluminum, beryllium, or silicon should be used, depending on the alloy desired. It is important that the lead content should not exceed 2½%.

General Design Considerations. *Wall Thickness.* A wall 0.040 in. thick can be regularly cast where the area does not exceed 2 sq in.; 0.0625 in. thick in areas up to 6 sq in.; 0.093 in. thick in areas up to 30 sq in.

Part Numbers, or Descriptive Matter. Markings can be either depressed or raised, as desired, and very fine lettering or designs can be reproduced clearly.

Casting Design. This method has great flexibility, because of its use of loose cores made by the same method as the mold and with the same degree of accuracy and smoothness of surface. Transverse holes and passages, undercuts and the like, can readily be incorporated.

For the most popular size of molds made today, the depth of parts that are to be produced depends on the location of the parting line and also on the maintenance of a reasonable margin of plaster over the pattern. Symmetrical parts up to 3 in. high are feasible. In nonsymmetrical parts, the maximum depth from one side of the parting line is limited to 2 in. Greater depths are possible in the larger special-size molds referred to above.

Gear teeth, ratchet teeth, stops, and other shapes difficult and expensive to machine, can be cast by this method.

General Manufacturing Problems. *Inspection.* To ensure the maintenance of a quality product, all products should be inspected rigorously. Original samples are usually submitted for the approval of the customer, and at periodic intervals thereafter the inspection department repeats the dimensional check. Gages are regularly used for checking dimensions. Every casting is inspected visually for defects.

For each heat of metal poured, test specimens are cast regularly in standard molds under standard conditions of production, with gating the same as that used for the commercial product in question. Thus, specimens are truly indicative of casting quality.

Table IV. Comparison of Casting Methods

The following is a table of evaluation of various factors involved in a comparison of casting methods for copper alloys. These factors are rated 1 through 4, number 1 being the most advantageous. The evaluation is based on castings in the as-cast state and may help the application engineer to determine which of the methods is most advantageous in the ultimate use of the product.

This table is based on casting sizes up to a maximum that can be produced practically in a 12 by 18 by 4-in. mold, or the equivalent die size required to produce a casting of similar size in brass or bronze.

Factor	Sand	Die	Perm Mold	Plaster Paris
Tolerances	3	1	2	1
Surface	4	2	3	1
Thickness of section	4	2	3	1
Structural density	1	3	2	1
Pattern cost	1	4	3	2
Speed of getting into production	1	4	3	2
Speed of production	2	1	3	4
Cost per piece	2	1	3	4
Flexibility as to alloys	1	3	4	2
Low casting stresses	2	4	3	1
Flexibility of design	2	3	4	1
Limitation of size	1	4	2	3
Reproducibility of successive castings[a]	2	4	3	1
Pressure tightness	2	4	3	1

(a) As to dimensions, surface finish and uniformity of physical properties for successive castings

Metal. For greater economy of plant operation, alloys that are being cast regularly have been standardized. However, many other alloys can be produced. Virtually all nonferrous alloys can be cast by this process. For fine surfaces it is desirable that from 1/10 to 2/10% Al, Si, or Be should be added to the alloy. It is also required to limit the lead content to 2½%, and nickel to approximately 7%, since these two metals in larger amounts react chemically with the plaster.

Temperature. In this method, lower pouring temperatures can be used than are required with sand molds, provided a sufficient hydrostatic head is employed, exceeding 2¼ psi.

At high pouring temperatures the hydrostatic head can be reduced so that sprue height is only an inch or so above the highest point in the casting.

Experience indicates that 2400 F is the maximum temperature of the metal to be poured into molds of the above composition if dimensional stability is to be retained.

Comparison. Table IV shows a comparison of the plaster molding method with sand, die, and permanent mold casting, as applied to copper alloys.

Plaster Molding

H. Hagemeyer, Trans AFA, 52, 758, 1944

The Production of Copper Alloy Castings for Working

BY THE SUBCOMMITTEE ON COPPER ALLOY CASTINGS FOR WORKING*

MANY TYPES of furnaces have been used for melting copper and copper alloys, but present practice is quite uniform throughout the industry. Crucibles heated by coal and oil have been virtually eliminated in large-scale operation. For copper, oil-heated and gas-heated reverberatories, and for brasses and bronzes, low-frequency (60-cycle) induction furnaces are generally employed.

The low-frequency induction furnaces are rated from 150 to 450 kw, with a capacity for holding from 800 to 3000 lb more metal than is needed to fill the heating duct. They are capable of melting any brass mill alloys, none of which require a pouring temperature higher than 1430 C.

Melting Practice for Copper Alloys. Electrolytic copper in the form of cathodes or ingots, fire-refined copper ingots, clean copper scrap from mill operations or secondary sources, slab zinc in one of five commercial grades, alloyed mill scrap, and clean secondary alloy scrap are the raw materials used for making copper alloy castings that are to be wrought. It is the general practice to melt copper, high-copper scrap and additions that have high melting points, before adding the required amount of zinc. Keeping the bath thus rich in copper until it is nearly ready for pouring probably results in the formation of less dross. However, some operators consider that copper additions will dissolve faster in a zinc-rich liquid, and consequently make zinc additions early.

All copper-zinc alloys require a protecting cover on the liquid bath in order to reduce heat losses and to prevent excessive loss of zinc through vaporization and dross. Charcoal is generally used for this purpose. Alloys con-

* The members of this subcommittee are F. F. Poland, *Chairman* (Revere Copper and Brass Incorporated), E. J. Dunn (Chase Brass & Copper Co.), D. R. Hull (The American Brass Company) and E. L. Wolff (Scovill Manufacturing Company).

taining 20% Zn or less form comparatively little dross; higher zinc content and the use of dirty or oxidized scrap will produce more and heavier dross, which holds an appreciable amount of metal globules in suspension. No flux has been developed to free this heavy dross completely from the suspended metal, but soda ash, common salt and borax are frequently used as fluxes to reduce it. Economy necessitates the reclamation of the metal content in the dross; this is accomplished by standard methods of screening and concentration.

Hydrogen and perhaps other gases have relatively low solubility in high-zinc alloys but, as the copper content increases above approximately 80%, the solubility of these gases rises rapidly and may be the cause for porous castings. The addition of lead or tin to these alloys increases the susceptibility to gas absorption. Even so, moderate precautions, such as avoiding excessively high temperature or adding fresh charcoal near the end of the heat, will minimize the absorption of detrimental quantities of gas.

Copper alloys that do not contain zinc require more precautions to prevent the absorption of gases. Oil or lubricating compounds, particularly if they contain sulfur, should be removed from scrap before melting; and if charcoal is used as a cover, it should be preheated. Charcoal may be used with caution on phosphor bronzes, but the use of an oxidizing slag is common. Charcoal is not used as a cover for aluminum or silicon bronzes. These alloys are melted in a slightly oxidizing atmosphere, using as a cover either their own dross, fused cryolite, a layer of molten glass, or slag.

Nickel silvers and cupro-nickels may be melted under charcoal but are always treated with manganese and sometimes with a further addition of magnesium. These additives, like the phosphorus in phosphor bronze, are deoxidizers in a strict sense, but at the time of pouring they serve the important additional purpose of preventing secondary reactions between air and gases dissolved in the metal. Such reactions are not perfectly understood but probably result in H_2O or CO_2, which are directly responsible for unsoundness.

A few high-frequency induction furnaces are used for melting copper alloys, and all statements concerning the low-frequency furnace apply also to these furnaces.

The rocking-arc furnace finds a small but well-established application for the melting of alloys. It is used for cupro-nickels, phosphor bronzes, aluminum bronzes and silicon bronzes; though not for alloys containing high percentages of zinc, because of the high local temperature in the arc zone, which overheats the metal and results in excessive loss of zinc.

A suitable pouring temperature for copper and copper alloys is usually from 100 to 150 C above the liquidus. Higher temperatures are destructive to equipment, favorable to gas absorption and serve no useful purpose. In the range of 25 to 40% Zn, the maximum pouring temperature is limited by the boiling point, which serves as a safeguard against overheating. Such alloys are poured at temperatures only slightly below the boiling point. Alloys with less zinc, or without zinc, have no such safeguard and it is usual to establish a definite pouring temperature for each alloy, a temperature that may vary slightly among fabricators, because of slight differences in pouring arrangements. A suitable pyrometer is used for temperature measurement.

Casting Practice for Copper Alloys. Copper alloys to be wrought are cast into the following forms: slabs for cold rolling into flat products, cakes for hot rolling into flat products, bars for hot rolling into wire rods, billets for extrusion into rods, shapes or tubes, billets for piercing into tubes, cored tubes for drawing, and rods for cold rolling and drawing. Two types of permanent molds are used for castings intended to be wrought. The older type is made of gray iron with small uniformly dispersed graphite particles. It is designed with a ratio of mold weight to casting weight from 1½:1 up to 5:1.

In the newer type of mold, which is water cooled, the surface in contact with the casting is usually copper. Water is circulated through these molds at the rate of approximately ½ gal per min for each pound of metal cast. The temperature of the inlet water is controlled and ranges from 100 to 160 F, depending on the size and shape of casting, on the alloy, and on plant practice.

It is general practice in the brass industry to use a "runner box" or "strainer" placed on top of the mold to receive the metal from the furnace. These boxes are generally made of mold iron, but when used with some alloys they have refractory linings or refractory inserts. In the bottom is either a single hole or a series of holes varying from ¼ to about ⅝ in. in diam, depending on the size and shape of the casting. The functions of the strainer are to control the rate of flow, distribute the metal evenly across the width of the mold, direct the pouring stream down the center, and keep the dross and dirt from entering the mold. It will be recognized from the functions of the strainer that its proper design and use for each particular application are very important in producing clean, sound castings.

Most nonferrous metal tubes are made by piercing or extruding a solid billet to make a heavy-walled shell of relatively large diameter, and by then drawing this shell, as described in the articles on working processes. However, some alloys cannot be pierced or extruded and equipment ordinarily available cannot be used for larger billets or all alloys. By pouring around sand cores positioned in chill molds, these alloys are cast into a heavy-walled tube shell. The cores are made on perforated steel pipes that are covered first with porous, shock-absorbing core paper, then with a coat of rough sand, including suitable binders —bran, molasses and such. After drying, a second finish coat of fine sand with clay is applied and dried. Cores are then finished with a wash of silica flour or whiting to prevent metal penetration and to obtain a smooth inside surface. After thorough baking, the cores are kept hot until used, since they will absorb appreciable moisture if allowed to stand in room atmosphere.

The production of castings of good surface quality necessitates a suitable dressing on the mold. The dressings in general use for copper alloys that contain zinc include lard oil, wool grease, tallow or mineral oil, or combinations of these, frequently with additions such as carbon black, graphite, silica flour, or the foundry preparation known as black lead. An important function of a mold oil is to produce a reducing atmosphere in the mold, in this way preventing the formation of excessive quantities of dross. Secondarily, oil on the mold evolves gas more or less violently as the molten metal comes in contact with it. This continuous agitation at the top of the metal column blows dirt and dross from the mold surface and so prevents the inclusion of these impurities in the surface of the casting. Too light a dressing or too slow a rate of rise in the mold will result in a casting with a poor surface. A dressing too heavy or a rise too rapid will cause some of the evolved gas to be entrapped, resulting in blowholes in the casting. There is a rather fine balance between the rate of pouring and the amount of oil on the mold. To ensure internal soundness it is important to pour at a rate that will give the lowest rate of rise in the mold consistent with a clean surface. In practice this rate varies between 0.4 and 1.5 in. per sec.

On the operating face, iron molds develop characteristic cracks, which increase rather rapidly and limit the useful life. When used for alloys that contain zinc, iron molds also develop a peculiar scale composed mainly of zinc oxide with some zinc, carbon, and small amounts of oxides of any other constituents of the metal. Soft and friable when first precipitated, mold scale hardens with further use of the mold and consolidates into a rocklike layer, which must be removed by chipping or scraping. Mold scale is important because, in combination with mold cracks, it soaks up oil and retains it too long after the metal rising in the mold has covered a given area. The gassy products of oil decomposition, thus entrapped, produce blowholes in the casting. The great advantage of water-cooled molds is that the cooled copper plate does not crack or build up a scale.

Alloys that do not contain zinc are all susceptible to hydrogen in solution and some of them are better poured without any oil on the mold. In this group, deoxidized copper and cupro-nickels are poured into oiled molds. The phosphor bronzes are sometimes poured into oiled molds, sometimes into dry molds. Such alloys as silicon bronze,

aluminum bronze and chromium bronze are usually poured into dry molds. Gas dissolved from the mold oil would cause these metals to "swell" or "spew" during solidification. "Dry" dressings may be composed of graphite, carbon black, bone black, bone ash, silica flour or like substances, in a vehicle of water or alcohol. The mold must be warm enough to evaporate the vehicle between the time of application and that of pouring.

A distinction is made between unsoundness caused by dissolved gas and that caused by entrapped gas. They both produce cavities in the casting, but the precautions for their prevention are different, as explained above.

A third type of unsoundness to which all alloy castings are more or less subject, has been called "interdendritic shrinkage" and is associated with the mode and rate of freezing in the center of the mass. Since there is substantial contraction in volume from liquid to solid, it is important that liquid metal be always available to a solidifying area to make up this difference. Thus, the end of a casting is always "fed" with fresh metal from the furnace to prevent the deep "pipe" that tends to form as the center shrinks away. But, deep down in the casting there is usually an area to which adequate "feed" was not available, resulting in a zone of low density or intercrystalline voids. If not too large, these voids will weld during hot working operations and at least to some extent during cold working and annealing. In this they differ from unsoundness caused by gas—either dissolved or entrapped—which does not weld readily.

In summary, the five important variables affecting the surface quality and the soundness of a casting are metal temperature, mold temperature, condition of mold surface including the amount and type of dressing, the rate at which the metal rises in the mold, and the pressure of gas either dissolved in the original melt or entrapped. These are interrelated and none of them can be varied without affecting the general result.

Melting and Casting Practices for Copper. Reverberatory furnaces, heated by natural gas, oil or pulverized coal, and having a capacity of 250 to 350 tons, are used for melting copper cathodes. Sulfur, hydrogen, and other gases absorbed by the metal are removed by blowing air into the metal until 5 to 8% is converted to cuprous oxide, which is held in solution in the copper. The copper oxide oxidizes the sulfur (present as Cu_2S) to sulfur dioxide (according to the equation $2Cu_2O + Cu_2S \leftrightarrows 6Cu + SO_2$). This sulfur dioxide is flushed from the metal along with hydrogen and other gases, by the nitrogen, which keeps the partial pressures of these gases below their equilibrium concentrations. The removal of sulfur and gas progresses as the oxide concentration of the bath increases, so that when the bath reaches the concentration of copper oxide stated above, the oxidizing process is complete.

Subsequently the excess oxide is removed by covering the copper with charcoal and forcing green wood poles under the surface. This operation is called "poling" and is continued until the oxygen is reduced to between 0.02% and 0.04%. The residual sulfur is between 0.001% and 0.002% and a sample at this point will have a wrinkled but flat "set" surface. This "tough pitch" copper is then cast into solid copper molds dressed with bone ash.

The casting of electrolytic copper is somewhat unique, because in this process a controlled amount of cuprous oxide, sulfide, and gases is left in the liquid metal.

During solidification, pure copper crystals solidify first, increasing the concentration of the residual oxide and sulfide in the remaining liquid. These react as shown above and the resulting sulfur dioxide is entrapped in the metal in numerous minute globules that prevent normal shrinkage.

Hydrogen and other gases reabsorbed during the poling operation and from the charcoal cover are also liberated and entrapped at the time of casting. Some metallurgists maintain that H_2O, formed at this point by reaction of liberated hydrogen with cuprous oxide, is chiefly responsible for the "level sets"; this theory is not accepted by all investigators. At any rate, proper control results in the finished castings having a flat to a slightly crowned set surface, which eliminates the necessity of cropping the gate or filling the pipe that normally forms when gas-free metal contracts as it solidifies.

The process of eliminating shrinkage by the evolution of gas can be used with copper, since the surface of the resulting porosity will weld during subsequent hot working. In all other copper alloys, every effort is made to have the liquid as free as possible from gas before casting.

Most copper to be wrought is marketed as "tough pitch", but there is a substantial volume of deoxidized copper. Just before casting, most of this is treated with about 0.02% P, which removes the last traces of cuprous oxide. However, some metal is treated with less than 0.01% P so that the resulting deoxidized copper will have an electrical conductivity comparable with that of tough pitch. Because such metal behaves like a copper alloy, it is poured into molds dressed with a relatively inert dressing and shrinks normally while solidifying.

A special type of copper is called "oxygen-free high-conductivity". In such "OFHC" copper the last traces of cuprous oxide are removed by charcoal treatment in the furnace and the metal is then transferred to the molds without contact with air. The result is an oxygen-free product that has the high conductivity of tough pitch copper, since it contains no residual deoxidizer.

Continuous Casting. Briefly stated, continuous casting can be defined as a process wherein liquid metal enters one end of a mold continuously at a substantially uniform rate and solid metal emerges simultaneously from the other end.

The concept of continuous casting is very old. However, this idea has been developed only recently on a practical commercial scale. The size and number of continuous casting installations are increasing both in the United States and in Europe.

Virtually all the large tonnage in production is confined to three processes, each of which, without stopping, produces castings of any desired length. The three processes have several factors in common: water-cooled copper, copper alloy, or graphite molds; mechanical means for withdrawing or controlling the billet speed through the mold; and traveling saws to cut the casting into desired lengths without stopping the continuous pouring.

The stationary mold process is one in which the mold remains fixed; the molten metal enters at the top and emerges at the bottom as a solid continuous casting. A mold of this type is usually in one piece and rather short. This process is used for copper and for alloys difficult to cast by more conventional methods.

The vibrating split-mold process consists of two water-cooled mold sections that together form the contour of the desired casting. These sections are mechanically opened and closed laterally, with a very small gap and at high frequency. The molten metal, entering at the top, solidifies, is withdrawn at constant speed, and is then cut into the desired lengths by integral saws. This process is used principally for casting copper.

In the reciprocating-mold process, the liquid metal is underpoured from a reservoir furnace through a downspout, and is discharged underneath the surface of the liquid metal in the mold. The mold has a downward and upward motion. The downward motion is synchronized with the speed of the billet, and the upward speed is about three times that of the downward speed. The total travel of the mold is about ¾ in. in each direction.

The surface of the molten metal at the top of the mold is protected from oxidization by a gas flame, and oil is occasionally sprayed on top of the liquid metal where it spreads to the edges and lubricates the casting surface of the mold. This process is used principally for copper-zinc alloys of all proportions.

In all the foregoing processes, further cooling is necessary after solidification. This secondary cooling is either by direct application of water sprays or by secondary cooling jackets, the choice and location of which are determined by the conductivity of the metal, the area of cross section, freezing range, nature of the alloy, speed of production, and amount of superheat in the metal. The linear casting rate of these machines varies from ■ to 20 in. per min, depending on the alloy and cross-sectional

area. Best results are obtained by using low temperatures for casting.

Copper, copper alloys, aluminum, silver, lead, magnesium, and possibly other nonferrous metals are produced by continuous casting in industry. The principal application of continuous casting is in large units, but the process is also applicable to small units for some alloys difficult to cast by other methods.

The metallurgical advantages are as follows: less segregation, high density, and absence of shrinkage porosity. The operational advantages for continuous casting are these: straight-line continuous production, lower pouring temperatures, elimination of gate scrap, exact lengths delivered to the mill, minimized hard labor, greater uniformity of composition, and general over-all economies. In continuous casting, care must be taken that all variables are under precise control. Disadvantages are the high initial cost and lack of flexibility of alloy changes.

The bulk of the tonnage produced by continuous casting is in the form of billets, slabs and rod for standard fabricating processes.

Characteristics of Copper Alloy Castings. The characteristics of copper alloy castings vary somewhat, depending on the type of mold used, the mold temperature, mold dressing, metal temperature, rate of rise in the mold, and heat conductivity of the metal or alloy.

Virtually all castings intended to be wrought are cast in some form of chill mold. A small number of castings are made in chill molds using a sand core; however, they are of minor importance and their general characteristics are quite similar to the chill-mold casting.

Copper alloy castings have four noteworthy features:

1 They are less ductile than wrought materials as a consequence of the coarse crystal structure and, in some instances, directional arrangement of the crystals. Castings are subject to cracking along crystal boundaries during shrinkage in the mold, and during the initial stages of rolling or other fabrication, and from bending.

2 The mechanical properties (such as tensile strength, elongation, reduction in area, and hardness) are usually lowest in the cast alloys. However, the hardness number on the outer skin is frequently higher than in the interior of the casting, because of the presence of a layer of very small crystals on the outer surface, because of segregation, or because of precipitation of a harder constituent.

3 Frequently more than one phase is present, and except in very pure metals, segregation or coring is encountered. Segregation—normal or inverse—occurs in certain types of alloys where constituents present have either a low solubility in the alloy or a freezing point that differs greatly from the major phase or phases. Usually a homogenizing treatment of the metal is desirable before working.

4 The surface of copper alloy castings may vary from one that requires complete removal during fabrication to one suitable for fabrication to the finished article without any overhauling or surfacing operation.

Pure copper is cast at the copper refineries with a surface suitable for fabrication to the finished product, but most copper alloys require removal of the surface during fabrication.

Castings of copper and copper alloys are generally considered free from residual stresses. However, some stresses are set up during solidification and subsequent cooling. These sometimes result in intercrystalline cracks on the surface and internal fractures between crystals.

The Hot Working of Copper and Copper Alloys

BY THE SUBCOMMITTEE ON HOT WORKING OF COPPER ALLOYS*

HOT WORKING is the plastic deformation of a metal at a temperature sufficiently high to prevent strain hardening or, as more commonly defined, it is the working of a metal above the recrystallization temperature. Hot working accomplishes the following purposes: (1) a reduction or change in the shape and cross-sectional area, (2) refinement of the grain structure, and (3) forming of a usable product—plate, sheet, bar, rod, tube or shapes.

Above the recrystallization temperature there is a limited temperature range (hot working range) at which the optimum hot working characteristics are obtained for each metal or alloy. These temperatures vary widely for various alloys. Copper, for instance, may be hot worked at temperatures ranging from 750 to 1900 F while leaded alpha brasses containing more than 64% Cu and more than 0.02% Pb are impossible to hot roll at any temperature, though they are workable to a limited extent in the other hot working operations. A metal that lacks sufficient ductility and malleability to permit hot working is commonly said to be "hot short".

Suitable temperatures for hot working many commercial copper-base alloys are listed in technical publications[1, 2, 3] and also in Tables II, III, IV and V.

Copper and copper alloys may be hot worked by any of the following operations, which are listed in the approximate order of importance, based on the tonnage of metal processed by the operation: (1) rolling, (2) extruding, (3) piercing, (4) forging and pressing, (5) bending and forming.

* The members of this subcommittee are B. J. Sirois, *Chairman* (Phelps Dodge Copper Products Corporation), L. G. Glesmann (Revere Copper and Brass Incorporated), F. M. Levy (Mueller Brass Company), J. C. Rowell (The American Brass Company) and M. L. Wood (Deceased).

In Table I are classifications based on the performance of the commercial alloys in these operations.*

The mechanical properties that a copper alloy requires if it is to be hot worked are known only generally, though the properties commonly accepted as best indications of the ability of a metal to be hot worked are good values of ductility and malleability at elevated temperatures. Considerable work has been done by various investigators, using different tests to determine the properties of alloys at elevated temperatures; thus data have been obtained concerning the ordinary static tensile strength and ductility of many commercial alloys.[4, 5, 6, 7] It should be pointed out, however, that these test results have not always been consistent, particularly when compared with known results of commercial hot working practice.

Another important factor affecting the hot working characteristics of a metal is the nature and quantity of impurities present in the metal. Small quantities of various impurities such as oxygen,[8] sulfur,[9, 10, 11] tellurium,[11, 12] selenium,[11] lead,[1] bismuth,[13,14] antimony,[15] arsenic,[16,17] iron,[18] cadmium, silver,[17] and phosphorus,[19] have effects on copper that are fairly well known. Impurities that are notable for their impairment of the hot working properties of copper are bismuth and lead. Selenium and tellurium in amounts as great as about 1% have been used to promote machinability with little adverse effect on the hot working of copper. Sulfur is generally regarded as being harmful to electrolytic tough pitch copper. Also particular note should be made that when this type of copper has been heated to elevated temperatures, exposure to highly reducing atmospheres should be avoided, since the cuprous

* Table I was adapted from a similar compilation that was prepared by R. S. Pratt for the 1939 edition of this Handbook.

Table I. Classification of Copper and Copper Alloys According to Hot Working Characteristics

Metal	Nominal Composition				Hot Working Operations				
	Cu	Zn	Sn	Pb	Rolling	Extrusion	Piercing	Forging & Pressing	Bending & Forming
Electrolytic Copper	99.92	...	...	...	E	G	E	G	E
Deoxidized Copper	99.94	...	...	...	E	G	E	G	E
Leaded Copper	99.0	...	...	1.0	P	F	P	P	P
Gilding Metal, 95%	95.0	5.0	...	...	E	G	G	G	G
Commercial Bronze, 90%	90.0	10.0	...	...	E	G	G	G	G
Red Brass, 85%	85.0	15.0	...	...	E	G	G	F	F
Low Brass, 80%	80.0	20.0	...	...	E	G	F	F	F
Cartridge Brass, 70%	70.0	30.0	...	...	G	G	G	G	G
Yellow Brass	65.0	35.0	...	...	F	G	F	P	F
Muntz Metal	60.0	40.0	...	...	E	E	E	E	E
Leaded Commercial Bronze	89.0	9.25	...	1.75	P	F	P	P	P
Low-Leaded Brass (Tube)	67.0	32.5	...	0.5	P	G	P	P	F
Low-Leaded Brass	64.5	35.0	...	0.5	P	F	P	P	F
Medium-Leaded Brass	64.5	34.5	...	1.0	P	F	P	P	P
High-Leaded Brass (Tube)	67.0	31.4	...	1.6	P	F	P	P	P
High-Leaded Brass	62.5	35.75	...	1.75	P	G	P	P	P
Extra-High-Leaded Brass	62.5	35.0	...	2.5	P	F	P	P	P
Free-Cutting Brass	61.5	35.5	...	3.0	P	E	P	P	P
Leaded Muntz Metal	60.0	39.5	...	0.5	G	E	F	E	G
Free-Cutting Muntz Metal	60.5	38.4	...	1.1	G	E	F	E	G
Forging Brass	60.0	38.0	...	2.0	F	E	F	E	G

(a) Normally, 0.3% Mn is found in the (A) bronze and 3.7% Mn in the (B) bronze.
(b) Other additions, including Sn, Ni, and Mn may be present to a total of 2.25%.
(c) This alloy is susceptible to heat treatment.
(d) One of the following elements—Fe, Zn, Mn, Sn—may also be present in the alloy to about 1%.
(e) One of the following elements—Fe, Zn, Mn, Sn—may also be present in the alloy to about 0.8%.

Explanation of Code letters used in classification:

E	Excellent	Capable of sustaining very severe total working, at high rates, within a relatively wide range of temperature, showing substantial freedom from hot shortness, consuming low power input, having a low rate of wear on dies and rolls, and using commercial equipment generally available.
G	Good	Somewhat less amenable to working with respect to one or more of the factors under Excellent, but still economically feasible.
F	Fair	Decidedly less amenable to working with respect to one and usually more of the factors enumerated under Excellent, and of questionable or marginal economy.
P	Poor	Either impossible to work, or so deficient in at least one of the factors under Excellent, that the operation is not practicable.

oxide present (the form in which oxygen is found in this type of copper) will be reduced to pure copper, leaving voids in the metal. When oxygen-bearing copper has once been so reduced (gassed) it is brittle and unusable.

In alpha brasses, lead in quantities exceeding 0.02% will cause brittleness at any hot rolling temperature. If bismuth[14] is present in the order of 0.006%, it also impairs the hot rolling of these brasses.

Alpha-beta brasses, that is, those containing from 55 to 64% Cu, may be hot rolled even if they contain 1% Pb. This characteristic is believed to result from the fact that the beta phase will hold 1% Pb in solution. It is also possible to hot forge alpha-beta brasses containing as much as 2.25% Pb, while brass containing as much as 3.75% Pb can be extruded. However, it is impracticable to hot roll a brass that contains as much as 3.75% Pb. Bismuth[14] also has an adverse effect on the hot rolling characteristics of the alpha-beta brasses, though the indications are that it need not be restricted to the small quantity permissible in the alpha brasses, especially if phosphorus is present.

Naval brass, which is a tin brass, can be hot worked readily in any operation. Admiralty metal, another tin brass, though fairly easy to extrude, can be hot rolled only provided the lead is kept to a trace; otherwise cracking will occur. It is helpful to soak the castings several hours at a temperature of 1350 to 1450 F to absorb the delta phase or eutectoid produced during solidification of the casting. The presence of delta produces hot shortness and causes cracking.[1] The addition of small quantities of either arsenic, antimony or phosphorus to inhibit corrosion, has no ill effect on extrusion of admiralty metal.

Aluminum brass is generally produced by the extrusion process and, as in admiralty metal, arsenic, antimony or phosphorus in small amounts does not hinder extrusion.

Among the nickel silvers (Cu-Ni-Zn), the alpha alloys have poor hot working characteristics. The alpha-beta alloys can be hot worked by any process. Lead, sometimes added to improve machining, makes these alloys unsuited for hot rolling but does not interfere with hot extrusion and forging.

The cupro-nickel alloys may be hot rolled or extruded without too much difficulty but close control is required.

The silicon bronzes can be hot worked readily, but lead

must be limited to a trace if the metal is to be hot rolled or forged.

The aluminum bronzes, both alpha (containing as much as 9% Al) and alpha-beta types, have excellent hot working characteristics. The alpha-beta type is less resistant to plastic deformation.

Copper-tin alloys (phosphor bronzes) are generally not considered hot working alloys, though some mills are now hot rolling copper-tin alloys containing as much as 4% Sn.

Hot Rolling. Hot rolling is a mechanical method of hot working by passing metal between two rolls while it is heated above the recrystallization temperature. In this operation the flow of metal is continuous and almost entirely in the direction of rolling.

Equipment. Hot rolling of rods and shapes is performed in a series of grooved rolls. The grooves are designed to reduce the cross section of the metal as it progresses from one pass to the next. Mills for hot rolling rods in sizes suitable for drawing into wire, are of the looping or continuous type. Rods in larger sizes are rolled in a merchant type of mill, which is slower than the looping or continuous mill, but can be employed for more kinds of work.

The mills usually consist of a three-high type of "breakdown" or "roughing" roll and a train of finishing rolls. In the "breakdown" mill, where the wire bar is reduced to a section suitable for the finishing train, the first passes are usually "box" type; that is, the grooves are designed to maintain a rectangular cross section so as to support the bar at all points and to avoid cracking the bar during the breakdown operation. The sequence of passes in this mill is from square to rectangular to square; the rectangular bar is turned 90 deg on its axis as it enters the square pass. Subsequent passes in the breakdown and finishing train are alternately oval and square in section. The oval sections are turned 90 deg as they go into a square pass, and the square sections are turned 45 deg as they pass into the succeeding oval. The finishing pass is from oval to the finished round size.

Rods. Rods for subsequent drawing to wire sizes are produced in coils approximately 36 in. in diam to facilitate handling. Rods produced on the merchant mills are either coiled or left in relatively straight lengths, according to their size or the capacity of the coiling equipment.

Rolls for the hot rolling of rods are generally made of cast iron or steel for the breakdown stands and of chilled iron for the finishing stands. A generous flow of water on the rolls cools them during the rolling operation.

In the production of copper rods, the starting material is commonly a tough pitch wire bar of electrolytic copper.[20] This bar is approximately 4 by 4 in. in cross section and is characterized by a "set" surface (the top surface of the casting exposed to the air during solidification). The bars are pointed on both ends to facilitate entrance into the rolls. For the last 10 or 15 years, because of the demand for rod of higher quality, the practice has been to remove the set surface by a "scalping" operation. Vertically cast bars with the "set" on one end are also available and one refiner now furnishes a "no set" bar. Electrolytic copper bars are subject to embrittlement if exposed at elevated temperatures to a reducing atmosphere. Careful control of the furnace atmosphere is therefore essential. Oxygen-free or deoxidized copper wire bars are not subject to this type of embrittlement, so control of the furnace atmosphere is less important for them, and also for bronze and brass alloys, than for electrolytic copper.

Besides copper, the alloys most commonly processed into rods by the hot rolling operation are the silicon bronzes, commercial bronze (90% Cu), red brass (85% Cu), low brass (80% Cu), cartridge brass (70% Cu), naval brass, Muntz metal, cupro-nickels (30% and 20% Ni) and the alpha-beta nickel silvers. These alloys are cast into billets that have approximately the same cross section as a copper wire bar. In designing grooves for rolling alloy rods, provision should be made for the greater tendency of some alloys—notably Muntz metal and naval brass—to spread. This spreading will result in overfilling improperly designed grooves, leaving in the rod a fin that will show up as a lap or sliver in the finished material.

Suitable temperatures to which copper and copper alloys should be heated before hot rolling are listed in Table II.

Shapes. The most common shapes that are hot rolled are round, wedge, square, and narrow rectangles. Though special shapes are produced, they are not common.

Flat Products. The hot rolling of flat products is restricted mostly to the production of heavy plates, or of the breakdown product that is subsequently finished to thinner gages by cold rolling.

Before 1940 the breakdown of flat products by hot rolling was generally limited to copper, commercial bronze (90% Cu) and red brass (85% Cu). All the nickel silvers, phosphor bronzes and brass mixtures having higher zinc contents were cold worked from the original casting. In the ten years preceding 1940, however, several manufacturers experimented with the hot rolling of all these alloys on a production scale, and demonstrated that hot rolling was possible if certain precautions were taken. The second World War made necessary a great increase in the nation's capacity for producing cartridge brass (70% Cu) and commercial bronze (90% Cu). The facilities added for this high production called for hot rolling exclusively in the breaking down stages.

The equipment for breaking down flat products consists essentially of a heavy pair of plain rolls made usually of chilled iron and cylindrically ground, with provision for cooling the rolls with water and further provision for applying oil to the rolls to prevent scaling or metal pickup. A pair of edging rolls is sometimes used in conjunction with the main reduction rolls and has marked advantages.

Copper, electrolytic or fire-refined, is available in either end-poured or wedge cakes.[20] Heating is usually performed in a continuous type of furnace with atmosphere controlled to prevent the formation of scale. Although theoretically a reducing atmosphere will deoxidize electrolytic copper, resulting in embrittlement of the metal, in actual practice a slightly reducing atmosphere is not harmful and is desirable if copper plates are to be produced without objectionable scaling.

Table II. Copper Alloys Commonly Hot Rolled

Metal[a]	Suitable Temperature for Hot Rolling, deg Fahr	Properties as Hot Rolled[b] Tensile Strength, psi	Percentage Elongation in 2 in.
Electrolytic Copper	1300 to 1600	33,000	50
Deoxidized Copper	1300 to 1600	33,000	50
Gilding Metal, 95%.....	1400 to 1600	36,000	45
Commercial Bronze, 90% ..	1400 to 1600	36,000	50
Red Brass, 85%.....	1450 to 1650	40,000	50
Low Brass, 80%.....	1450 to 1600	45,000	55
Cartridge Brass, 70%.....	1350 to 1500	48,000	55
Muntz Metal	1250 to 1450	55,000	50
Naval Brass	1250 to 1450	55,000	45
Phosphor Bronze, 1.25% (E)	1450 to 1600	40,000	45
High-Silicon Bronze (A) ...	1350 to 1550	55,000	60
Low-Silicon Bronze (B) ...	1350 to 1550	40,000	50

(a) See Table I for nominal compositions of these metals.
(b) The mechanical properties shown are *average* and are not to be used as minimum requirements.

The cakes or castings are heated to approximately 1600 F as a maximum, before being fed to the rolls. A series of passes applied as rapidly as possible will reduce the metal to whatever gage is desired since, during cooling, copper has no temperature at which it becomes hot short or brittle. It merely becomes more resistant to further reduction. Hot rolling of copper normally stops at thicknesses of approximately 0.200 in. Further rolling beyond this point is generally done cold, though there are some exceptions where copper sheets are hot "pack" rolled; several sheets are packed one on top of another, thereby permitting hot rolling to relatively light gages.

When castings are being heated for hot rolling, care should be taken so that the temperature is right for each alloy and so that the castings are heated uniformly throughout to the right temperature. Rolling the metal at temperatures outside the proper temperature range will result in considerable cracking, since most of these alloys are hot short at temperatures below and above the correct hot working range. In rolling these alloys too cold there is also the danger of breaking the rolls.

The advantage in hot rolling strip metal, as compared with cold rolling, is that the hot rolling method is more economical and lends itself more readily to the handling of a larger cake, producing longer finished rolls.

Extrusion. Hot extrusion of metal is an operation in which metal, while heated above its recrystallization temperature, is made to flow through a restricted orifice by the application of sufficient pressure, thereby forming a greatly elongated product that has uniform cross section. The shape is controlled by the orifice or die opening. Although essentially the same in principle, two distinct methods of extrusion are possible;[21] one is known as "direct" extrusion, the other as "inverted" extrusion. In the direct method the extruding die is located at one end of the extruding-press container and the metal to be extruded is driven toward it (thus moving relative to the container) by the ram entering the extruding container from the opposite end. In inverted extrusion the die is placed on the end of the ram, which has been bored out to allow passage of the extruded product, and the die moves through the container from one end; the opposite end is closed.

Inverted extrusion of copper and copper alloys was not developed until after 1926, and resulted from attempts to eliminate the characteristic defect commonly known as "pipe", encountered in the products made by direct extrusion. Although the inverted process has roused considerable interest, not much headway has been made, and the direct method is still generally preferred both in this country and in Europe.

Equipment. During the past decade, numerous mechanical improvements applying to copper and copper alloys have broadened the scope of the extrusion process appreciably. Mechanically operated presses, though still in use, are being replaced at a steady rate by presses operated hydraulically, since these presses are more flexible, more compact, more easily controlled and less subject to damage from improper operation. For hydraulic presses also, the trend has been towards greater capacity. Small vertical-tube presses that have a capacity from 600 to 1100 tons, are now being replaced by horizontal presses that have 2200 to 7500-ton capacity, enabling the use of billets as large as 10 in. in diam, whereas billets as small as 4 in. in diam were previously extruded. The majority of presses now being installed for producing rods and shapes, have capacities of about 2500 tons. Another innovation has been the adoption of hydropneumatic accumulators, wherein the hydraulic fluid is pumped into a group of steel "bottles", compressing the residual air in them to act as a pressure reservoir for the extrusion operation. This has replaced the previous alternatives of directly connected pumps or the pumping of fluid into a gravity accumulator, and has the advantages of greater flexibility and simplicity.

Today the principal limiting factor in extrusion of copper alloys is the inability of the steels used for container liners, dies, rams and dummy blocks to withstand pressures of much more than 125,000 psi at the extrusion temperatures required. In this connection, dies of the tungsten-carbide type have shown considerable promise, although the inherent brittleness of the material and its low resistance to thermal shock cause some difficulties.

Extrusion Pressures. The pressure required to extrude the more common alloys—for example, free-cutting brass and naval brass—which all fall within the range from 60 to 63% Cu (*see* also Chapter VI of reference 21), is relatively low (about 35,000 psi); whereas some of the silicon bronzes, leaded phosphor bronzes, and other engineering alloys, may require pressures as high as 140,000 psi, and extrusion of these alloys is somewhat restricted by the previously mentioned limitation of pressure on tools. The required pressure depends on extrusion temperature, reduction in area from billet to extruded product, and speed of extrusion; the influence diminishes in that order. Generally, the pressure at the beginning of extrusion will be high, diminishing gradually as the action proceeds, and returning rapidly to ■ pressure as high as the initial pressure, or higher, at the end of the operation when only a thin "butt" is left in the container. It is always necessary to preheat the container, dummy block and die before their introduction into the machine, because the plasticity of copper alloys decreases rapidly with decreasing temperature in the extrusion range. A suitable temperature for continuous operation is maintained by abstraction of heat from the billet. Sometimes it is necessary to cool the ram, container, die and dummy block either with direct water sprays, oil or an air blast.

The flow of metal during extrusion depends on numerous factors, including the copper content of the material, the amount of lubrication employed, and the design of die aperture and dummy block. Generally the first metal extruded through the die is very slightly deformed, giving evidence of little departure from the cast structure. As the billet is shortened progressively, metal emerging from the die becomes more and more fine-grained until, at the end of the operation, the metallographic structure usually bears little resemblance to that of the end extruded first. The variation in microstructure is accompanied by a corresponding variation in physical properties, and some alloys require subsequent cold working and annealing to enable the entire length of the extrusion to meet physical specifications.

Flaws. One characteristic flaw encountered in extruded products is known as "pipe" or "extrusion defect", caused primarily by the rough, oxidized outer surface of the billet flowing into the center of the extrusion. Because of interfacial friction with the container wall, the forward flow of the billet "skin" is retarded, while metal at the center is forced through the die. This causes the skin at the dummy-block end of the billet to flow toward the center, and thence downward in the direction of the die opening; the resulting action amounts to turning the billet inside out. The point at which the skin first emerges as "extrusion defect" in the extruded product, may occur halfway through the operation, but it usually comes in the last 15 or 20%, and the skin continues to emerge for the duration of the extrusion.

With the alloys that have high copper content, the flow is somewhat modified, so that the skin emerges as a subsurface layer separating a sound central portion and a clean outer layer. Although the outer layer is generally fractured and split, appearing as rough bark, it may sometimes show only as unbroken blisters, or may even give no visual evidence of its existence. With alloys that have intermediate copper contents, modifications of either or both types of extrusion defect may appear. Consequently, it is necessary to examine internally the back ends of all extrusions. This is done by cutting the product progressively with a nick-and-break shear, starting at the end extruded last, and continuing until visual examination of the breaks indicates sound metal. The examination is not completely reliable, since occasionally the defect may be intermittent. For many years the usual method of avoiding excessive defect in the extruded piece, was to stop the operation at the approximate point where the outer skin began to flow through the die as core, leaving a heavy butt end unextruded in the container, amounting to as much as 20% of the billet weight.

This defect has been largely overcome during recent years by widespread adoption of the practice of extruding so as to leave a "shell" or "sleeve" in the container, simply by using a dummy block about ¼ in. smaller in diameter than the container bore. If all elements of the press are in good alignment, the dummy block will shear through the billet, and will leave in the container the aforementioned "shell", consisting principally of the rough, oxidized outer surface of the billet. This practice reduces the extrusion defect to a minor quantity; the weight of the shell is so slight that net operational scrap may be 10% or lower. Extrusion pressure with this practice is midway between that obtaining when a "dry" container is used and that obtaining when a lubricated container is used. No lubricant may be used on the container when extruding with a shell, and care must be taken to have the shell as concentric and continuous as possible.

Another common defect in extrusion practice is known as "checked" rod. This is simply a series of closely spaced cracks occurring transverse to the direction of extrusion, and especially prevalent on sharp corners of extrusions, as in a hexagonal cross section. Although the direct cause is obscure, checked rod can usually be corrected by reducing

Table III. Copper Alloys Commonly Processed by Extrusion (Rod, Bar and Tube)

(b) The mechanical properties shown are *average* and are not to be used as minimum requirements.

the temperature of the billet or the speed of extrusion, or can be traced to a deformed die.

Dies. Extrusion dies are a controversial subject. The design of the die depends somewhat on whether the extrusion is a rod, tube or shape. In general practice a die blank of alloy steel is used, hardened to about Rockwell C 40, and having a diameter-to-thickness ratio of approximately 4:1. When in use, the die is supported in the die holder by ■ "backer die" with a slightly larger aperture. The great majority of extrusion dies fail because the aperture becomes smaller as a result of the upsetting pressure on the blank. A die must be resistant to flow at elevated temperatures, and yet withstand high thermal shock.

Die profiles may range from the 135-deg bell used in the extruding of tube, to an almost parallel-sided profile; the most common type has an opening with radius of approximately 45 deg.

Rods. Most extruded rods are of round, hexagonal or square cross section. Rods as small as $\frac{9}{32}$ in. in diam may be extruded in particularly soft alloys, but standard practice is not to extrude rods smaller than $\frac{7}{16}$ in. or ½ in. in diam. Multiple-hole dies are in general use for sizes smaller than about 1 in. in diam, depending somewhat on limitations of pressure and diameter of the billet. Rod smaller than about ¾ in. in diam is usually coiled hot as it comes out of the die; rod larger than about ¾ in. in diam is extruded in straight lengths. With multiple-hole dies, the extrusion pressure is approximately the same as for dies with one hole equivalent in area.

Billets for the extrusion of rods and bars are usually cast with diameters ranging from 6 to 10 in., depending on the capacity of the press, and in lengths ranging from 4 to 10 ft. These billets are then sawed into lengths from 10 to 32 in., depending on the container available, the alloy, and the required weight of the extruded product. One exception to the use of cast billets for extrusion is in the production of oxygen-free copper by the "coalescence" process,[22, 23] in which electrodeposited copper cathodes are extruded into rods and bars without being melted. This operation is based on the principle that when cathode copper is subjected to reducing gas at a high temperature, and the clean surfaces of the copper are brought together under pressure, the copper will cohere or coalesce, resulting in complete metallic union with intergrowth of crystals across the surfaces of the particles. By this process, brittle copper cathodes broken into small pieces are processed cold into cylindrical briquettes 9¾ in. in diam and approximately 16 in. long. These briquettes are heated in a highly reducing atmosphere for approximately 3 hours and are then transferred from the furnace to a hydraulic press. To avoid reoxidation of the copper, special measures are taken to keep the briquettes in an atmosphere the same as that used in the furnace.

Alloys that are commonly processed by extrusion are listed in Table III along with their tensile characteristics.[2]

Shapes. Successful extrusion of complex shapes depends almost entirely on die design. Considerable skill is required in order to obtain a uniform velocity of flow through the various components of the shape. The regulation is obtained by varying the length of bearing and the angularity of the entrance bell of the components—in other words, choking the flow through the larger elements and expediting it through the smaller ones. This manipulation depends largely on experience and common sense. Before each time it is used, the die may be lubricated by a mixture of cylinder oil and graphite in order to obtain preferential flow. There is also a limit to the depth of recesses in the shape, since the corresponding spur on the die cannot exceed about 1:1 as a ratio of length to thickness. Wide shapes, such as corrugated stairtread stock, are commonly extruded in a semicircle and subsequently flattened so that a finished section perhaps 12 in. wide can be obtained from a billet 9 in. in diam. Another practice often used to advantage is to finish a hollow shape by extruding it partly open with matching lugs on each open end. The lugs are closed and locked when the stock is drawn through a forming die.

Tube. Tube is extruded on both vertical and horizontal presses in this country. Horizontal presses are used increasingly. Original claims that vertical extrusion would produce more concentric tubing, through better tool alignment, have not been substantiated.

The common type of press for extruding tubes has a supplementary piercing mandrel operating within the main ram and concentric with it. The sequence of operations in extrusion of tubes is as follows:

1 Place the hot billet in a container, and place a dummy block behind it. The dummy block has a central hole for the piercing mandrel.
2 Advance the main ram to the point where the billet is compressed sufficiently to fill out the container, but does not extrude.
3 Advance the piercing mandrel through the billet, and thence through the die, until it projects slightly beyond the outlet end of the die.
4 Advance the main ram, forcing the metal through the annular space between mandrel and die, until extrusion is complete.

In some presses not equipped with an auxiliary piercing ram, the piercing mandrel is affixed to the main ram.

Another method, not commonly used on copper alloys, employs a "porthole" die. This consists of a die assembly, split at right angles to the direction of extrusion. Operation of the die consists simply in forcing several "streams" of metal through the ports into the central chamber. In this chamber, in the absence of oxidizing agents, the streams weld into a homogeneous mass and pass out, through the space between the mandrel and die, as a tube or hollow shape.

The production of extruded tubing within close tolerances of eccentricity is not easy. The present trend is toward the use of centrally drilled billets to ensure against

deflection of the mandrel during the piercing operation. For extrusion of drilled billets, a single-action press may be used advantageously, with a "floating" attachment of the mandrel to the ram. When the regular double-action press and solid billets are used, alignment of ram and container must be as nearly perfect as possible or eccentric tubing will result; and maintenance of this alignment is a difficult problem. The floating mandrel, which is more or less self-centering, obviates this difficulty.

Piercing. The first patent on a device for rotary piercing was granted to the Mannesmann brothers in 1885. The process is considered a probable development from a type of straightening machine in which a pair of rotating rolls —one concave and one convex, inclined at an angle to the horizontal but with intersecting centers—moves the tube or rod forward and straightens out kinks and bends.

Equipment. The development of the piercing process was a result of increasing demand for seamless steel tube for bicycle manufacture. Later, the advantages of seamless tube in automobile parts, in gasoline manufacture and as boiler tubes gave further impetus to progress, in spite of the waning popularity of bicycles. A number of variations of the original Mannesmann machine were evolved—the Steifel mill, for example. In this mill, beveled disks replaced barrel rolls as working members. In another machine, three barrel-shaped drive rolls were used instead of the original two. In spite of variation in detail, all these machines embodied the same basic principle of

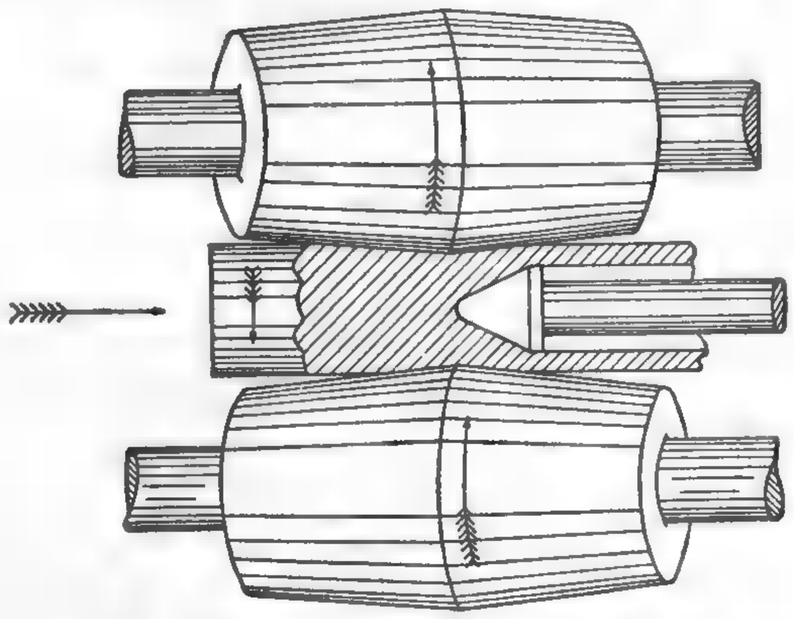

Fig. 1 Fundamental operations involved in piercing (Mannesmann patent, 1886)

forming a hollow shell from a solid billet by rapid rotation of the billet between roll surfaces that give a forward movement over a specially shaped piercing point or mandrel. A popular misconception is that metal is actually forced over this point. In reality, the point serves as a rolling surface to reshape the metal at the outlet side of the roll pass.

In present practice there is considerable variation in details of design. (*See* "The Piercing of Steel", page 351 of this Handbook.) The values given in the following discussion represent current practice in large-scale production of copper and copper alloy tubes but these values are not applied everywhere. Limitations of equipment and varying opinion bring minor changes in the various plants.

Process. Figure 1, taken from a Mannesmann patent granted in 1886, is still an excellent illustration of the fundamentals of the piercing process.[24] In modern mills, the two barrel-shaped driving rolls are coupled, by means of long spindles with universal joints, to a common reduction-gearing unit, so that both rolls rotate at the same speed and in the same direction. The usual drive is by an electric motor connected directly to the reduction gearing.

The rolls are inclined at an angle to the horizontal with intersecting axes to provide the necessary helical rotary motion. Parallel rolls would merely rotate the billet without advancing it. Although in many instances the angle of inclination is fixed, in certain designs the rolls are mounted in cradles held at both sides by adjusting bolts. This arrangement permits the selection of various angles as the need arises. An increase in the angle of inclination, increases the rate of travel through the roll pass to a point where slippage becomes excessive and rupture of the metal begins. On the other hand, if the angle is too small, the forward feed will not open the last portion of the billet to pass over the piercing point. A good compromise for copper and copper alloys is ▮ deg, although this value is not particularly critical.

The driving rolls are mounted in housings that permit lateral movement in reference to the piercing axis, for adjustment for the various sizes of billet. An approximate rule is to have the space between the maximum roll diameters, called the "gorge", about 0.8 of the billet diameter. In general this works fairly well, but closer regulation must be made by trial and error for different piercing conditions, various alloys, or different types of copper, since metal flow differs widely with different materials or even with temperature variations for the same alloy.

The center of the roll pass may or may not coincide with the center line of the machine. If it does coincide, the billet is held in position by adjustable idler rolls both above and below. These rolls should not be adjusted too closely in contact with the billet, since the resulting added frictional drag would then prevent the forward feed of the billet. Because of the necessity for some clearance, vertical movement of the billet is possible between the idler rolls. Copper is not harmed by this action, but alpha brasses may have breaks on the inside surface because of the added working of the metal incident to this movement.

The recent trend is to have the center of the piercing pass below the center line of the machine, necessitating only a single idler roll. Some machines have been made in the reverse manner; that is, having the piercing axis above the machine center. In such machines, a single idler roll is provided. Each of these three roll systems holds the portion of the billet that is in contact with the working surface of the rolls, in the proper position in relation to the piercing axis.

The piercing point is mounted on a long mandrel or arbor, which, depending on the length, may have sliding bushings of approximately the same outside diameter as the pierced shell. The purpose of the bushings is to prevent the mandrel from whipping and consequent disturbance of the relation between point and gorge.

The outlet side of the piercing machine is provided with adjustable table rolls, which guide the shell as it emerges from the piercing operation. It is quite important to adjust these rolls so that there is no whip of the mandrel and so that the forward progression of the pierced shell does not deviate greatly from the piercing axis. This adjustment is more important for copper alloys than for copper, which apparently has a considerable amount of hot ductility and does not develop breaks on the inside surface. Movement of the point, because of the whip of the arbor, may result in nonuniform gage and eccentricity. Shape and position of the idler roll are very important in the control of the horizontal position and helical rotation of the shell in the roll pass.

The far end of the mandrel is mounted in a thrust bearing that permits free rotation of the mandrel. This thrust bearing is on a reciprocating carriage with provision for adjustment of the point position. During piercing, the carriage is latched in position but can later be moved horizontally along the axis of the machine to permit withdrawal of the point from the pierced shell.

The shapes of the driving rolls, the point and the idler rolls are all interrelated with the particular operation, that is, size of billet, size of point, and alloy. In general an inlet roll angle of about 5 deg has been adequate to provide driving force to pierce billets completely in the range of diameters from 3 to 9 in. This angle, together with the lateral spacing of drive rolls previously mentioned, gives a length of contact with the driving rolls approximately equivalent to the billet diameter. Smaller inlet angles may produce excessive internal rupture of the metal before the point is reached in the roll pass, especially in the alloys that are more susceptible. This rupturing is particularly noticeable in commercial bronze (90% Cu) and red brass (85% Cu) billets, 7 and 8 in. in diam.

The outlet angle of the rolls may range from 3 to 10

deg. The smaller angle is used when shells are desired that have a diameter smaller than that of the billets; the larger angle allows for the flare that results in shells of a diameter greater than that of the billets. If the pierced shell is to have approximately the same diameter as the billet, which is ordinary practice for brasses, an angle of about 8 deg is sufficient.

Copper tubes of large diameter are frequently produced in two separate piercing operations. For example, billets 7, 8 or 9 in. in diam may first be pierced to the same diameter and then expanded or "rerolled" in a second operation until the outside diameter is 10 to 12 in. In such instances, the outlet angle must be increased to allow for this expansion. Angles of the order of 12 to 14 deg have proved satisfactory. It is advantageous also to increase the angle of taper of the idler roll in order to allow for the increase in diameter.

The function of the idler roll is to hold the billet in the proper position in the pass. Vertical adjustment is provided for different diameters of billets. Small adjustments can be made to vary the "pinch" on the billet as the need arises. The metal is in contact with the idler roll in two separate zones but not along the entire length of the working pass. On the inlet side the idler roll is at a point opposite that where the billet is first gripped by the driving rolls. This zone may be only about 1 in. wide. On the outlet side of the pass, the idler roll reshapes the shell and controls the final dimensions. The last point of contact is with this idler roll, leaving a light helical marking on the shell. Opinion differs as to the best shape for the idler roll, but a straight taper of a few degrees, with the smaller end on the outlet side of the pass, has served satisfactorily with all the copper alloys when there is little change in diameter. Such a roll permits comparatively free movement of the shell as it is formed.

In experiments with a number of shapes of piercing points, the best results have been obtained with a simple rounded point that has a radius of curvature slightly larger than the diameter of the point.

In the action of piercing, a heated billet is forced through a guide tube, or "cannon" as it is sometimes called, into the inlet side of the working pass. The helical rolling motion imparted by the driving rolls reduces the billet until the maximum drive-roll diameter or gorge is reached. In this reduction, which may be greater than one-third of the original cross section, the billet is compressed between the rolls as it is rotated, setting up torsional forces, in the zone near the gorge, which finally result in pulling metal away from the center of the billet and causing internal rupture.[24]

A shell with a somewhat irregular hole can be made by merely putting a steel or copper billet through a piercing machine without a piercing point, because of the formation of this ruptured area in the converging or inlet pass. When a piercing point is used, with its tip adjusted so that it anticipates the zone of internal rupture, a shell or tube that has a relatively smooth and uniform diameter may be formed by rolling the metal between the point and the driving rolls. This tube, at first slightly elliptical in shape when the metal is rolled away from the point, is rounded out by contact with the idler roll. During the rolling over the point, any irregularities formed in the metal at the converging pass are smoothed out under the action of pressure and high temperature.

Piercing practice in brass mills differs from that in the steel industry in that brass billets are pierced in the as-cast state, while steel billets are rolled to size from large ingots. This makes a great difference in ease of piercing and limits the alloys that can be pierced. Metal in the as-cast state is much more hot short than it is in the wrought condition.

Alloys. The binary copper-zinc alloys can be pierced, provided the lead content of the alpha alloys is held to less than 0.01%. However, medium-leaded alpha-beta brass can be pierced without difficulty. An example is leaded naval brass with 1% Pb. The addition of tin or aluminum to alpha brass always causes severe breakup during piercing, because of coring in the as-cast structure. If tin or aluminum bronzes are first extruded in billet form, they can be pierced under carefully controlled conditions, but such a process is not economical. Naval brass and leaded naval brass, which are alpha-beta brasses containing tin and tin plus lead, are readily pierced.

Temperature. Close control of temperature is necessary in the piercing of brass, since the permissible temperature ranges are narrow. Temperature controllers of the radiation type, which sight directly on the billets, are satisfactory for indicating the temperature of the billets. Each alloy has a temperature range within which it is sufficiently plastic to be worked, yet stiff enough for the pierced shell to remain straight and free from bulges. If the metal is overheated, cracks may form on the inside surface. The temperatures required for those alloys commonly processed by piercing are listed in Table IV.

Table IV. Copper Alloys Commonly Pierced (Tube)

Metal[a]	Suitable Temperature for Piercing, deg Fahr	Mechanical Properties as Pierced[b] Tensile Strength, psi	Percentage Elongation in 2 in.
Electrolytic Copper	1500 to 1600	33,000	35
Deoxidized Copper	1500 to 1600	33,000	35
Commercial Bronze, 90% ...	1500 to 1600	35,000	40
Red Brass, 85%	1500 to 1600	40,000	40
Cartridge Brass, 70%	1400 to 1450	45,000	45
Muntz Metal	1300 to 1400	50,000	45
Naval Brass	1350 to 1450	52,000	45

(a) See Table I for nominal compositions of these metals.
(b) The mechanical properties shown are *average* and are not to be used as minimum requirements.

Time. The values for piercing time and consumption of power depend on so many factors that they must be considered comparative only for the particular machine and operation. Piercing time shorter than 20 sec has been maintained for copper billets ranging up to 9 in. in diam and 4 ft long. During this short time, pierced shells approximately 10 ft long are produced. Billets made of copper, commercial bronze (90% Cu) and red brass (85% Cu) measuring 3 in. in diam and 4 ft long are pierced in about 15 sec to a 10½-ft shell, in a piercing machine with 12-in. diam driving rolls, having a surface speed of 700 fpm at the maximum roll diameter. Alloy billets higher in zinc content tend to whip and chatter violently under the same conditions. When the surface speed of the roll is reduced to about 500 fpm, the piercing action is smooth and the piercing time is again about 15 sec.

Power. The following tabulation shows the difference in amounts of power consumed during the piercing of red brass (85% Cu) and deoxidized copper (approximately 0.01% P) at 1550 F with billets 5 in. in diam. The copper followed directly after the brass, on a machine equipped with rolls 24 in. in diam with a surface speed of 760 fpm, a point 4⅜ in. in diam, a 4-in. gorge and a 6-deg angle of feed or inclination of the rolls.

Metal	Horsepower Required	Piercing Time, sec	Size of Shell
Red brass (85%)	1400	15	5¾ by ½ in.
Deoxidized copper	1000	15	5⅜ by ½ in.

The hot working characteristics of the various alloys differ markedly, as shown by the helical markings on the pierced shell. These markings, which come from the last point of contact with the idler roll, are harmless as long as an ample flow of water is kept on all the rolls. A study of these markings has given valuable information, since they indicate the progress through the rolls. Cartridge brass (70% Cu) tends to form much wider bands at slow roll speeds than copper does at higher speeds. This fact indicates a more rapid rate of feed through the rolls.

The various types of copper likewise have distinct characteristics. Deoxidized copper (high-phosphorus, 0.025% P) requires the most power to pierce, while tough pitch copper requires the least. Deoxidized copper (low-phosphorus, 0.01% P) and oxygen-free copper not phosphorized, are

intermediate. An attempt to evaluate these differences under identical conditions is not possible because of the necessity for making minor adjustments of point and rolls for each type in order to obtain the same size of shell. This fact has been demonstrated repeatedly when the type of copper has been changed in the same setup, and is thought to be caused by differences in flare in the outlet pass, because of the differences in plasticity. In the comparisons cited, the temperature was closely controlled.

In studying the piercing operation, it has been found very instructive to obtain a sample by stopping the machine purposely when a billet is partially pierced. The section of billet and shell in contact with the rolls may be cut out and split and the section may be etched. Such samples give a clearer picture than can be obtained during the actual operation. They show the degree of breakup in the converging pass and the rolling on the point in the diverging or outlet pass. Excessive distortion in the outlet pass shows improper shaping of driving rolls or idler.

Such information has been particularly valuable in piercing billets of commercial bronze (90% Cu) and red brass (85% Cu) having larger diameters. The as-cast billet has a large central zone of equiaxed grains, which tend to break up ahead of the point more rapidly than in copper billets of the same diameter. The use of sharper points to direct the flow of the metal earlier in the zone of internal rupture, helps reduce the incidence of internal defects, and a bevel of a few degrees on the inlet side of the idler roll, gives the billet more support and also helps prevent undesirable breakup. However, an extremely sharp point has a very short life and in actual practice optimum results are obtained with a point that has a somewhat elongated tip shaped like a Gothic arch, the arc of which has a radius approximately 1⅛ times the point diameter.

Because of the many mechanical and metallurgical factors involved, close prediction of behavior is difficult. It is unfortunate that trial and error methods must still be used. Undoubtedly closer definition of conditions will be obtained with further study, since the use of the piercing process has greatly increased in the copper industry during the last few years.

Forging and Pressing. The growth of the copper alloy forging industry may be divided into three periods. The first period took place during World War I, when brass forgings were first introduced and were used principally for ammunition fuse parts. During the second period, between 1919 and 1938, the commercial market for forgings was developed in the fields of refrigeration, automotive parts, plumbing, compressed gas equipment, and engineering, and alloys were developed that had high strength and resistance to corrosion. The third period has been during World War II, when forgings were used for the same purpose as in the first two periods, as well as in the aviation industry. During this period the copper alloy forging industry attained a sizeable production.

Forging or pressing may be defined as the hot shaping of metal by single or repeated blows under a hammer or press, in open or enclosed dies. Briefly, the process consists in heating, to a semiplastic state, suitably shaped bars or "slugs" that have been extruded previously, or chill-cast and scalped; then placing these bars between a set of accurately machined, highly polished, hardened steel dies in a press or hammer, and subjecting the bars to one or more blows under great pressure. The plastic metal is caused to flow and fills the contour of the die; the excess metal becomes flash, which is later trimmed cold. Thin flash in cavities is usually pierced out. Although the process is generally used for irregularly shaped parts with cavities in one plane, parts can be made with cavities in two planes by the use of split dies and side rams. Copper alloy forgings may range in weight from a fraction of an ounce to more than 130 lb.

Stock. Round extruded stock is generally used, since it is the least expensive. For certain forgings that are unsymmetrical in form, extruded shapes approximating the cross section of the forging may be used to advantage. Forgings of large diameter and weight can be made from scalped chill-cast billets cut into slugs.

The extruded rod is cut into lengths, with care to avoid rough ends that might cause forging laps. Excess metal should be minimized to increase die life. Some forgings are forged directly from the heated end of a long bar.

Equipment. The types of machines generally used for forging copper alloys are the following: hammers, varying in size from 1000 to 5000 lb; crank or screw presses, varying in size from 200 to 2500 tons; and forging machines or upsetting machines.

Hammer forgings are especially suitable when the parts are to be unsymmetrical in shape, or when special shaping or bending is required before actual finish forging.

Crank presses or screw presses are more suitable for symmetrical shapes and for operations sometimes designated as "forging-extrusion", which combine forging and extrusion in the same operation, as in the production of parts that have a long shank and a greatly enlarged diameter at the base of the shank. Modern crank presses may utilize a blocking impression and finishing impression, the same as are used on a drop hammer.

Forging machines or upsetting machines are used for producing certain types of small forgings and for enlarging the ends of bars used in making valve stems, bolts and the like.

Dies. Forging dies are designed with draft so that the resultant forging can be removed readily from the die. The draft on hammer forgings may vary between 3 and 7 deg, while on press forgings the draft is usually between 1 and 5 deg, depending on the forging design. To increase die life and to aid in metal flow, no sharp corners should be left in die cavities. An allowance for shrinkage between 0.010 and 0.015 in. per in. must be made on the die, for the cooling of the forging to room temperature. A flash allowance of 0.035 to 0.080 in. is made on the die, depending on the design of the forging and the alloy used. Where the design of the forging permits, dies are made with multiple impressions.

For discussion of the composition and heat treatment of die blocks, die inserts, and tools for forging machines, see the TOOL STEEL SECTION of this Handbook.

It is common practice to lubricate the die with oil to which a little graphite has been added. This lubricant facilitates the flow of metal in the die, prevents overheating, and keeps the forgings from sticking to the die. The use of a lubricant also has a marked effect on the life of the die.

Die life depends on the steel used for the die, the design of the forging, the alloy used for the forging, tolerances required on the forging, and the care taken by the operator in using the die—for example, preheating the die before using, lubricating the die, cleaning the die at proper intervals and operating the press at the proper speed to avoid overheating the die excessively. Dies fail as a result of heat checking, washing, cracking, or becoming oversize from cleaning. Die life may vary between 5000 and 100,000 pieces, depending on all these factors.

Alloys. The copper alloys commonly used for forging are listed in Table V. Most of the alloys are of the alpha-beta type. As shown in this table also, not all copper alloys can be cold sheared successfully. When stock for shearing is ordered, the purpose should be specified.

The tolerances on forgings will vary with the diameter. While forgings can be made to a tolerance of plus and minus 0.005 in., a tolerance of plus and minus 0.010 in. is generally used. Objectionable draft can be removed from small parts by a cold shaving or piercing operation.

Forgings are furnished with a bright dip finish by pickling in a bichromate-sulfuric acid solution and then rinsing in both cold and hot water.

The advantages obtained in a forging include high mechanical properties, freedom from porosity, excellent surface finish, close tolerances, good machinability and low scrap loss.

Bending and Forming. Under this heading can be grouped all the forming operations that have for their main purpose a change in the shape of the article fabricated. Any reduction that may occur in the cross-sectional area of the article is largely coincidental rather than intentional. In this respect hot bending and forming operations differ from the other hot working operations, which both change the shape drastically and reduce the cross section of the material being processed.

Table V. Copper Alloys Commonly Hot Forged and Pressed

Metal[a]	Suitable Temperature for Forging, deg Fahr	Probable Range of Mechanical Properties[b] as Forged: Tensile Strength, 1000 psi	Yield Strength, 1000 psi	Percentage Elongation in 2 in.	Rockwell Hardness	Ability to Be Cut by Cold Shearing
Electrolytic Copper	1400 to 1600	30 to 38	8 to 10	45 to 50	F 25 to 65	Yes
Deoxidized Copper	1400 to 1600	30 to 38	8 to 10	45 to 50	F 25 to 65	Yes
Muntz Metal	1150 to 1450	45 to 60	20 to 30	25 to 50	B 35 to 50	Yes
Forging Brass	1200 to 1500	45 to 60	20 to 30	20 to 35	B 35 to 50	Yes
Naval Brass	1200 to 1500	50 to 65	25 to 35	35 to 55	B 45 to 60	Yes
Leaded Naval Brass	1200 to 1400	50 to 65	25 to 35	20 to 35	B 45 to 60	Yes
High-Silicon Bronze (A)	1300 to 1600	50 to 65	18 to 24	50 to 70	B 35 to 50	Yes
Low-Silicon Bronze (B)	1300 to 1600	40 to 55	16 to 22	50 to 70	B 30 to 45	Yes
Aluminum Bronze	1450 to 1600	75 to 90	33 to 40	15 to 30	B 75 to 90	Yes
Aluminum Bronze	1450 to 1550	80 to 90	36 to 45	15 to 30	B 80 to 95	No
Manganese Bronze (A)	1150 to 1450	60 to 75	35 to 45	25 to 45	B 65 to 80	Yes
Manganese Bronze (B)	1150 to 1450	85 to 105	55 to 75	15 to 30	B 85 to 100	No
Nickel Silver, 10% Leaded	1350 to 1500	65 to 75	40 to 50	20 to 40	B 62 to 77	No

(a) See Table I for nominal compositions of these metals.
(b) The mechanical properties shown are *average* and are not to be used as minimum requirements.

Hot bending and forming operations are usually performed when sharp bends are desired in the shape of the metal, or other drastic changes are required that are impractical to perform cold because of possible strain hardening of the metal to such an extent that rupture may occur. This hot method is employed also whenever the available equipment for bending or forming, and the size of the article to be fabricated, are such that cold fabrication is impractical.

The bending of heavy pipes, tubes, rods, bars and shapes, or dishing of heavy plates for large heads of pressure vessels, are typical operations that may be performed hot with relatively greater ease and without the possibility of strain hardening that could lead to early failure of the material.

The equipment generally used in these operations includes sledge hammers, bending hickeys, bar folders, brakes, drawbenches, roll-forming machines and hydraulic presses.

Since the bending or forming operations are often restricted to only a portion of the article, it is common practice to heat only the portion to be worked. As in other hot working operations, care must be taken so that the temperature will be correct for the metal fabricated, in order to avoid the possibility of cracking.

To avoid possible collapse of thin tubes at the point of bending, it is sometimes advisable to fill the tube with a material such as sand before the bending operation.

The Cold Working of Copper and Copper Alloys

BY THE SUBCOMMITTEE ON COLD WORKING OF COPPER ALLOYS*

THE ABILITY of a metal to be cold worked depends largely on its mechanical properties, such as tensile strength or hardness and ductility. Ductility is particularly necessary, since without it no cold work can be done, but strength is also an important factor, controlling the ability to support loads and influencing machine capacities, tool life and lubrication. Ductility is highest and strength is lowest in fully annealed metal; therefore such metal has the greatest potential capacity for cold working.

The effect of cold working is to increase the tensile strength, yield strength and elastic limit, and to reduce the elongation and contraction in area. This relationship is best expressed in the form of characteristic curves, showing some of these properties (*see* Fig. 1). Besides recording the properties resulting from cold work, these curves give an approximate indication of the extent to which cold working is possible. The elongation curve, for instance,

* The members of this subcommittee are R. S. Pratt, *Chairman* (Bridgeport Brass Company), O. B. Atkin (Chase Brass & Copper Co.), W. R. Hibbard (The American Brass Company), D. H. Mead (Revere Copper and Brass Incorporated), F. R. Reutter (Scovill Manufacturing Company), J. S. Rodgers (Wolverine Tube Division, Calumet & Hecla Consolidated Copper Co.) and R. A. Schatzel (Rome Cable Corporation).

indicates from its starting point in the annealed condition, the extent of cold working that can be accomplished by free-stretching operations, as in expanding or bulging processes. This same curve indicates, relatively at least, the amount of cold work that can be accomplished in a single operation by drawing. The decrease in elongation values with cold work indicates the lack of capacity for stretching operations in the cold worked condition, but does not measure the ability of the metal to be redrawn.

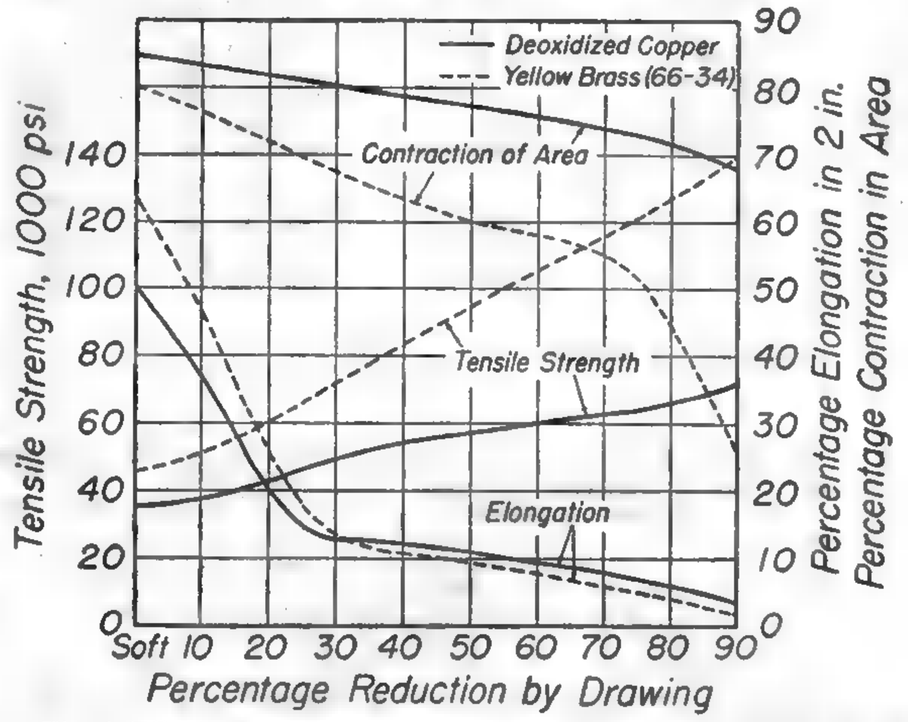

Fig. 1 Effect of cold reduction on the mechanical properties of copper and brass

The values for contraction in area are more useful in this respect, because material with a flat curve depicting contraction in area, and with high values for that property, is most likely to be capable of repeated cold working operations. Material with low initial values and rapidly decreasing values of contraction in area is not usually capable of repeated cold working operations. The curves shown in Fig. 1 indicate these differences.

The initial values shown in these curves may vary somewhat for the annealed material, depending on the temperature of annealing and other factors, but such variations affect the general level of the values rather than the shape of the curves. Alloys that consist of two structural constituents, such as alpha-beta or leaded alloys, are ordinarily less readily cold worked than are the single-phase alloys. In the alpha-beta alloys, this reduced ability is shown by the characteristic curves. In the leaded alloys, the normal mechanical properties do not give so clear a picture, possibly because these properties do not indicate the increased tendency toward failure by shearing in these alloys.

The rate at which metals harden during cold working is also indicated by the curves of tensile strength. The forces involved in cold working, the pressures on tools, and the lubricants are related not only to the initial strength of the original material but also to the rate at which the metal hardens during the operation. This rate is indicated by the slope of the tensile curves as a result of cold working, and it varies considerably in the different copper alloys. While the tensile strength increases at a relatively uniform rate, the yield strength increases very rapidly in the early stages of cold work and then parallels the tensile strength after about 20% reduction. Based on tensile strength alone, copper work hardens at a rate of about 400 psi for each 1% of reduction in area by drawing. In comparison, yellow brass hardens at a rate of about 880 psi, silicon bronze at about 1100 psi, and some of the aluminum bronzes at 1400 psi. Although these figures are only approximations, they do indicate the range of variations fairly well. Generally the rate increases together with an increase in initial annealed strength of the different alloys, although there are exceptions to this rule, such as cupronickel, which work hardens at a rate similar to that of the 85-15 copper-zinc alloy.

This outline of the relation of mechanical properties to the ability to be cold worked is of particular interest here, but other effects of cold work are equally important. For information on the more theoretical aspects of cold working, the reader may refer to the article on page 259.

Cold Working Flat Products

Rolling. "Rolling" is a term applied to the operation of reducing metal in thickness by passing it through rolls which compress it. The rotation of the rolls causes the metal to proceed at a uniform rate of speed.

The first stage of rolling is known as "breaking down". This covers rolling from the casting to a thickness of about ½ in. for alloys, and to about ¼ in. for copper. The surface of alloys is usually removed by a scalping or milling operation at this stage.

The next rolling, known as "running down", takes the metal to a point approximately 2 to 4 times the finish gage. The rolling from this point on to the finish is known as "finish rolling". For metals that require acid cleaning following the anneals in lighter gages to remove oxide and scale, the rolling after such cleaning operations is commonly conducted on rolls of the finishing type.

Rundown and finishing rolls are ordinarily of forged alloy steel, subsequently hardened and ground, although for some types of work cast-iron rolls and cast steel rolls may be used. During the rolling, lubricants of various types are used on the metal to decrease friction and to avoid excessive heating, which would change the roll shape. Rolls must be ground frequently to maintain proper surface and shape. Since rolls are subject to spring or deflection during a heavy roll pass, it is common to compensate for this by grinding them with a crown, a practice that prevents a heavy center and wavy edges in the rolled strip.

A limiting factor in rolling has been the difficulty in obtaining satisfactory bearings to operate under the high pressures involved. Early bearings were bronze, later improved by babbitt coating. With the advent of higher speeds and heavier reductions, the former bearings have been replaced by those of the antifriction type, such as pressure-lubricated sleeve bearings, phenolic bearings and roller bearings.

The most common rolling equipment is the two-high mill, consisting of two parallel horizontal rolls, one above the other. The rolls are of the same diameter and rotate at the same speed, but in opposite directions, so that their surfaces travel in the same direction at the point of contact. Metal introduced into the rolls is driven between them during the pinch or reduction, commonly termed a "roll pass".

Copper ordinarily receives breakdown rolling when the metal is hot, and a large amount of sheet copper was formerly rolled hot all the way to the finish gage, with such intermediate reheating as was necessary. As the metal becomes thinner, such rolling is conducted in packs (several sheets on top of one another). This type of rolling results in a large amount of scrap on the end and side of each sheet, inferior control of gage, and poor surface quality. As equipment suitable for the cold rolling of coils in wide widths became available, the range of widths that could be rolled was increased. Copper that is cold rolled to finish has more uniform dimensions and better mechanical properties.

Most copper alloys were formerly broken down cold and cold rolled to finish. When rolled on conventional rolls, these alloys will not stand much more than 50 to 65% reduction in thickness without serious cracking at the edges. Thus the amount of reduction between anneals is limited, and it is necessary to anneal frequently to soften the material for further cold rolling. The early castings were of thin cross section to avoid an excessive number of cold roll passes and anneals. For cold rolling, castings are usually limited to a maximum thickness of about 2 in.; the maximum bar weight is limited also, since attempts to increase the cast length met with difficulties in casting quality. In recent years the industry has adopted hot rolling for the breakdown rolling of a number of the more common alloys, thus permitting a considerable increase in the weight of the bars.

After the breakdown rolling, the alloys are rolled cold

during the rundown and finishing rolling. The increase in bar weight has resulted in a decrease in time interval, and in scrap from the ends. The heavier units have necessitated the use of improved handling equipment.

Tandem rolls consist of two to as many as five stands of rolls in a series. In such equipment the strip is reduced in gage simultaneously in the several stands. The speed of each roll requires careful adjustment to give proper tension between successive roll stands. Tandem rolling results in less manual and mechanical handling. Disadvantages include inflexibility when changing from one type of work to another, and the fact that the number of passes is fixed by the number of rolls in the installation.

So far only conventional two-high rolls have been considered. For breakdown rolling, a large number of passes is needed, and the time required to return each bar to the entering side of the rolls for each subsequent pass was such that the metal cooled off too much to be hot rolled to the desired thickness. This led to the development of three-high rolls. A roll stand of this type incorporates one additional roll above the conventional pair of two-high rolls. The metal receives a reduction when traveling in one direction between the lower and center roll, and in the other direction between the center and upper roll. This type of equipment was rather commonly employed before reversing mills became usual. With this kind of roll, the direction of pass is changed by the use of a reversing motor, and each alternate pass is taken in the opposite direction, which saves moving the metal by hand from one side of the roll to the other.

Four-high rolls, as the name implies, are designed with four rolls, one on top of another. The middle two are the work rolls between which metal is reduced in thickness. The other two rolls are back-up rolls, for the purpose of supporting and lending rigidity to the work rolls. The back-up rolls generally run idle; the work rolls are driven. The work rolls are of considerably smaller diameter than the ordinary two-high rolls. Most of the modern tandem installations make use of four-high rolls.

It has been found that as the working rolls are decreased in diameter, the power requirements are lower, and the amount of reduction may be relatively increased. Since it is possible to reduce the metal more between anneals without cracking the edges, the number of anneals is decreased.

The proven advantages of small working rolls supported by back-up rolls have led to the development of numerous types of mills that have four or more rolls. Some of these mills are still in the experimental stages; some are already in use for production purposes. On many of the newer installations of rolls, powerful take-up reels and tension devices are used at the front and back, helping to keep the metal flat and straight.

Slitting. This process is used to bring rolled flat products to final width by cutting them on a rotary slitter. The operation serves the dual function of eliminating imperfect edges and of bringing the rolled flat material to the desired width.

The machines used for slitting consist of rotary cutting shears mounted on two parallel shafts that are rotated in opposite directions and are driven by a motor through suitable reduction gearing. The rotary cutters are from about 4 to 13 in. in diam, and from ⅛ to ¾ in. thick. Good service is obtained from cutters made of high-carbon tool steel. In addition to the removal of imperfect edges in the slitting operation, it has been found expedient also to slit several strips from one roll of material. When numerous pairs of properly spaced cutting shears are employed, several different widths of strip or several strips of the same width can be slit simultaneously from the same roll. A coiling mechanism at the exit end of the slitter is used for rewinding the slit strip. The maximum thickness that can be slit on modern slitting machines in the copper and brass industry is about ¼ in.; however, this value depends somewhat on the capacity of the slitter, the number of cuts per roll, the alloy, and the temper of the rolled material. Rolled flat products more than ¼ in. thick must be sheared or sawed to width.

Flattening and Shearing. Shearing is a process used to bring rolled flat products to final width and length by cutting on a press shear. The operation is performed when it is desired to produce metal with accurately straight edges and with ends at right angles to the edges.

Material with sheared edges is first flattened by rolls and cut to a predetermined length on an automatic cutoff machine; then it is brought to final width and length by press shearing. The automatic machines used to flatten and cut the rolled material have an upper and a lower set of rolls staggered so that when the sheet or strip passes through, the metal is flexed repeatedly but is not reduced in thickness during this operation. An automatic shear built into the machine, next cuts the product to the predetermined length. The entire operation offers a means of flattening and cutting rolled products rapidly and efficiently without the danger of scratching the high-quality surface. Annealed or lightly worked material may or may not be stretcher-straightened or patent-leveled to remove buckles, ripples or wavy edges after being flattened and cut to length.

When it is desired to produce metal with accurately straight edges and with ends at right angles to the edges, the material is press-sheared and the product is classified as square sheared metal. This material is available in lengths up to 120 in., and in widths up to 60 in.

Blanking. Blanking is a process used to cut or to punch flat pieces of desired shape from rolled flat products, and offers a rapid method of cutting identical flat pieces. The blanking operation is performed through a shearing action applied by means of a punch and blanking die, each of which has a sharp edge and clearance in proportion to the thickness of metal cut. Ordinarily the die is fixed in a horizontal rigid position and the punch moves up and down in relation to it. The press is usually equipped with an automatic gage to regulate the forward movement of the strip or sheet between successive strokes of the punch. Guides keep the strip properly aligned in the press, and a stripper plate strips the skeleton from the punch. Since the blank takes the shape of the face of the punch, this face is usually ground flat and normal to the axis to reduce distortion of the blank. However, if the dies are ground at a slight angle to the plane of the blank-cutting edge, so that the punch enters the metal progressively, the maximum blanking pressure can be greatly reduced. This progressive shearing is particularly helpful in cutting blanks from relatively thick sheet or strip.

A number of factors influence the maximum pressure required for the blanking operation. The alloy composition and mechanical properties of the sheet or strip, the thickness and temper of the rolled flat product, the size and shape of the blank, the clearance between the punch and blanking die, the angle at which the tools are ground, and the sharpness of the cutting tools—all exert an influence on the maximum working pressure and ease of blanking.

In blanking sheet or strip of the same thickness and temper, yellow brass and cartridge brass have greater resistance to shearing than low brass, red brass and commercial bronze. Copper has still lower resistance to shearing than this latter group of alloys. In blanking sheet or strip of the same alloy and thickness, cold worked material is found to have greater resistance to shearing than annealed material. As an approximation, the shearing strength of the copper alloys is about 60 to 75% of the tensile strength.

Some clearance must be maintained between the punch and the blanking die in order to facilitate the shearing action. A greater clearance is required for soft materials than for hard, and a greater clearance is required for non-leaded brasses than for the leaded alloys. The size of the blank is determined by the size of the blanking die. The clearance is subtracted from the die size in order to determine the size of the punch.

Punching. Although "blanking" and "punching" are terms often used synonymously, the two operations are not the same. The ultimate product of the blanking operation is a flat shape cut from the sheet or strip. Later the blank may or may not be formed, bent or drawn. "Punching", on the other hand, is a term applied to the making of holes or irregular openings in flat products.

As a general rule, the minimum diameter of the hole that is punched in a sheet is approximately equal to the

thickness of the sheet. If it is desired to make holes smaller in diameter than the thickness of the sheet, these holes should be drilled. The size of the punched or pierced hole is determined by the size of the punch, and the clearance is added to the punch in order to determine the diameter of the die. The shear also is applied to the punch in piercing holes in sheet or strip.

Stamping, Coining, Embossing.* The making of coins and simple stampings, probably one of the earliest methods of cold working metals, was a practice in England as early as 1750, and probably earlier in Southern Germany or Northern Italy. Coffin and coach hardware was embossed shortly afterward. Embossing of buttons and novelties of various kinds followed.

The early dies were the so-called "hinge" type, which were struck with a sledge; later, pressure was exerted by a screw. Mechanical presses were introduced about 1833. On these presses the earliest known mechanical feed was installed, consisting of a tube filled with blanks and a pair of finger levers to carry the blanks to the die and to remove the coined blank.

Stamping, coining and embossing are accomplished in various types of mechanical or hydraulic presses and rope stamps. The comparatively thin metal blank is confined and forced to take the outline of the die. The cold work varies from the flattening of a small washer or disk to the formation of a radiator shell, automobile part or section of an aircraft wing.

The earlier machines were the rope stamps. Then followed dual-action and knuckle-joint presses, hydraulic presses, and presses with or without hydropneumatic, pneumatic or spring-pressure equalizing equipment. Many articles are formed and embossed in the same operation. Tools for stamping, coining or embossing may be used at positions on an eyelet press.

Among articles made on such equipment are coins, tokens, vanity cases, jewelry, brass novelties, flatware, key blanks, clips, gear blanks, handles, emblems, arms, nuts, segments, tacks, rivets, washers, disks, cover plates, buttons, bottle tops, box tops, wall plates, name plates, builders' hardware and parts for electrical, radio, automotive and other industries. Castings and forgings are sized to final shape on stamp presses to avoid costly machining.

Many articles are now made by stamping two or more parts and then assembling them by lock-seam joints, soft solder, silver solder or welding. Articles formerly forged or cast are made in this manner at lower cost.

Stamping presses are also used for preforming slugs of copper or copper alloys before hot pressing or forging. This provides better flow and distribution of the metal in the finished forging or pressing.

All copper or copper alloys that can be cold formed or drawn can be stamped, coined or embossed. Because of its ductility, copper cold works more easily than the others of this group. Sometimes, depending on the thickness and the amount of cold work in the operation, the metal is one-eighth or one-quarter hard temper instead of annealed material in order to give the finished product the stiffness desired. The material with some temper in it will blank better and give a better finish to the article.

Bending and Forming. The forming of strip by blanking and subsequent bending operations is a very important factor in the production of springs, clips and similar widely used parts in the electrical industry.

In most of the copper alloys, spring properties are improved by cold working and, as a result, the strip used in forming springs and clips is not in the annealed condition but has been cold rolled to increase the tensile and yield strengths. The operation of bending does not change the temper of the part except locally at the point of bending. The amount of forming or bending that can be done, depends on the gage, temper of the strip, radius of the bends, and also on the direction of the bend with respect to the direction of rolling. The more forming the part is to receive, the less cold rolling it can be given. Thus the design of the part and the layout of the bending operations are limiting factors in the development of maximum spring characteristics in the finished parts.

* Stamping, coining and embossing are similar to press drawing and forming, which are described on page 874 of this article.

Cold rolled strips vary in ductility with the direction of the applied stress. The least ductility is shown when the strips are stressed across the direction of rolling. It is therefore necessary to arrange the strip for blanking so that no severe bends are made in that direction. This frequently results in the blanks being cut at 45 deg to the direction of rolling and bent so that the major bending stresses are at 45 deg or parallel to the direction of rolling. Quite often this results in a more economical use of material than when the blanks are cut square with the length of the strip.

Considerable work has been done to determine what effect the gage, temper, and radius of the bend have on the degree of bending possible. In general the thinner gages, smaller amounts of cold work and larger bend radii, will permit the larger angle of bend.

In forming the bends, allowance must be made for spring-back. This requires that the metal be bent slightly more than the required angle of bend so that after forming, the spring-back will result in a final bend of the desired amount. The same effect can be produced in parts of lighter gage by stamping the angle of the bend to set the metal in place.

Occasionally strip parts that are not required for spring parts are formed by bending operations, and in such instances annealed material will permit more severe bending operations. In applications of materials capable of hardening by heat treatment, it is sometimes desirable to do the forming before hardening while the metal is in the fully softened condition. Material such as beryllium copper is formed before hardening if the forming operation is particularly severe, but even in this material it is desirable, if possible, to work with metal that has been at least partially hardened by cold work, since this will improve the ultimate spring characteristics after final heat treatment.

Many of the copper alloys can be formed by bending operations, but the materials most commonly used for springs or clips are phosphor bronze, nickel silver, cartridge brass, silicon bronze and beryllium copper. The usual requirements involve metals of high elastic limit, fatigue limit and resistance to corrosion. When maximum electrical conductivity is required, some of the higher-copper alloys or pure copper can be used, although this will necessitate some sacrifice of desirable spring properties.

Production of Rod and Wire

Cold Rolling. The cold working of rods was probably started in this country in about 1873. In the early process, square cross sections of brass were slit or sawed from brass sheet or plates and then rolled into rod. Usually the rods were finished by a drawing operation.

Later, castings 2 or 3 in. in diam were made in the so-called "cannon" molds and were rolled to size by various passes, according to equipment in the rod mill. After each pass, the rod was turned 90 deg around its axis to avoid the formation of fins and to straighten it.

The operations are usually divided into roughing rolls, intermediate rolls and finish rolls. After roughing, the rods may be die scalped or rotary scalped.

A typical practice for the production of an annealed phosphor bronze rod 1½ in. in diam is as follows:

Cast 2⅛ in. in diam by 72 in. long.
Medart straighten.
Anneal at 650 C.
Roll to 1⅞ in., to $1\frac{13}{16}$ in., to 1¾ in. successively.
Anneal at 650 C.
Roll to 1⅝ in., then to 1½ in.
Spring.
Anneal at 600 C.

This method is used today in some mills, although largely as a breakdown operation on alloys that are not readily hot worked. The number of suitable anneals and the amount of reduction in cross-sectional area between anneals is determined by the composition of the metal or alloy. Brass rods containing 70% Cu and 30% Zn can be given greater reductions than leaded hardware bronze or leaded commercial bronze. These last two alloys are red brass and commercial bronze with additions of lead to

make them free-machining. Phosphor bronze can be given greater reductions than leaded phosphor bronze.

In other mills, the castings are square cross sections of suitable length instead of long cylinders. These bars are rolled in either alternate diamond or oval grooves and round grooves in the rolls, until the final rolling is accomplished. Suitable anneals and scalping are used, as mentioned before, depending on the metal or alloy.

The selection of lubricants used during cold rolling depends on the alloy and the amount of cold work between anneals.

Among the alloys that are commonly cold worked without extrusion or hot rolling are the phosphor bronzes containing more than 4% Sn, leaded phosphor bronze, nickel silvers both leaded and unleaded, beryllium copper, hardware and leaded commercial bronzes.

The most modern method of cold rolling rods and wire rods on multiple cold rolling rolls is described later.

Cold Drawing. Most wrought copper alloys are available in rod form and in one or more tempers or degrees of reduction. Cold drawing is a process by which these alloys can be produced with desired size, section and mechanical properties. Rods—either extruded, hot rolled or cold rolled—are brought to final dimensions by one or more cold drawing operations with suitable intermediate anneals when necessary. After the final draw, the rods are straightened mechanically and cut to desired length.

Rod of large diameter is drawn on a drawbench, which consists of a horizontal frame that has a mechanical drive at one end and, at the opposite end, a die through which the rod is drawn. An endless square-linked chain runs through the center, lying in a channel at the top of the frame and returning beneath the bench. The chain passes over a sprocket at the driving end of the drawbench, and over an idler at the opposite end of the bench. The sprocket is driven by a variable-speed motor. A carriage, equipped with jaws to grip the pointed end of the rod, runs on tracks along the top of the drawbench and is automatically engaged with the continuous chain. Modern drawbenches are constructed to draw a single rod or often two or three rods simultaneously.

Both intermediate and final drawing reductions on small rod are performed customarily on a block, which has provision for a die and a rotating drum on which the drawn material is coiled. Particularly in the drawing of long coils, it has been found advantageous to use a variable-speed motor and suitable reduction gearing, so as to permit slow starting and subsequent high-speed drawing. After being drawn to final size, the coiled material is subsequently straightened and cut to predetermined individual lengths on an automatic rotating-head straightener and cutoff machine.

Regardless of size, the extruded or drawn and annealed rod is first pointed. This pointing operation is accomplished either in a rotary swaging pointer or in a rotary cutting pointer. The pointed rod is next pickled in a 10% sulfuric acid bath to remove any abrasive oxide. It is then rinsed in cold and hot water and dipped in a hot aqueous soap solution. An additional lubricant is usually employed in drawing the rod through the die. Various materials are used for this purpose; some of the more popular include lard oil, pulverized soap, tallow, and specially prepared drawing compounds.

Hardened steel dies yield satisfactory results in drawing copper and copper-zinc alloys. However, the use of sintered carbide dies assures longer life for the die and less tendency toward scratching of the die, particularly in drawing the refractory alloys.

Cold drawing of copper and copper alloys increases the strength, hardness and stiffness, and at the same time reduces the ductility of the material. The amount of increase in strength and hardness, and the extent of reduction in ductility effected by cold drawing, depend on the alloy, the total reduction in area and the number of draws used to obtain this total reduction. Copper, nonleaded brass, silicon bronze and cupro-nickel about 1 in. in diam are usually drawn with reductions of 20 to 35% in area, depending on the ultimate mechanical properties desired. The leaded brasses in this size range are usually drawn with reductions from 15 to 25% and the naval brasses and aluminum bronzes are usually drawn with reductions from about 10 to 20%.

Drawing Shapes. Drawn shapes include all sections other than the simple symmetrical ones, such as round, hexagonal, octagonal, square, rectangular, and so forth that are brought to final dimensions by drawing through a die. The origin of the shapes is in all instances determined by the complexity and the specific dimensions. The more massive sections, or sections where there is a considerable change in thickness of section from one portion to another, are started most frequently by extrusion, but sometimes by hot rolling. Shapes of considerable complexity but relatively light uniform thickness are more commonly started from rolled flat strip. Finally, any generally tubular section, regardless of complexity, is commonly started from round seamless tube.

The production of extruded sections is discussed in the article on "Hot Working Copper Alloys", page 859. A large number of extruded shapes are not drawn to final dimensions and would therefore not properly come into the present category. Only the relatively simple shapes lend themselves to such final drawing, and this is resorted to usually when greater precision is required than is obtainable in the material when merely extruded. The reason why such sections are not more frequently drawn to final size is that the alloys most commonly used, namely, architectural bronze and free-cutting brass, do not lend themselves well to cold drawing except in simple rod.

When drawing shapes from either flat strip or round seamless tube, it is usually necessary to use at least two drawing operations in order to bring the material to the desired shape and accuracy of dimension.

Regardless of the starting procedure, the shapes must be pointed by cutting, swaging, rolling or a combination of two or more of these procedures in order to start the section through the die. The shape is next pickled in a 10% sulfuric acid solution to remove any abrasive oxide, then rinsed in cold and hot waters and dipped into a hot aqueous soap solution. The section is then drawn through a hardened steel die on a drawbench. An additional lubricant is usually employed in drawing the shape through the die. The cold drawing operation increases the strength, hardness and stiffness, and at the same time reduces the ductility of the material. Various means are employed for straightening drawn shapes. Mechanical roll straightening, stretcher straightening and hand straightening methods are used, depending on the intricacy of the section.

Drawn shapes fabricated from extruded sections are commonly made from copper, architectural bronze, free-cutting brass, naval brass or manganese bronze. Obviously the alloys that are not well suited for extrusion cannot be processed in this way.

Shapes formed from either strip or tube are commonly made from copper or any of the brasses containing 65% Cu or more, with or without the addition of lead for machinability. Such shapes are also somewhat less frequently drawn from silicon bronzes, phosphor bronzes and nickel silvers. As indicated above, the choice of the alloy depends partly on the size and complexity of the shape, but is frequently influenced by color and less frequently by the mechanical properties desired.

Multiple-Stand Rolling of Wire. Modern production requirements encountered in the nonferrous wire industry have led to the comparatively recent development of multiple-stand rolling equipment for breakdown and rundown operations. These multiple-stand rolling machines consist usually of ten pairs of grooved rolls of graduated reduced sizes. The rolls are mounted in a straight line and each pair of rolls is assembled at 90 deg to the next pair.

The three popular size 10-stand mills reduce 0.750-in. wire to 0.325 in. square, 0.625-in. wire to 0.250 in. square, and 0.500-in. wire to 0.187 in. square respectively. A 12-stand mill that will reduce 0.75-in. wire to 0.250 in. square will be in production soon.

The 10-stand mills that reduce 0.750-in. wire to 0.325 in. square and 0.625-in. wire to 0.250 in. square are operated by 125 hp, variable-speed d-c motors and the finished wire comes from the mills at the maximum rate of 180 fpm. The mill that reduces 0.750-in. wire has grooved rolls 7 in. in diam by 2 in. thick and the mill that reduces 0.625-in.

wire has grooved rolls 6 in. in diam by 2 in. thick. The rolls have a 90-deg groove with a small radius, and the shape of the resulting wire is approximately a round-cornered square. Excellent service has been obtained from rolls made of carburized SAE 3115 steel. The rolls are geared independently of each other to a solid line shaft. Reference to Table I will show the groove sizes of the individual rolls and the approximate reduction per pass in rolling 0.750-in. wire to 0.325 in. square. A tolerance of plus and minus 0.002 in. is maintained on the setting of the rolls in order to prevent slippage during the rolling operation and hence, to prevent scoring of the rolls.

Table I. Groove Size and Reduction on Rolling from 0.750 in. to 0.325 in. Square. Total Reduction Approx 81%

Roll Number	Groove Size, inch	Approximate Percentage Reduction of Area
1	0.652	24
2	0.601	15
3	0.554	15
4	0.511	15
5	0.472	15
6	0.434	15
7	0.400	15
8	0.369	15
9	0.340	15
10	0.325	9

Extruded, hot rolled or annealed coils are first fed through a five-roll straightener before entering the ten-stand mill. A three-roll coiler at the opposite end of the mill forms the cold worked wire into coils approximately 24 in. in diam.

A lubricant composed of 80% machine oil, 15% kerosene and 5% lard oil is flowed continuously onto each roll while in operation. The lubricant falls into a trough, which runs the entire length of the mill, and is collected in a tank beneath the floor. From here it is pumped through a filter, which removes any grit or sharp particles that might be injurious, and redistributes the oil on the rolls. All bearings are lubricated with a suitable grease by means of a semiautomatic lubricating system, and indicators on each grease line to the bearings are visible to the operator. The wire passes through a stream of compressed air that removes all excess oil after the wire has left the last pair of rolls, but before it enters the coiler.

In the brass industry, nonleaded alloys with a copper content of about 58 to 100% Cu are successfully rolled to a total reduction of 80% in these multiple-stand machines. Alloys with a lead content up to 1% Pb can be reduced 70% by rolling from 0.625 in. square to 0.325 in. square. The cupro-nickels, nickel silvers, phosphor bronzes and silicon bronzes possess sufficient ductility to withstand 80% reduction, although the roll life experienced with these alloys may be somewhat less than that obtained with the copper-zinc alloys.

Wire Drawing. Wire drawing is one of the oldest commercial arts and has until recent years remained an art rather than a science. This is particularly true of copper wire, because of its great ductility.

Copper has been drawn from 1-in. diam rod to 0.002-in. diam wire with no intermediate anneal. However, this is not good commercial practice in industry where high-speed continuous drawing and exacting requirements of application make necessary an understanding and control of factors influencing the properties of the wire and the process of wire drawing. Even with copper the process of drawing has a definite bearing on the characteristics of the finished wire. This applies with greater force to the alloys of copper. In general, good practice is to anneal copper after each 90% reduction in area. Copper alloys may be reduced 25 to 60% in area before annealing, depending on the rate at which the alloy work hardens. The percentage reduction in area, annealing time and temperature are factors in determining grain size and ultimate properties. In drawing alloys it is therefore necessary to set up definite drawing and annealing schedules for the particular alloy under consideration. The following are important factors in wire drawing:

Composition. Copper that complies with ASTM specifications is so pure that if the material is properly hot rolled, the impurities present have little influence in limiting the drawing of wire. Where extreme conditions are required for the mechanical working of copper wire, and where the surface must be free from flaking or other minor imperfections, special grades of copper or additional operations are used. These include oxygen-free copper, scalped wire bars and shaved copper rod.

Dies. In the drawing of copper, difficulty with dies is the greatest source of trouble. The shape and alignment of dies may cause difficulties frequently ascribed to copper. In general, it is good practice to use well-polished dies of tungsten carbide, having an angle of approach of approximately 17 deg and a land approximately one-half the diameter of the wire drawn. In processes employing a single die or slow speed, the shape and alignment are less critical but are still important. For wire sizes smaller than No. 18 AWG when finished, it is customary to use diamond dies. A volume could be written on dies alone; the importance of die shape, polish and maintenance justifies strong emphasis.

Lubricant. In the drawing of copper and its alloys, soap solutions are generally used. It is important that such solutions be only slightly alkaline. The fat content generally varies from ½ to 3%, depending on the size of wire.

Machines. In high-speed machines, too tight drafting may produce the defect known as cuppiness or cup and cone fracture, even when properly shaped dies, suitable lubricant and proper compositions of alloy are used. Care in the alignment of dies and proper relationship in the delivery of wire to each die is of prime importance in continuous drawing at high speed. Where single passes or machines with a high percentage of slip are used, the drafting schedule need not be so closely controlled but power is wasted and flakiness often occurs because of abraded surfaces.

Many studies have been made in recent years to develop satisfactory theories of wire drawing; these have been useful in determining the shape of the die and in designing more efficient machines. It is now rather generally accepted that a reactive tension, which reduces pressure in the die, also reduces power requirements.

Cold Heading* Cold heading is an upsetting operation by which a head is formed on a piece of wire or rod, or a flange is upset at some portion of the blank. The cold heading properties of various materials may be compared quite accurately by stating the number of "diameters" that may be upset. The "diameters upset" is the ratio of the length of the portion of the wire to be upset to the diameter of the wire.

The nonleaded high brasses, ranging from 60 to 70% Cu, have very good heading properties, and as a general rule can be upset about three diameters. The low brasses, ranging from 85 to 100% Cu, can be upset more than three diameters in many instances. However, the shear strength of the material may easily be exceeded in the formation of certain head shapes, causing shear failures.

The leaded high brasses, containing less than 2% Pb can rarely be upset more than 2½ diam, and 2 diam would be the general rule. A lead content of more than 2% will limit the upset to approximately 1½ diam. Naval brass, containing a small percentage of tin, behaves in somewhat the same manner as leaded brass except that the stiffness is perceptibly greater and more power is required to perform a given upsetting operation.

Silicon bronze, Type A, is a moderately useful cold heading alloy and Type B is an extremely useful one. In the tensile range usually supplied for cold heading, three diameters can be upset, and a strong corrosion-resistant product will result.

In the manufacture of screw blanks in particular, consideration must be given to the machinability of the raw material concerned, if there is need for performing machining operations later. It is common practice to sacrifice some cold heading qualities in order to gain better machinability in products involving many secondary operations.

Cold Forging and Extrusion. These operations are closely allied with cold heading. The term "forging" implies a

* See also the article on page 43 of this Handbook.

lengthening or spreading action formed in a drop hammer or similar press with open dies. This type of operation has fairly limited application in cold working procedures, although it is widely used in hot working. The alloys used in cold heading can be as readily forged. Cold extrusion of rod or rod blanks implies the production of a reduced section by compressive forces transmitted through the blank. Such operations are frequently combined with heading operations in the same types of alloys.

The term "extrusion" also applies to the production of tubes or shells by the "Hooker" process and impact extrusion process, both discussed below.

Thread Rolling. Threads may be rolled on solid cylinders or on hollow cylinders where the wall is thick enough not to collapse if metal is displaced to form threads.

Rolled threads are produced on solid or heavy-wall cylinders by placing predetermined cylinder blanks between two hardened steel dies that have surfaces machined to the proper thread pattern. One of these dies is mounted on a stationary unit and the other is attached to a reciprocating member. The blank cylinder is wedged between the two dies and rotates about its own axis while moving between them; at the end of the stroke, the threading operation is completed. This is "flat-die thread rolling".

Cylinder-die thread rolling is accomplished by using three cylindrical dies in a rotating type of machine. Cams open and close these cylindrical dies. The open position is used for placing and removing the blanks, and the closed position for forming the threads.

These rolling operations have been described as cold forging the threads into shape by forcing the ridges on the dies into the blanks to approximately half their depth, thus forming the roots, while the displaced metal forms the crests of the threads. Rolled threads are generally stronger, and sometimes smoother and more uniform than cut (machined) threads.

Most of the copper alloys are suitable for roll threading, although free-machining rods and other leaded alloys will not take as deep a thread as the copper-zinc alloys. The aluminum and manganese bronzes are also difficult to roll-thread because of their greater hardness.

Production of Tubes

Drawing. Bench drawing to smaller sizes is the principal cold working process performed on copper alloy tubes that are made by extrusion or piercing methods.

The drawbench is essentially a machine for cold working by pulling tubes through a die in order to reduce the diameter or cross-sectional area, to make various shapes from round tubes, and to increase strength and hardness with resultant loss in properties of elongation.

Cold drawing reduces the outside and inside diameters and at the same time reduces the wall thickness and circular area of the tube. The inside diameter, as a general rule, is reduced slightly less than the outside diameter, and the operation results in a smooth finished surface inside and outside. During this operation the metal becomes hardened; hence, at intermediate stages the tubes are annealed. Actually, copper is so ductile that it can be reduced without intermediate annealing. However, to ensure the highest standard of quality, after two or three drawing reductions, the tubes are annealed to restore maximum ductility and refine the grain structure. Brasses and bronzes, however, work harden so rapidly that ordinarily the alloy is annealed after each draw.

Benches are usually rated in capacity by the pounds pull that the main chain and die block will withstand, and vary in capacity generally from 1000 to 200,000 lb.

Fundamentally, drawbenches are similar in operation and are usually constructed of steel or cast iron. The most widely used are those of the fixed-mandrel type, which may have a single or double mandrel.

Benches consist essentially of a mandrel support or table on the feed end and means for adjusting the position of the mandrel relative to the die. The draw die is held rigidly in a die stand or die block. The drawing end is of heavy structural sections with planed surfaces on which the main chain and tong carriage ride; the main chain is driven continuously in one direction. The carriage is returned either by cable or by friction. Actual drawing then requires a loading rack, movement for the mandrel in line with the loading rack, and a pusher motor or pinch rolls to feed the tubes on the mandrel. On heavy or large benches, mandrels are raised or lowered in line with the loading rack or draw die, either hydraulically or by air cylinders. Tube drawing is normally accomplished by one of three methods: (1) drawing over a fixed mandrel or "plug", (2) drawing by sinking through a die with no mandrel on the inside, and (3) drawing on and with a mandrel on the inside; in this method, the mandrel or arbor travels through the die with the tube. Before drawing, the tubes are pointed.

Pointing consists in hammering or squeezing the end of a tube between die blocks to a predetermined diameter and to a length governed by an adjustable stop on the pointer spindle.

Fixed-Mandrel or "Plug" Drawing. The draw die, which is usually of carbide or chromium-plated steel, is held rigidly in the headblock of the drawbench. The pointed end of the tube, which has been threaded over the hollow mandrel rod, is passed through the die until the point extends slightly beyond the outer face of the die and is gripped there by the jaws of the bench tongs. A suitable lubricant is immediately pumped onto the outside of the tube and through the hollow rod onto the mandrel, or the tubes may be dipped into a suitable soap solution for lubricating. Efficient lubrication ensures minimum friction, prevents tool scratching and imparts a highly polished finish to the tube, inside and outside. When the hook of the tong is dropped into the link of the endless chain, tension or pull on the tube causes the jaws to bite tightly into the point. The tube is thus pulled through the die and over the mandrel until the entire tube has passed through the die. When the tube is free from the die, release of the tension opens the jaws, disengages the hook and releases the tube, which is thrown into a rack while the tong returns to the headblock for further drawing.

Sink Drawing. This operation is similar, in all respects, to drawing over a mandrel except that the tube is simply pulled through a die with no mandrel on the inside. Both the outside and the inside diameters are reduced. However, since there is no plugging action, the thickness of the wall increases slightly and the inside surface is not smoothly polished.

Movable-Mandrel or Arbor Drawing. The tube to be drawn is threaded over a mandrel bar, which is usually tapered 0.006 to 0.010 in. in its length, to facilitate extraction from the tube when drawing is completed. Tubes are not pointed on the end. The mandrel bar and tube are simply drawn through a die; hence the travel of the mandrel bar, controlling the inside diameter of the tube, coincides with the travel of the tube. The extension of the tube, because of reduction of circular or cross-sectional area, is absorbed in the extra length obtained. A similar type of drawing has been done in hydraulic pushbenches using a movable arbor or mandrel and stripping the tube on the reverse stroke against mechanical strippers behind the die.

Generally, copper, copper-zinc of 70% Cu or more, Muntz metal and leaded brasses, are readily made into tubes.

Alloys difficult to fabricate are cupro-nickels, nickel silver, beryllium copper, and brasses and bronzes containing tin, aluminum, silicon or manganese.

Tube Rolling (Rocking). The first Pilger rolling machine, which is the predecessor of the tube-reducing machine, was developed by the Mannesmann brothers, who built the machines for piercing tubes. Consequently the Pilger or Pilgrim process for making tubes has been used in Europe, while the tube-rocking process, which was developed in this country, has been used more often here.

Tube rocking or tube reducing is the cold sizing of a tube by means of semicircular grooved dies that are rocked back and forth over the tube on a mandrel that controls the inside diameter of the tube. This is a decided departure from the previous method, whereby a tube is drawn through a die and over a mandrel.

The grooves of the semicircular dies are tapered, one end of the grooved section is somewhat larger than the outside diameter of the tube to be sized. The gradually

decreasing cross-sectional area of the grooves pinches the tube walls against a correspondingly tapered mandrel, which results in reduction in the wall thickness and increase in the tube length. The tubes are fed longitudinally and a suitable mechanism turns the tube on its axis so as to distribute the cold work over the entire circumference of the tube. These operations are timed after the dies have completed their forward stroke. The resulting tube is concentric, with accurate dimensions and close tolerances.

Tapered tubes, bimetal tubes and tubes with special bores, may be made by this process. Tube-rocking methods may be used with all alloys that can be drawn on tube drawbenches. The tube-rolling machine may require some adjustment or change of the grooved dies, according to the alloy being processed.

Spinning. This process is a method of forming tubes by spinning to a predetermined shape without the application of external heat. The process combines reducing, closing the tube end and thickening the wall on the closed end section. One of the advantages of spinning is the possibility of forming closures and at the same time increasing or maintaining the original thickness of the tube wall. Generally, tubes having walls 0.015 in. or thicker can be successfully spun. There is virtually no limit to maximum wall thickness.

The process, unlike that used in the spinning of sheet metal, where very little heat is developed, depends on the controlled plastic flow of metals at elevated temperatures developed by friction between the tube and die, one of which is rotating while the other is stationary.

The operation can be performed on lathes, screw machines, drill presses, spinners and other rotating machines. Large production runs are made on automatic machines designed for continuous operation. In the process, the tube may be held stationary in a suitable holder with practicable means for feeding the tube into the die. Equipment includes a suitable die holder, a recessed die of the required shape, and means of rotation at speeds of approximately 1200 to 3000 rpm. The process works as well if the tube is rotated and the die is held still.

The process is very rapid and usually the desired shape can be obtained in a matter of seconds.

The inside diameter can be controlled by a mandrel; the outside diameter is controlled by the dies.

Temperatures developed during spinning are sufficiently high that in the copper alloys, as a general rule, annealing takes place in the spun section, or stresses produced by cold drawing are removed from that section; the remaining length of tube is of unaltered temper. Because of this softening, and hence increased ductility, subsequent forming can be performed readily on the spun section.

Tube Bending. The operation of bending pipes or tubular products is one requiring considerable care. The nature of the operation is such that the circular cross section is severely deformed if not well supported on the inner surface. When the wall of the pipe or tube is great in comparison with the diameter, more severe bends can be taken without collapse of the unsupported tubes. Therefore, with the standard pipe sizes and annealed tempers it is possible to make bends that have a large radius without internal support. This is particularly true of the smaller sizes of pipe when wall ratios are 10% of the diameter or more. Also in the heavier gage type of copper water tubes with annealed tempers, bends can be made on large radii. In all this type of bending, however, a certain amount of departure from a perfectly round cross section is not objectionable.

Some form of support is necessary in tubes with wall ratios of less than 5% and in larger tubes generally. In occasional bending jobs the tube section can be supported with sand or resin, and in some instances with alloys such as Woods metal that have a low melting temperature. For quantity production jobs of this type, the tubes are supported by flexible arbors that will bend as the tube bends and can be pulled from the tube readily after bending. Removing the flexible arbor corrects any deformations from a true circular cross section during bending.

Annealed tempers are ordinarily used for bending operations, particularly when accurate cross sections are required. Tubes of some drawn tempers can be bent in the smaller diameters and heavier wall thicknesses, although such bends must be on a larger radius and some deformation permitted. Copper and all the alpha solid solution copper alloys are suitable for bending, although high brass and copper are most commonly used.

Press Drawing and Forming

Cupping. The first step in press forming is the conversion of a flat strip to a cup or short shell with a closed bottom. The simplest form of this cupping operation is the conversion of a circular blank into a cylindrical cup. The operation may be performed in several ways, but the most conventional method is by use of a double-action press. Some consideration of the metal flow in this operation will be helpful in understanding all press drawing and forming operations.

During the cupping operation the diameter of the blank is reduced by circumferential forces in the perimeter of the blank, which would tend to produce wrinkles if the metal were not held tightly by the blank holder. The outer punch of the double-action press is designed to do this. Although the blank holder is intended to prevent wrinkling, it must not be so tight as to prevent thickening of the blank while it approaches the drawing radius of the die. This thickening is the natural result of the contraction in diameter and, if it is prevented, there will be a consequent increase in the force required to form the cup and fracture of the cup may result. The clearance between the inside of the die and the punch, is slightly greater than the gage of the metal, so as to allow for some thickening of the cup wall near the top. Generally only a short length of the cup is actually squeezed between punch and die. This action that pinches or thins the wall is usually called ironing.

The portion of the cup first formed by the punch is required to support the load during the remainder of the operation. This portion of the cup is therefore stretched and thinned slightly, so in a conventional cup the wall is thinnest at the bottom and thickest at the top. An excessive pinch between punch and die or excessive hold-down pressure is likely to cause failure by stretching in the bottom of the cup. The metal is supported to some extent by friction on the punch or deep cups could not be made by this process.

Two radii are important in this operation—the radius formed on the bottom of the punch, which is often controlled by further operations to be performed on the cup, and the radius on the drawing edge of the die. Large radii at both of these points will promote easy flow of metal. On the punch, a large radius will permit thinning of the bottom of the cup, whereas a small radius has the opposite effect and may localize severely the normal thinning of the side wall at this point. Too large a radius on the die permits wrinkling of the blank, and results in a poor surface or tears and folds at the top of the cup. Too small a radius may tear the outer surface of the cup by the sharp reversed bend that the metal is forced to undergo. The usual die radius is between ▮ and 10 times the metal thickness, but occasionally certain designs require sharper radii, particularly if the cup is to be left with a flange.

The surface finish on the tools that are used is frequently an important factor in the success of the operation. In cupping or drawing there is little relative motion between the metal and the punch, while there is a great deal between the metal and the die; therefore, careful polishing of the die is highly desirable. The die should be lapped and polished in such a way that any scratches left are in the direction of metal flow. Cupping punches are usually polished less than the dies because of the need to control metal flow in the bottom radius. Since failure may occur by pushing out the bottom of the cup, actual roughening of the lower side wall and radius may prevent excessive thinning and failure. Such roughening should not be carried to the point where it interferes with the normal stripping action. Chromium-plated tools, particularly dies and punches for deep drawing, are helpful in reducing friction and "brassing up" of tools, but me-

chanical strippers are usually necessary with chromium-plated dies. If it is desired to hold the metal at the bottom of the punch, chromium-plated punches are not so satisfactory. When the quantity of production and the size of the tools permit, hard alloy tools such as the sintered tungsten carbides are found useful. These tools also may reduce friction and generally permit much more uniform control of gage and dimension, as well as longer tool life.

A double-action press is ordinarily set up in such a way as to permit the outer punch to cut the blank as well as to provide the necessary blank-holding pressure. In the single-action process, the blank-holding pressure is provided by rubber pads that deform under pressure but are quite effective in providing a smooth flange. Flanged cups may be produced on either single-action or double-action presses, but in both types the cup must be pushed back through the die. Single-action presses may also be used to produce complete cups of heavy gage, such as cups for cartridge cases, in which the blank is heavy enough to contract without wrinkling.

The extent of reductions in diameter between blank and cup cannot be standardized because of the variety of conditions under which cups can be made. In the production of the normal cup for redrawing, it is customary to reduce the diameter between 40 and 45%. In very thin blanks, 0.015 in. or less, these reductions are not so readily obtained, although in heavier blanks somewhat larger reductions can be made.

The lubricants used in cupping operations vary considerably, depending on the exact type of operation, tools, design, condition of the metal and other factors. In many of the lighter cupping operations, it will be found that a simple solution of high-grade soap and water is the best that can be used. With heavier blanks and greater depths of cupping, a soap paste is preferable that contains some fatty acids and animal or vegetable oils. Where the cup is ironed severely or a large reduction in gage is involved, heavier pastes that contain solid lubricants such as talc or graphite are sometimes found desirable. The use of mineral oils is seldom found necessary, except when they may be compounded as a diluent in some paste lubricants. Lard oil is sometimes used for severe cupping operations, but generally a paste that is soluble in water is just as good a lubricant and is much easier to remove. Ease of removing the lubricants is an important factor if the cups are to be annealed for reworking. Lubricants are one of the most common sources of the red stains frequently found in redrawn yellow brass shells.

Drawing. Further cold working of cups by redrawing operations is normally performed in single-action mechanical presses or hydraulic presses. Redrawing can be achieved by two general procedures: one involves a reduction in diameter of the shell with little or no pinching or ironing of the wall; the other involves a relatively slight reduction of diameter and considerable reduction of wall thickness. These two procedures represent extreme conditions, and it is probable that all copper alloys lie between these two extremes, but wall pinching is much more common with the brasses than it is with steel. However, there are occasions when both methods of drawing must be followed. In reductions of diameter, the original shape of the cup bottom is maintained during drawing, in order to prevent wrinkling and tearing.

It is also possible, of course, to accomplish some reductions in diameter without a sleeve, but the extent of such reductions is limited to about 20%. This amount varies somewhat with the diameter and wall thickness. During redrawing with a heavy wall pinch, the amount of reduction in diameter should be very small with just enough difference in inside diameter to permit insertion of the succeeding punches. This method of drawing proved very effective in reducing the number of operations required for producing brass cartridge cases during World War II.

Two general practices are followed in the press drawing of brass: (1) to start with a small thick blank and reduce it by ironing, and (2) to start with a larger but thinner blank and make reductions in the diameter. With regard to the number of draws and annealing operations, the first method seems preferable; but other factors, such as the shape of the final product, cost of metal and scrap loss, may affect the relative advantages and change the selection of procedures.

For most redrawing, forming or reducing operations on brass, a simple soap solution is perhaps the best possible lubricant—best not only for performance but also for ease of removal after drawing. Within recent years a heavily concentrated soap solution has been used for coating the shell; such a solution, when dried, leaves a film of soap on the surface. This film makes a very effective dry lubricant that helps to eliminate the sloppy conditions normally found in pressrooms. Dry soap is not satisfactory for finish work that must be buffed or plated, because it eliminates much of the surface ironing required in producing highly polished work. Both the dry soap and the soap solution can be removed by washing in warm water.

The amount of cold work that can be done on the various copper alloys in press drawing, is as much affected by the tool design and lubricant used as it is by the properties of the alloy. The alloy strip is always furnished to the press room as annealed material. The grain size of the strip is a considerable factor since it is well known that material of coarse grain size generally permits greater reductions than fine-grained material of the same alloy. There are instances, however, in which coarse-grained thin strip will not be strong enough to support the depth of cup required, and the bottoms will break out. For material of heavy gage, coarser grain sizes generally permit deeper drawing with less load on the press. For finishing work directly from the cup, without subsequent annealing and ironing draws, coarse grain is objectionable because it develops a rough "orange peel" surface and is very difficult to polish. In some classes of press drawing, fine grain is essential for this reason, and frequently the extent of forming must be limited by what this fine-grained metal will permit. It is impossible to be specific about the maximum permissible grain size, because it depends entirely on the amount of stretching or ironing and on the amount of polishing or buffing that the finished piece can be given economically.

The most common brass alloy for press drawing is yellow brass (65% Cu, 35% Zn) and the amount of redrawing that it can be given without annealing is limited by the rate of hardening under cold deformation. Copper and some of the softer copper alloys can be redrawn indefinitely in the form of tubes with open ends, but in press drawing there are limitations. Deoxidized or phosphorized copper, for instance, can be redrawn almost indefinitely without annealing, if the reductions in diameter are held to a minimum, and the piece is a simple straight-sided shell. If, however, the diameter is to be reduced appreciably, a sleeve is required to prevent folding and tearing, and the extent of redrawing without annealing is limited. To a slighter extent, this is also true of some of the other soft alloys, such as red brass and gilding metal. Reductions in diameter are difficult without annealing, because the relatively soft bottoms that must first be drawn before the diameter can be reduced, are not strong enough to withstand the load; consequently the bottoms are punched out and failure occurs.

The harder and more refractory copper alloys, such as phosphor bronze and silicon bronze, are not widely used in press drawing, but they can be drawn if the abrasive tin and silicon oxides are eliminated by bright annealing. This also applies to the nickel silver and cupro-nickel alloys, which can be drawn readily if bright annealed, or if processed by successive reductions of the wall thickness so as to eliminate the need for annealing. The low-copper Muntz metal type of alloy is not normally used in press-drawing operations, and if so used may be difficult to form, requiring extra operations and extra care in annealing.

Spinning of Sheet Metal. As a general rule, sheet metal is spun only when the required quantity of an article is small. High rates of production cannot be expected. However, the initial outlay for equipment and maintenance of tools is relatively small; hence for small production lots, the cost per piece is low.

The equipment required consists of a lathe with a drive

on the headstock capable of providing speeds of 1200, 1400 and 2400 rpm; the lower speeds are used for thick and large sections where heavy pressures are required; the higher speeds for thin and small sections.

Chucks may be of wood, cast iron or steel, preferably chromium-plated to produce a very smooth planished surface. Where the part to be spun is of a shape that does not allow removal of a solid chuck, sectional chucks are used and care must be taken to have all sections fit perfectly; otherwise the impression of the joint may show on the spun part.

Spinning rolls or form rolls may be made of hardwood or steel. Depending on the shape to be produced, specially shaped tools are made usually from steel rod of 1.1% C and are chromium plated. A tool flat on one side and rounded on the other side is considered suitable for general spinning. All such tools are usually mounted on the compound rest of the lathe. Lubricants may be lard oil, soap, beeswax, or paraffin, depending on the preference of the operator, the speed, and the pressure required.

The metal section to be spun is mounted on the lathe by clamping between the chuck and the wood form, with a hardwood pad on the tail spindle. The spinning tools are mounted in the compound rest and are moved into and against the metal section to be spun, with just sufficient pressure to deform the sheet into and against the form.

In bulging operations, a form roll is used that is generally of hardwood and placed on the outside of the spun part. The spinning roll is usually mounted on an extension to the compound rest of the lathe. The roll is set on an angle and moved into the inside of the metal form; pressure is then applied by the roll forcing the metal outward and against the form roll.

In all spinning operations the edge of the metal must be slightly flared, thus avoiding wrinkling or buckling. The correct amount of flare is largely a question of operational experience. The number and sequence of operations to produce the finished part depends on the shape and area of surface to be spun. The production of cylindrical shapes or shells usually requires three steps—dishing, cupping and finish shaping. Since copper is ductile it can be shaped almost at will; however, the alloys strain harden rapidly. The sheet metal that is being spun at room temperatures, and the extent of cold working and strain hardening govern the necessity for annealing.

The metals most commonly used for spinning are copper, gilding metal, commercial bronze, red brass, yellow brass and nickel silver. Any choice among these metals depends largely on the color desired in the spun part, though occasionally the mechanical properties may be the controlling factor.

Temper of the sheet metal should be soft, annealed to a grain size of 0.015 to 0.030 mm. Where the spinning and number of operations is not excessive a special temper may be used.

Impact Extrusion. Impact extrusion and extrusion by the Hooker process are closely related and are sometimes confused with each other, but are two distinct processes. All types of copper can be used successfully; the best, however, is oxygen-free copper that has maximum ductility. Copper-zinc alloys are also used, but the amount of cold working is reduced as the copper content is lowered.

Crank presses of the conventional type are used, but best results are obtained with high ram speeds; a sharp impact blow is superior to a slow-moving ram. The reason for the high speed of the ram is to move the required amount of material quickly, without hesitation.

In impact extruding, either a slug sawed from bar stock or a blank cut from sheet metal is used. The material is generally ordered as cold worked, to facilitate either the sawing or the blanking operation. Parts are then annealed and should be pickled to remove all traces of copper oxide. The blank or slug is fed into a shallow set edge, the diameter of which should be a few thousandths of an inch larger than the diameter of the part to be impacted. Directly under this set edge is a flat solid die. The punch has a slight angle on the face and a straight portion from the face of approximately ⅛ in., with a relief of a few thousandths of an inch from there back in order to minimize friction. Pressure exerted by the punch forces the metal upward around the punch to produce a shell, the inside diameter of which is controlled by the punch.

By this process a shell is produced with a relatively heavy bottom. Decreasing the bottom thickness increases greatly the pressure required. Where shells with heavy bottoms are needed, this process is ideal. Shells that have relatively thin sidewalls can be produced, but care must be taken in proportioning the size of the punch and the wall, and also the length. These punches are under extraordinary pressure and there is a possibility of bending, which will result in uneven wall thickness and high maintenance costs for tools.

Cold Extrusion. This process is generally referred to as the "Hooker" process. The metals and alloys used in impact extrusion can be used in the Hooker process. The presses and equipment used are also similar, with a like need for a sharp, rapid blow, but the initial form of blank is different.

In extrusion, either a cup or a shell is used, depending on the size and length of the finished extrusion. Two methods are used to prepare the cup or shell for the extruding operation: (1) employing a double-action press to produce a cup and performing secondary redrawing operations to provide the correct size of shell; (2) using rod sawed off to the required length, impacting it and redrawing, if necessary, in order to produce the required size of shell.

If the shell to be extruded has been severely cold worked during preparation, it should be annealed before the extrusion operations. It is essential that the annealed shells be cleaned thoroughly to remove all traces of copper oxide.

The shell produced is fed into a sleeve, the diameter of which is a few thousandths of an inch larger than the shell; directly under this sleeve is located the extrusion die, the diameter of which is determined by the finished diameter of the required extrusion. The punch has a front-end diameter that fits into the inside diameter of the shell, and also has a shoulder that is equal to the outside diameter of the shell. The shoulder on the punch exerts pressure on the open end of the shell and extrudes it through the smaller opening in the die. Relatively little heat is generated in this operation because the material is moved rapidly and the bearing in the die is very short, which minimizes friction.

Bulging. In bulging, a mechanical operation performed on copper and copper alloys, the center portion or body of a shell having a straight wall is expanded or enlarged to form some desired shape. The operation is carried out in a mechanical press of suitable construction, by means of a rubber insert or similar device, such as a segmented or split die.

A drawn shell is placed in the die in such a manner that, with the action or stroke of the press, an insert enters the shell and expands, causing the metal to expand or bulge and assume the inside shape of the die. Devices involving split dies act in a similar manner. The amount of cold work must be controlled in order not to exceed the plastic working properties of the metal, thus causing fracturing or splitting. An extreme bulge may be obtained in several steps with intermediate annealing between the bulging operations.

Articles such as kettles, pots, cans and pitchers are typical illustrations of bulging operations.

Flanging. Flanging is an operation that consists of turning out the open end or edges of a hollow article made of sheet metal in cylindrical, rectangular or other shapes. Thus the operation is somewhat in the nature of a beading action and, since it is similar to beading, the equipment for flanging resembles that used for beading. A flanging operation is very common in can-making.

The most usual flange is a component part of a drawn shell, where the edges at the open end are not completely drawn into the die. When it is impossible to produce a desired flange by this method, the flange is formed either by a series of rolling operations or by a forming operation with a punch and die.

A combination of the above methods may be used, sometimes with intermediate anneals, where it is necessary to accomplish a particularly severe flanging operation.

Beading. The operation of beading consists in the formation of strengthening ribs or beads around hollow shapes, usually cylindrical. The beading may be accomplished by one of several methods. The simplest consists in rolling a bead on suitable equipment, such as a formed arbor and shaped roll placed parallel to each other. The arbor is usually a rotating fixed member, while the rotating roll is ordinarily operated by a cam that moves it into position toward the object; the beading is thus accomplished by squeezing the object between roll and arbor.

A less common and more complicated method requires the use of segmental dies. This method is similar to that used for bulging.

A shallow bead is frequently formed on a drawn shell or tube by the use of a punch and die. The portion of the body beneath the bead is held closely in a confined die, while a shouldered punch applies pressure at the open end.

Necking. Necking, as applied to the working of copper and copper alloys, is a combination of mechanical operations involving tapering, swaging or reducing the circumference of drawn shells, and is accomplished on various types of mechanical equipment. For example, tubes are tapered in rotary swaging machines, while the tops of drawn shells and caps are reduced in diameter in redraw dies. Usually the metal should be soft and ductile in order to prevent cracking. Depending on the amount of cold work to be performed, or on the extent of reduction, it may be necessary to make use of intermediate anneals during a series of necking operations.

Thread Rolling. Threads may be rolled on thin metal cylinders by means of rolls and arbors that have the desired thread pattern machined on them. The shells or caps that have a thin wall are fed onto the arbors, and the roll, which is cam operated, is pressed against the outside of the shell or cap to form the desired depth of thread, which is predetermined by the design of the arbor and rolls. The peripheral speed of arbor and roll must be determined carefully to ensure properly rolled threads. Screw shells for lamp sockets, bottle caps, canning jar caps and similar articles are threaded in this manner and special thread-rolling machines are used for high production of these parts.

The Annealing and Heat Treating of Copper and Wrought Copper Alloys

BY THE SUBCOMMITTEE ON HEAT TREATING COPPER ALLOYS*

DURING PRODUCTION and fabrication, copper and wrought copper alloys may be heated for homogenizing, for hot working, for reworking and control of final temper, for stress relief, for solution treatment and precipitation hardening.

Heating for Homogenizing. "Homogenizing" is defined as a heat treatment at high temperature to eliminate or decrease segregation in an alloy by equalizing the chemical composition throughout the casting. When applied to alloys that have been cold worked after casting, the homogenizing period may be decreased and the treatment can then also change the shape of the crystals.

The rate of diffusion of atoms of one metal through an alloy, depends to a large extent on the fundamental characteristics of the two metals. The following observations serve to illustrate this generalization: When brass is annealed, some zinc is volatilized from the surface. Ordinarily, however, the surface color does not change to red, typical of a higher copper content, but remains yellow because zinc diffuses very readily through the alloy from the interior, and therefore the composition of the brass is rapidly equalized at a slightly lower zinc content during annealing. In silver-copper alloys, the surface layer is frequently found to be free from copper because the copper originally present there has been oxidized during annealing and removed by pickling or machining. Little or no copper diffuses from the interior, during annealing, to replace that oxidized and removed from the surface.

The coring found in castings of the plain, leaded or special brasses is removed, in most instances, by the regular process anneals. Diffusion and subsequent homogenization are somewhat slower and more difficult in the silicon bronzes, cupro-nickels, nickel silvers and phosphor bronzes than in most of the other copper alloys. Therefore with these alloys special prolonged homogenizing anneals are frequently resorted to.

For instance, high-tin bronze castings have a cored structure and unstable hard delta crystals that make the metal brittle. When the alloy is heated at 1100 to 1450 F, diffusion of tin decreases irregularities in composition and makes the crystals more uniform in shape and size. At the same time, strength and ductility are increased and hardness is decreased.

Heating for Hot Working. Many alloys are quite plastic within some range of temperature higher than the recrystallization point but lower than the melting point, and in that range these alloys will withstand much more extensive working with considerably less expenditure of power than when cold. Such alloys are usually hot worked in the early stages of fabrication when heavy reductions can be made. Such hot working operations include hot rolling of cakes and bars for sheet and wire, extrusion for rod, shapes and tube, piercing for tube, and hot forging or pressing for special shapes.

Heating for hot working usually requires higher temperatures than annealing for cold working. Most alloys have a relatively wide hot working range, but some have a narrow range. The working temperatures depend on alloy and operation and may vary from about 1150 F for high brass to about 2000 F for cupro-nickels, with copper and high-copper alloys in the range from 1350 to 1650 F.

Drop-hammer tests will establish the highest practicable temperature below the melting point, at which the best results may be expected. The empiricism necessary in this work is well stated by Morris: "For instance, we wish to extrude a metal *M*. We know that we can extrude another metal *Q* at temperature *T*. We make a drop-hammer test of metals *M* and *Q* and find that in order to obtain the same reduction in height as we find in metal *Q* at temperature *T*, we must heat metal *M* to temperature *T'*. *T'* is therefore the temperature at which we first try to extrude the metal *M*, with fair assurance that we shall be able to force the metal through the die." Much the same kind of reasoning can be applied to hot rolling. However, the tendency to crack in extrusion, piercing or rolling must be ascertained largely through experience.

No hard and fast rules can be established for hot working temperatures. They can be formulated only after all the contributing factors of each specific job are known and considered, as affected by variations in equipment and the types of working operations that are being performed. The temperatures commonly used both for heating for hot working and for annealing after cold working are given in Table I. Where hot working temperatures are not listed, it means that the alloy is not commonly hot worked except for initial extrusion of the casting.

(a) These alloys are usually hot extruded after casting but further hot working is uncommon.

Heating for Reworking and for Control of Final Temper. The drawing of wire or tube, rolling of sheet, drawing of shells, and other cold working operations, result in straining and distortion of the grain structure of a metal with accompanying increase in hardness and decrease in ductility. In progressive cold working, a point is reached at which further deformation cannot be made economically or without structural damage to the metal. To restore the ductility for further cold working, the metal must be heated to a temperature where it will recrystallize and the grain will change to the proper size. This process is known as "annealing".

The requirement for annealing, in preparation for further working, varies considerably and depends on a number of factors—the alloy composition, the extent of previous cold working, the amount of additional cold working yet to be done, the thickness of the metal, the proximity of the anneal to the final operations, and the final specifications of the article. For the more commonly used copper alloys, annealing consists simply of heating the cold worked metal to the recrystallization temperature and, if necessary, somewhat beyond that so as to cause grain growth. Annealing is primarily a function of metal temperature and time at temperature. Except for the alpha-beta type alloys and the special alloys described below under Precipitation Hardening, the rates of heating and cooling are relatively unimportant, provided uniformity is maintained. Source and application of heat, design of furnace, kind of atmosphere, shape of work piece, and other factors are also important since they affect the uniformity, finish and costs of the operation.

Because of the factors mentioned above, it is difficult to tabulate a definite schedule for time and temperature that will result in a specific grain size of a completely recrystallized metal after annealing. The following general statements explain these factors as applied to commercial coppers and brasses. The curves of Fig. 1 through 5 illustrate the effects of time, temperature and deformation for 65–35 Cu-Zn alloys, and represent generally all wrought copper alloys.

After complete recrystallization, any increase in the temperature of the metal results in an increase in grain size. The grain growth is not directly proportional to increase in temperature but tends to accelerate with such an increase (Fig. 1). The mechanical properties of the metal also change with grain growth. Tensile strength, elastic limit and hardness decrease while elongation and reduction in area increase.

With any fixed temperature of metal, an increase in time at that temperature results in an increase in grain size (Fig. 4). In promoting grain growth, this time factor is not nearly so effective as an increase in temperature.

An increased amount of cold work before annealing, lowers the recrystallization temperature (Fig. 2).

The average grain size is larger, the smaller the degree of prior deformation (Fig. 2).

For fixed duration of annealing and temperature of the metal, the larger the original grain size before working, the larger is the grain size after recrystallization (Fig. 3).

The general effect of alloy composition on annealing is as follows: For a fixed time and metal temperature and for the same previous cold working in copper-zinc alloys, an increase in copper content above 65%, results in a decrease in grain size after annealing (Fig. 5).

In commercial mill practice copper alloys are usually annealed at lower temperatures as the material approaches the final anneal, with intermediate cold reductions of at least 35% and as high as 50 to 60% wherever practicable. The higher temperatures initially used, serve to accelerate complete homogenization and the resulting large grains permit more economical reduction during the early working operation.

During subsequent anneals, the grain size should be decreased gradually to approximate finally the grain size required. This point is usually reached one or two anneals before the final anneal. With such a sequence and with sufficiently severe intermediate reductions, it is then possible to produce a uniform final grain size within any lot and from lot to lot.

The grain size and mechanical properties required for further cold working, will vary considerably with alloy and amount and kind of further cold work to be done. The object of the annealing for cold working is to obtain the maximum combination of ductility and strength and, if

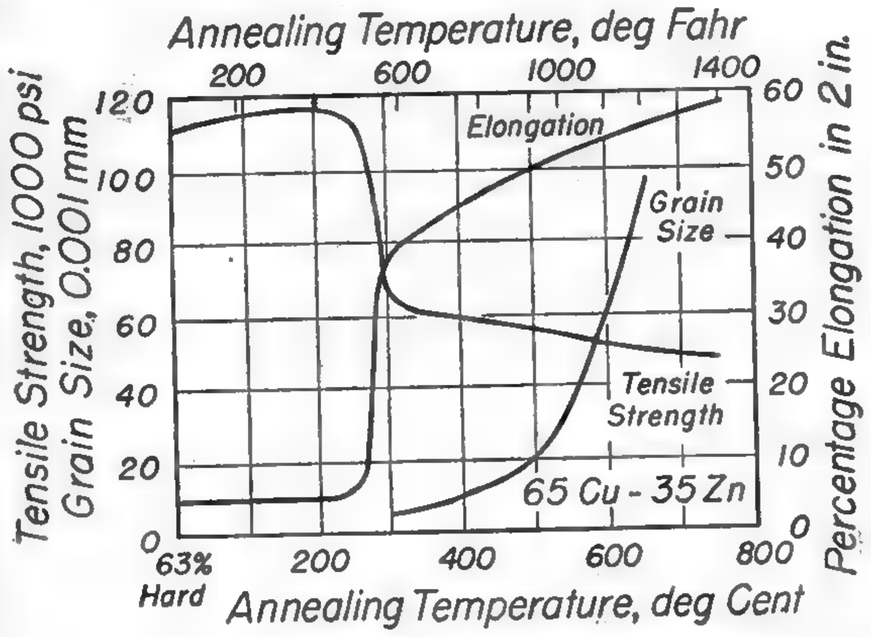

Fig. 1 Characteristic annealing curve for yellow brass wire drawn 63% hard and annealed 1 hr at indicated temperature (Pratt)

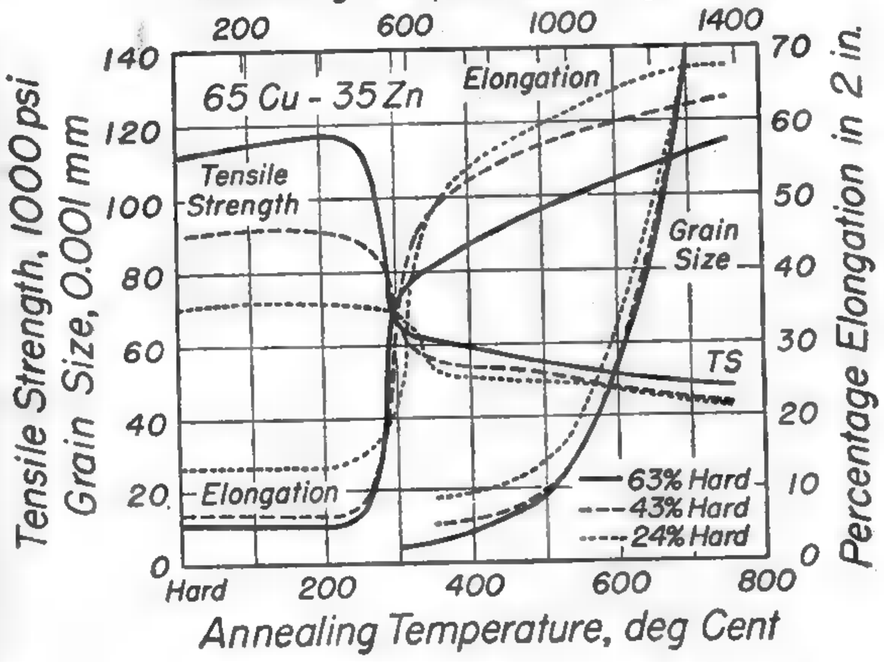

Fig. 2 Effect of varying amounts of cold working on annealing characteristics of yellow brass wire (Pratt)

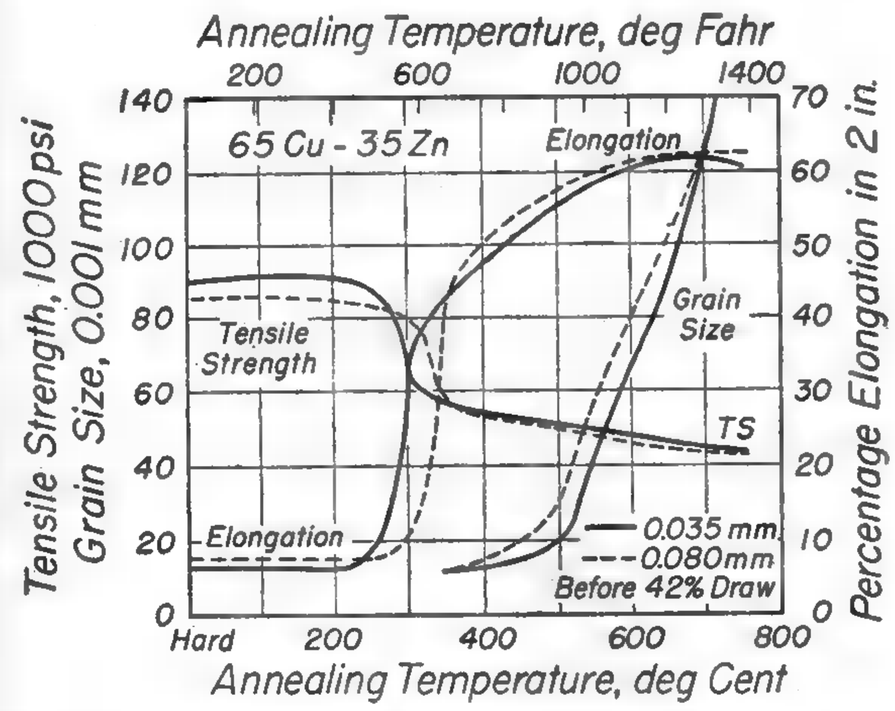

Fig. 3 Effect of varying anneals before drawing, on annealing characteristics of yellow brass wire (Pratt)

preliminary to final drawing operations, to keep the surface texture refined sufficiently to obviate the necessity for excessive buffing. The anneal must be governed by definite specifications and co-ordinated with cold working operations to give the desired properties when finished. Table II is informative in a general way, and applies only to the type of copper alloys usually considered; that is, alloys that consist of a single solid solution.

The full range of grain size in Table II is applicable particularly to copper-zinc alloys that contain 30 to 35% Zn. It is relatively difficult to obtain the larger grain sizes in brasses that contain less than about 20% Zn.

The best and most accurate test for the extent of anneal is the size of the average grain. Grain size is the standard test for most metals, and acceptance and rejection usually depend on the grain size. This determination requires special equipment that is not always available in the plants of consumers or fabricators. For convenience in testing, the Rockwell or Rockwell-type hardness testers are used as approximate and informative. ASTM specifications list Rockwell hardness and values of grain size for many alloys of copper.

Heating for Stress Relief.* Metals that are subjected to nonuniform plastic deformation below the recrystallization temperature, develop residual stresses of varying magnitude. When subjected to service conditions at atmospheric temperatures, some materials are susceptible to a type of

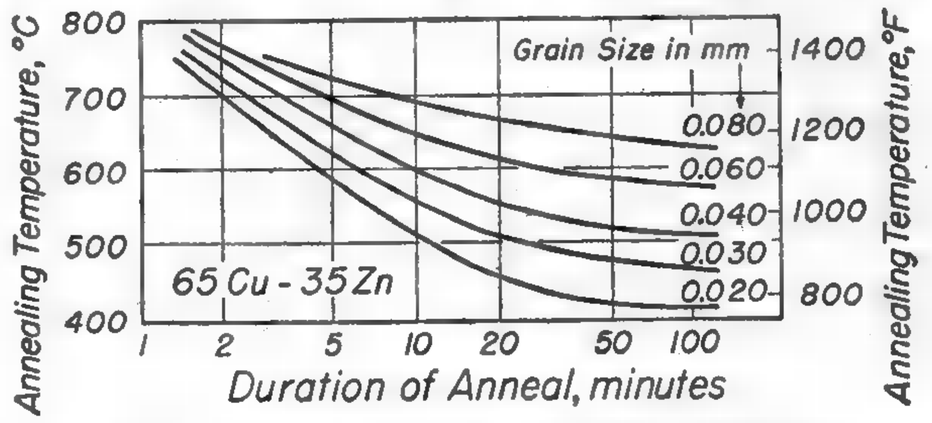

Fig. 4 Effect of time on annealing yellow brass strip, gage 0.050 in. (Pratt)

failure known as "stress-corrosion cracking", or "season cracking", which is most frequent in drawn rods, tubes and hollow ware. Cracks in deep-drawn articles may be longitudinal or circumferential, and in rod and tube, either parallel or transverse to the length, or sometimes in spirals. Similar cracking, encountered when the parts are heated rapidly to above the recrystallization temperature, is known as "fire cracking".

Generally the alloys most subject to cracking are brasses containing 20% Zn or more, and the susceptibility increases with the zinc content. Phosphor bronze, cupro-nickel and some other copper alloys have a comparatively slight tendency toward season cracking, but are susceptible to fire cracking.

Fundamentally, there are three methods of reducing or eliminating the detrimental effects of residual stresses: (1) thermal stress relieving, (2) the application of special cold deformations, and (3) combinations of both.

Treatments for relief of stress by means of special cold deformation do not completely eliminate the residual stresses, but when such treatments are suitably applied,

Table II. Grain Size of Cold Worked and Annealed Copper Alloys

Nominal Grain Size, mm	Typical Use
0.015	Slight forming operations
0.025	Shallow drawing
0.035	For best average surface combined with drawing
0.050	Deep drawing operations
0.100	Heavy drawing on thick gages

they do eliminate the detrimental effects of these stresses. This type of treatment is frequently applied to alloys before annealing, when there is a possibility of fire cracking. In this category are alloys that contain lead, and rolled and drawn shapes that have been cold worked to such a slight extent that complete recrystallization is not attainable in the subsequent anneal. The special deformations in this relief treatment are many and varied; essentially, they are bending operations or roller straightening.

Heating for stress relief is usually applied to finished parts. Emphasis should be placed on the use of the terms

* For additional information concerning this subject the reader may refer to the article on "Relief of Residual Stress", page 237.

"thermal stress relieving" or "stress-relief heat treatment" instead of "stress-relief anneal". The word "anneal" implies softening, which is unnecessary and usually undesirable for articles that are being stress relieved. In stress relieving, materials are heated to a temperature lower than the recrystallization point, for a time sufficient to relieve the stresses. The usual temperature for this treatment is approximately 100 to 200 F lower than the recrystallization point. Occasionally, when the best mechanical properties are desired, a lower temperature is used for a considerably increased period of time—as long as 24 hr in some instances, as compared with perhaps 1 to 2 hr at higher temperature.

When the optimum combination of time and temperature is used, there is virtually no decrease in hardness or strength, but there may be an increase in elastic properties. Severely cold worked material will usually exhibit an increase in hardness and strength, particularly when the lower temperature is used.

The best practice in thermal stress relieving is to use as low a temperature and as long a time as is commercially practicable. Since the stress relieving is conducted at a relatively low temperature—usually between 300 and 650 F—and since excessively high temperature is hazardous to results, very little temperature head can be carried in the furnace without danger of overheating some part of the load. Furnaces provided with forced convection at high velocity, or well-agitated salt or oil baths are best suited for stress-relieving operations.

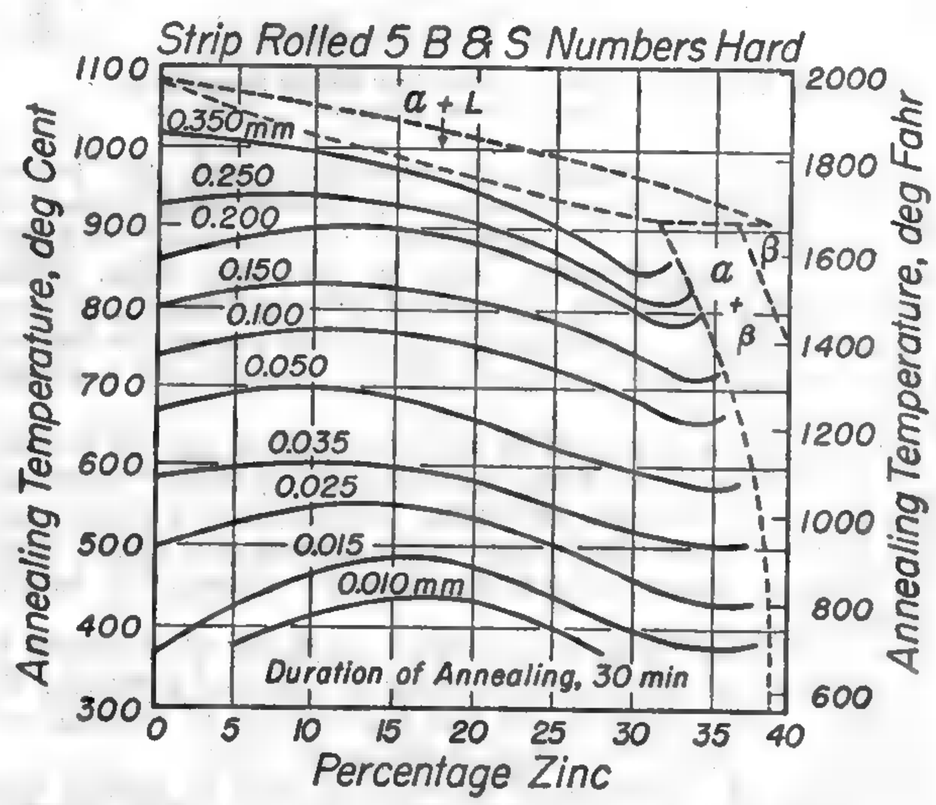

Fig. 5 Grain size of copper-zinc alloy strip cold rolled 5 B & S numbers hard and annealed 30 min (Bassett and Davis)

Solutions of mercury salts are ordinarily used to determine whether or not a copper alloy is free from dangerously high residual stresses. The test procedure, as described in ASTM Standard Method B 154, requires freedom from cracks after an immersion for a specified time. This test is the most reliable guide in selecting a time-temperature combination for thermal stress relieving, and in obtaining material free from the detrimental effect of residual stresses.

Solution Treatment and Precipitation Hardening. The single common characteristic of all precipitation hardening alloys is the greater solid solubility of some phase or constituent at an elevated temperature rather than at a lower temperature. In such systems, cooling at appropriately rapid rates from a temperature within the field of highest solubility will preserve the alloy in a condition of supersaturated solution with relatively high ductility and low hardness, strength and electrical conductivity. This treatment is known as a "solution anneal". Although the objective is to produce a single solid solution during this treatment, in practice some amount of the second phase may exist. A second heat treatment at a lower temperature will cause precipitation of the unstable phases, usually accompanied by an increase in hardness, strength and conductivity, and is known as a "precipitation hardening heat treatment".

The hardening heat treatment may follow the solution treatment with no intermediate working; the material may be subjected to some cold work between the solution and precipitation treatment; or cold work may follow the combined solution and precipitation treatment. The most effective sequence of operations depends on the alloy and the specific properties desired.

A number of copper alloys respond to precipitation hardening. Some of the alloys more commonly used are listed in Table III.

Table III. Precipitation Hardenable Copper Alloys

Alloy	Composition, percentage					
	Cu	Be	Ni	Co	Cr	P
Beryllium copper	97.65	2.00	0.35 or 0.35		....	....
Nickel beryllium copper	98.10	0.40	1.50	....	....	....
Cobalt beryllium copper	97.00	0.40	....	2.60	....	....
Chromium copper	99.40	....	....	....	0.60	....
Copper nickel phosphorus	98.50	....	1.25	....	....	0.25

Since beryllium copper has gained the widest industrial application of all the alloys listed, specific reference will be made to the treatment of this alloy.

All the alloys listed in Table III require a rapid quench after the solution anneal. Heavier sections are usually quenched in water; thin sections can be quenched sufficiently by contact with water-cooled drums, a blast of cold air, or water spray. For batch annealing, the water quench is required; for strand annealing, the other quenching methods are frequently used. If the material has not attained the required temperature, or if quenching is delayed, the properties obtained in the final hardening treatment will be affected adversely.

The precipitation hardening process is a function of time and temperature; hardening occurs more rapidly at higher temperatures. The temperature that can be used is limited because optimum hardness is not obtainable at higher temperatures. In short-time treatments at the higher temperatures, the time factor is so critical that considerable skill is necessary in order to obtain good results. For beryllium copper, a temperature between 600 and 625 F and a time period of 1 to 3 hr are commonly used. A lower temperature can be used, but with a considerable increase in time. From 625 to about 700 F, a treatment can be conducted for time periods less than one hour and even as short as 10 min, but this treatment is critical. At more than 700 F, the highest values of hardness are not obtained. If heating is continued too long or if the temperature is too high, a condition of "overaging" or resoftening occurs.

An increase in cold work following the quench, results in a more rapid rate of precipitation and higher obtainable hardness. The commercial requirements for beryllium copper strip, as covered by ASTM Tentative Specification B 194-46aT, specify the tensile strength and hardening treatments listed in Table IV.

Table IV. Tensile Strength and Hardening Treatments for Beryllium Copper Alloy Strip (ASTM B 194–46aT)

Condition	Tensile Strength, psi	Precipitation Temperature, deg Fahr	Time, hours
Soft	150,000	600	3
¼ Hard	160,000	600	2½
½ Hard	170,000	600	2
Hard	180,000	600	2

Most of the hardenable copper alloys, except for beryllium copper, may be cold worked after a combined solution and precipitation treatment.

General Precautions. If the following general precautions are heeded, they may be of considerable help to those who are responsible for the annealing and heat treatment of the copper alloys:

Control of Temperature. In all annealing, the actual temperature of the metal is not necessarily the same as the temperature indicated by the furnace control instru-

ment and may vary from it by as much as several hundred degrees. Great care should be used to locate the control thermocouples where they will represent the temperature of the work material as accurately as possible, and the work material should be loaded in such a way that all parts are heated uniformly. Thermocouples and instruments should be checked regularly for accuracy. (*See* the article entitled "Pyrometry", page 174.)

Sampling and Testing. When anneals are checked, care should be taken to ensure that test specimens are representative of the extreme conditions found on a load. Much trouble and many complaints can be eliminated if good judgment is used in selecting specimens for testing.

Effect of Pretreatment. Since the amount of cold working and also the anneal prior to that cold working, greatly affect the results obtained from annealing after the cold working, any schedule that is set up must take this pretreatment into account. Once a schedule has been established, both the anneal and the pretreatment must be adhered to for consistent results.

Effect of Time. In most furnaces there is a definite difference between the temperature of the metal and that of the furnace; consequently the time in the furnace has a very important effect on the final temperature of the metal. For a fixed anneal and furnace temperature, time must vary with the type of load.

Oxidation. It is generally economical and advisable to keep oxidation at a minimum in order to reduce loss of metal and costs of pickling and to improve finish. In some instances specially prepared atmospheres are used, which result in a bright or clean annealed material, depending on the alloy and the condition of the metal before annealing. Control of furnace atmosphere usually results in better furnace economy as well.

Effect of Lubricants. Lubricants on metal to be annealed, may cause staining that is very difficult to remove. Regardless of the type of furnace or the article to be annealed, it is advisable to eliminate as much of the lubricant as possible before the metal is heated.

Hydrogen Embrittlement. When copper that contains oxygen is to be annealed, the hydrogen in the atmosphere must be kept to a minimum in order to reduce the danger of embrittlement caused by the combination of the hydrogen in the atmosphere with the oxygen in the copper, forming water vapor under pressure, and resulting in minute ruptures in the metal. For temperatures lower than about 900 F the hydrogen should preferably not exceed 1%, and as the temperature is increased, the hydrogen content of the atmosphere should approach zero.

Impurities. Occasionally it is difficult to obtain proper grain growth when annealing under standard conditions that have previously given the desired grain size. This trouble may sometimes be traced to impurities in the alloy, and if other causes cannot readily be found for the retarded grain growth, it would be well to have the material analyzed in the laboratory.

Annealing to Obtain Desired Tensile Properties. It is impracticable to anneal for definite properties of tensile strength or hardness between the normal cold worked and the fully recrystallized or softened range, because of the extremely rapid rate of change of properties with only a small change in metal temperature. Rates of heating and control of temperature are not accurate enough to obtain any desired tensile strength or accompanying physical property. The best practice is to anneal completely and then to obtain the desired properties by controlled cold working to the necessary extent.

Loading. It is usually not practicable to anneal a variety of different sizes or kinds of material in the same charge, because of the different rates of heating and the resulting final metal temperatures.

Fire Cracking. This is a type of cracking that occurs when some alloys that contain residual stresses are heated too rapidly. Leaded alloys are particularly susceptible to this cracking. The remedy is to heat slowly until the stresses are relieved. Special cold deformations, such as "springing", aid considerably in preventing fire cracking.

Thermal Shock. Hot short materials should be heated slowly to avoid thermal shock.

Sulfur Stains. Excessive sulfur in the fuel or lubricant will cause discoloration of the metal; red stains appear on yellow brass and reddish brown on copper-rich alloys.

Joining Copper and Copper Alloys

By the Subcommittee on Joining Copper Alloys*

COPPER and copper alloys can be joined by welding, soldering and brazing. The application of these methods is considered here under the subdivisions: carbon-arc welding, gas welding, metal-arc welding, resistance welding, and soldering and brazing.

Welding

All the welding methods commonly employed are applicable in the joining of copper and copper alloys, but all are not suitable for any one of these metals. In fusion welding, it is desirable to consider the metallurgical characteristics of the filler metal in relation to the method in order to produce a weld of high quality. In turn, the characteristics of the joining method should be considered, because they may influence the metallurgical and physical properties of the metal or alloy to be joined. To facilitate such considerations the copper-base materials may be grouped according to the effect of the main alloying element, as follows: coppers, special bronzes, brasses, cupronickels and nickel silvers, tin bronzes, and other alloys.

Carbon-Arc Welding. *Coppers.* This process is applicable to the welding of tough pitch copper, provided comparatively high rates of progression (10 to 20 in. per min) are attained without preheating, in order to minimize the time-temperature effect on the remigration of cuprous oxide to the grain boundaries, causing an appreciable reduction in the mechanical properties of the base metal immediately adjacent to the joint. The fluid phosphor-bronze filler metals, which may be employed to attain the necessary speed, must be used in conjunction with a long arc to minimize porosity. Their use is generally limited to flat welding and to plate thicknesses that may be welded in one layer. Although the welds produced are of satisfactory strength, the ductility is erratic because of porosity. The less fluid silicon and aluminum bronzes, which may be employed with shorter arc lengths, yield much sounder welds, but because of the limited speeds possible, their use is restricted to the oxygen-free and deoxidized base metals. Such metals may be preheated for lower rates of progression, or lower arc currents.

Special Bronzes. The carbon-arc method is the most widely employed and most satisfactory for welding the copper-silicon alloys, since its use is accompanied by the rapid cooling necessary to prevent hot cracking at joints where allowances cannot be made for the high shrinkage characteristics. The carbon-arc method may be employed either manually or automatically for sheet metal fabrication, and manually for the layer welding of plate. Best results are obtained when the work material is kept in a flat position. Carbon-arc welding is also applicable to the copper-aluminum and the copper-aluminum-silicon alloys with which coated aluminum bronze electrodes may be employed for filler metal. Bare wire, in conjunction with a flux high in cryolite, may also be used as filler metal for these alloys.

* The members of this subcommittee are J. J. Crowe, *Chairman* (Air Reduction Sales Company); J. L. Christie (Handy & Harman); R. T. Gillette (General Electric Company); J. Imperati (The American Brass Company); James Hunter (Revere Copper and Brass Incorporated) and C. W. Steward (Westinghouse Electric Corporation)

Copper-Zinc Alloys. Although the carbon-arc method has been employed to weld the copper-zinc alloys with copper-zinc filler rods of the "low-fuming" type, this method is generally employed with zinc-free rods, made of material such as the silicon, aluminum or phosphor bronzes. The arc is struck and maintained on these filler metals to minimize fuming. Preheating of the base metal to allow the use of reduced currents is also helpful in this respect. In conjunction with the shrinkage of the weld metal, the sharp temperature gradient obtained in the absence of moderate preheat temperatures will establish a stress gradient in the base metal adjacent to the joint. Stress relieving should follow the welding of alloys containing more than 15% Zn, in order to preclude failure through stress corrosion.

Copper-Nickel Alloys. The carbon-arc method has no particular merit recommending it for the cupro-nickels and nickel silvers, and its infrequent use is restricted generally to the very thin gages for which the metal-arc electrodes of small diameter present problems in the low-current ranges.

Copper-Tin Alloys. The tin bronzes are readily welded by the carbon-arc method, utilizing the standard phosphor-bronze filler rods previously mentioned. The alloy rods for carbon-arc welding contain appreciably higher percentages of phosphorus than either the base metal, electrode core wire, or gas welding rods, to ensure that a sufficient phosphorus content will remain after subjection to the intense heat of the carbon arc. The best results will be produced by striking and maintaining medium to moderately long arcs on the added filler metal.

Other Alloys. The coated aluminum bronze electrodes employed for the metal-arc welding of beryllium copper can also be used as filler rods for carbon-arc welding, with comparable results if the procedure is properly controlled.

Gas Welding. Compressed coke-oven gas and bottled liquid gases find some use in low-temperature joining and preheating operations on the copper-base alloys, but the oxyacetylene flame is the most widely employed, because of its high temperature and the variety of atmospheres readily obtainable.

Coppers. The gas method is considered the most satisfactory for producing copper welds in copper base metal. Because the effects of time, temperature and atmosphere are such that hydrogen embrittlement of tough pitch copper cannot be avoided, and internal oxidation, followed by embrittlement of unprotected oxygen-free copper, is likely to be encountered even with the best of practice, the use of both these coppers is to be avoided in gas-welded fabrication. The filler rods available for use in conjunction with phosphor-deoxidized base metal may be added to the first two in order to increase the strength of the weld metal at high temperatures. Soundest welds are produced by the silicon-deoxidized filler metal, which, in conjunction with a slight alloying effect, accounts for weld strength slightly superior to that of the dead-soft base metal adjacent to the joint. The phosphor-deoxidized and manganese-deoxidized welds tend to be porous unless welded with care, yielding weld strengths varying from one-half to the full strength of dead-soft copper. When such rods are employed, it is common practice either to hot peen in the course of welding or to cold peen on completion of the joint, in order to produce a weld joint comparable in strength with the base metal.

Special Bronzes. Although the gas method will yield very satisfactory results in the copper-silicon alloys, its use is generally restricted to joints where compensation can be made for the high shrinkage of the weld metal, so as to avoid cracking caused by hot shortness. Proprietary fluxes are available that should remove adequately any refractory silicon dioxide formed. The coated aluminum-bronze electrodes employed for both metal-arc and carbon-arc welding may also be the source of filler metal for gas welding of the copper-aluminum and copper-aluminum-silicon alloys.

Copper-Zinc Alloys. The gas method is the preferred choice for making welds comparable with the base metal in composition. The available filler rods are slight alloy modifications of the 60–40 copper-zinc composition (Muntz metal); however, where necessary for better corrosion resistance or color match, filler rods cut from the base metal may be employed. Because of the tendency for zinc to volatilize, it is common practice to employ an oxidizing flame to develop an oxide film that is quite effective in suppressing such fuming. The addition of silicon to the welding rod is by far the most practical method for suppressing such losses with their attendant effect on the soundness of the weld metal. Lead-free alloys are always to be preferred for welded applications since lead, because of its low melting point and insolubility in the metal, produces hot shortness.

Copper-Nickel Alloys. Because of the refractory nature of nickel oxide, which is formed, and the difficulties that nickel oxide introduces in gas welding, this method is rarely employed. A small addition of silicon to the filler rod helps appreciably both in preventing the formation of oxide, which is difficult to handle, and in producing sound welds. The presence of zinc in the nickel silvers improves, but does not eliminate, the oxide problem. Because strips cut from the base metal can be employed as filler metal, the gas method is, in general, the most versatile for producing color-matching welds.

Copper-Tin Alloys. The gas method is the least practicable method for welding tin bronze. The slow cooling rates often obtained with this method, along with characteristic high shrinkage, may lead to cracking of the weld as a result of hot shortness. The filler rods for gas welding contain considerably less phosphorus than those produced for carbon-arc welding; use of carbon-arc filler rods for gas welding only aggravates the above difficulties.

Other Alloys. The formation of an oxide difficult to flux makes gas welding unsuitable for beryllium-copper.

Metal-Arc Welding. *Coppers.* Because of the high heat conductivity of the coppers, the metal-arc method is not applicable to any but the light gages without the use of a preheat. Although copper welds of satisfactory strength have been produced with coated electrodes, they are not widely employed for vessels of code quality because of poor ductility resulting from microporosity. Somewhat better results can be obtained with alloy electrodes, such as the phosphor bronzes, but the soundest welds are produced by coated aluminum bronze electrodes. Because of the high preheat temperatures necessary to offset heat losses, phosphor-deoxidized base metal is always to be preferred. The time-temperature relationships are such that the hydrogen in preheating flames (resulting from only partial burning) will embrittle tough pitch copper, and the possibilities of an internal oxidation-reduction cycle make oxygen-free copper a questionable choice.

Special Bronzes (Copper-Silicon, Copper-Aluminum, Copper-Aluminum-Silicon). The reduced thermal conductivity resulting from alloying, obviates preheating for metal-arc welding. Coated copper-silicon electrodes are available, but their deposition characteristics are such that they find little use in the metal-arc welding of the comparable base metals. The newer copper-aluminum coated electrodes weld all alloys in this subgroup satisfactorily.

Copper-Zinc Alloys. The loss of zinc through volatilization necessitates the use of a substantially zinc-free electrode. Phosphor bronze and aluminum bronze electrodes are the ones commonly employed; aluminum bronze electrodes produce sounder welds and stronger, more satisfactory joints. Preheating is necessary to permit use of electrodes of proper diameter within their range of working current, to offset heat losses by conduction, and to minimize zinc losses from the fused base metal with attendant deleterious effect on the soundness of the weld. Preheat temperatures between 500 and 600 F are desirable for the alloys of moderate thermal conductivity (such as manganese bronze and Muntz metal) and temperatures as high as 800 to 1100 F may be necessary for the alloys of higher conductivity (such as gilding metal, 95% Cu–5% Zn). Minor base-metal alloying elements, such as tin, aluminum, iron and manganese, are not detrimental; but because of its insolubility, lead, frequently employed to improve machinability, will promote hot short cracking.

Copper-Nickel Alloys. The low-conductivity 70–30 composition is the most widely employed in the fabrication of weldments. Coated electrodes with core wire of the same composition as the alloy being welded have the best depo-

sition characteristics of any in the copper-base alloy group, approaching those of steel electrodes. This preferred method may be employed in all positions, but best results are obtained when the work material is laid flat. The addition of varying amounts of zinc to copper-nickel alloys of reduced nickel content, in order to produce a variety of nickel silvers, alters the conductivity only slightly; however, the presence of zinc with its low boiling point permits some loss through volatilization, which may be minimized by the use of low current strengths made possible by moderate preheating of the base metal.

Copper-Tin Alloys. The wrought phosphor bronzes are alloys of moderate thermal conductivity, and while the lighter gages may be metal-arc welded without preheating, on medium to heavy thicknesses of plate a preheat of 200 to 400 F is desirable in order to employ the coated phosphor bronze electrodes in the lower current ranges and to obtain maximum weld soundness. Preheating temperatures should be held as low as possible, consistent with the foregoing recommendations, since rapid cooling is essential in the prevention of hot short cracking.

Other Alloys. Metal-arc welding with coated aluminum bronze electrodes is the preferred method for fusion welding beryllium-copper. Fusion welding cannot be accomplished without partial destruction (in the region of the joint) of the superior mechanical properties obtained in the alloy through heat treatment.

Submerged-Arc Welding. This process has been successfully adapted to the welding of sheet and light 70–30 cupro-nickel plate. A modified flux has been employed and there are indications that, when further improved, submerged-arc welding will be applicable to the production of code-quality welds in the copper-silicon alloys.

Resistance Welding. Resistance welding is being used increasingly for copper and copper alloys. Several factors common to all these materials will be mentioned first; then each group of alloys will be treated separately.

Welding Equipment. Welding machines—whether they are spot, projection, seam, or butt welders — must have sufficient electrical capacity to make welds in a minimum length of time, since most of these materials are good heat conductors and long welding times tend to heat too large an area, so that excessive oxidation and distortion result. With extremely low input of energy it might be possible to conduct heat away so rapidly that a weld could not be made at all.

The moving member of these welding machines should be as light as possible to reduce inertia, and as free from friction as possible to ensure rapid follow-up or application of pressure as soon as fusion temperature is reached. Because these materials have little or no plastic range, the welding machine must follow rapidly in order to apply pressure at the proper time and to prevent expulsion of molten metal with consequent weakening of the weld as a result of cavitation.

All resistance-welding machines should be equipped with precisely synchronous electronic controls, since copper and copper alloy materials are particularly sensitive to variations in welding procedure, and this type of control is capable of repeating application of power to the machine with the accuracy of the circuit frequency.

The precisely synchronous control also eliminates transient currents sometimes encountered in random switching of power to the welding machine. The current in these transients may be several times the normal current value and, since the heating effect is as the square of the current, a transient may burn a hole through the work material, and may also destroy the electrodes.

Cleaning. To weld satisfactorily, copper and copper alloys must be carefully cleaned so that no oil, grease, oxide or scale remain, because, though some of these oxides are quite refractory, other oxides are of high resistance and consistent results cannot be obtained unless they are removed.

Use of the proper type of electrode material is also important. Generally materials of high conductivity require electrodes of low conductivity and materials of low conductivity require electrodes of high conductivity. Ordinarily the leaded copper alloys weld less satisfactorily than those containing no lead.

Coppers. The spot, projection, and seam welding of the various types of copper are difficult; however, the materials of thinner gage are sometimes weldable by the use of electrodes faced with material like tungsten or molybdenum and possessing high resistance. A trace of tin, as from tinned wire or sheet, is helpful in welding copper. Tinned wire of relatively small size can sometimes be spot or projection welded to other members. Copper can be butt welded quite easily. However, high input of energy and short times with a somewhat special procedure are required.

Commercial Bronzes, Red Brass, Low Brass. Copper alloys of this class weld slightly better than copper, but in general the same factors hold true as with copper.

Brazing, Spring, Admirality, Commercial, Alpha and Yellow Brasses. These brasses, with lower thermal and electrical conductivity than copper, may be welded by the various types of resistance welding. However, because they are sensitive to any variations in surface condition and procedure, these metals must be carefully cleaned and all welding procedures carefully controlled.

Muntz Metal, Tobin Bronze, Naval Brass, Manganese Bronze, and Extruded Brass. Materials of this group may be welded by all the methods of resistance welding but they require careful handling with high current and as short a time as can be used practicably. All the copper alloys must be clean and free from oxide, dirt, oil and grease.

Nickel Silver. This alloy can be welded successfully by the various methods of resistance welding. Preferably somewhat higher pressure and lower input of current are used than for welding the alloys of higher conductivity.

Phosphor Bronze. Phosphor bronze can be welded quite readily by all the resistance welding methods; the procedure is similar to that for welding low-carbon steel. However, this alloy is inclined to be hot short in the heavier sections and care must be used not to overheat it or to employ excessive welding pressures.

Copper-Silicon Alloys. The copper-silicon alloys are perhaps the most easily resistance welded of all the copper alloys. The procedure should include relatively short welding time and average pressure. As with all the copper alloys, the material should be thoroughly cleaned.

Cupro-Nickel. Cupro-nickel is a good alloy to weld by the various resistance welding methods. All the types of resistance welding may be used. Since the oxides of this alloy are quite refractory, the metal must be carefully cleaned before welding.

Soldering and Brazing

Definitions. Brazing and soldering are methods of joining metals in similar or dissimilar metal combinations by means of a nonferrous filler metal, without fusion of the base metal. Brazing is ordinarily understood to refer to those processes that use filler metals with melting points higher than 800 F, while soldering covers the processes carried out at temperatures lower than 800 F.

Accordingly, brazing includes the processes that use the silver brazing alloys with melting points ranging from 1175 to 1600 F, those that use the copper-phosphorus alloys with melting points from 1300 to 1530 F, and those that use the high zinc-copper alloys with melting points from 1600 to 1650 F.

Commonly, soldering refers to the use of the so-called soft solders, most of which melt below 700 F.

With the few exceptions noted below, all these materials can be used successfully on all the coppers and the copper alloys. The choice of an alloy for any particular application will be influenced by several factors — cost of the alloy, cost of flux, and cost of heating to the required temperature, strength and ductility required in the finished joint, required resistance to corrosion, operating temperature for the finished joint, and color of the joint.

Methods of Application. Usually brazed and soldered joints are made by flowing the molten filler metal between closely fitting surfaces of the metal or metals to be joined. Examples are the common lapped and scarfed joints. In the one special process, known as the "bronze

welding process", a copper-zinc alloy filler rod is used with the flame of the oxyacetylene torch to fill an open V-groove or a fillet.

Heating of joints is accomplished by the following methods: by use of flames from the oxyacetylene torch or other gas torches; by use of furnaces, with or without special atmospheres; by use of a soldering iron or copper for the soft solders; by use of carbon holders heated by electric resistance (*see* Resistance Welding).

Materials. The common brazing alloys and soft solders are listed in Tables I and II, along with the fluxes usually employed with them. The silver brazing alloys include the eight ASTM grades and two proprietary alloys.

Fluxes used with these alloys are ordinarily the proprietary paste fluxes (mixtures of borax and boric acid with fluorides and potassium salts) that are fluid at 1100 F. For the alloys that melt at temperatures higher than 1400 F it is possible to use the common borax and boric acid fluxes made for brazing purposes.

The common solder fluxes are solutions of zinc chloride with some ammonium chloride. A noncorrosive flux is made by dissolving rosin in alcohol or kerosene.

Applications. The brazing and soldering alloys described above and the accompanying fluxes may be used with facility on all the coppers and copper alloys except the following: (1) The soft solders will not bond readily with the copper-silicon alloys. (2) The silver brazing alloys will not bond with the aluminum bronzes unless a special flux is used that contains halogen compounds. Proprietary fluxes of this type are available.

Table I. Copper Brazing Alloys

Type	Composition, percentage	Approximate Flow Point, deg Fahr
1[a]	Copper-phosphorous alloys in rod or strip form 4 to 8 P 0 to 1 Sn Remainder Cu	1300 to 1530
2[b]	Brazing metal, Muntz metal in rod or wire form 38 to 42 Zn Remainder Cu	1625
3[b]	Spelter brazing alloys in powder or lump form 45 to 55 Zn 0 to 10 Ni Remainder Cu	1550 to 1650
4[b]	High zinc-copper alloys in rod form—the commonly used "bronze welding" alloys 0 to 0.50 Mn 0 to 1.50 Sn 0 to 1.50 Fe 0 to 10 Ni 0 to 0.15 Si 38 to 42 Zn Remainder Cu	1600 to 1650

(a) Brazing alloys of type 1 are self-fluxing when used on copper. For the other alloys it is advisable to choose one of the proprietary paste fluxes made for the low-melting silver brazing alloys. These fluxes are usually mixtures of borax and boric acid with fluorides and potassium salts and are fluid at temperatures higher than 1100 F.

(b) Fluxes for types 2, 3 and 4 are usually mixtures of borax and boric acid. They are generally used in powder form, although it is preferable to use them as pastes made by mixing with hot water.

Machining Copper and Copper Alloys

BY THE SUBCOMMITTEE ON MACHINING COPPER ALLOYS*

FREE-CUTTING brass rod has always been considered one of the most easily machined metals, and in this discussion of the machining of copper and wrought copper alloys, free-cutting brass rod serves as the standard.

"Machinability" is a term not readily defined but usually described by its effect on cutting properties. Where wrought copper alloys are concerned, machinability depends more on chemical composition than on physical or mechanical properties. Metal to be machined must be rigid enough to stand up against the turning tool without distortion. Accordingly the temper of wrought copper alloys for automatic screw machining should be hard, but the alloys may need to be soft enough to withstand other subsequent cold working. Generally machinability improves with an increasing amount of lead (usually 0.5 to 4.0% Pb; also 0.5% Te or 0.5% Se) and decreases with increasing amounts of tin, silicon, aluminum, nickel and other elements. For the purpose of discussion, copper alloys may be divided into three principal groups.

Rating of Machinability. *Group 1. The Free-Cutting Alloys.* These are copper alloys to which a small percentage of lead, tellurium or selenium has been added. This group includes the alloys that have a machinability rating of 70 to 100, as given in Table I. (Free-cutting yellow brass = 100) These alloys, most frequently used in rod form for the production of screw-machine parts, give short brittle chips when machined.

Group 2. Moderately Machinable Alloys. These have a machinability rating of 30 to 70, and include the group of nonleaded brasses from Muntz metal or naval brass containing 60% Cu, to red brass containing 85% Cu. This group also includes leaded phosphor bronze, leaded silicon bronzes and leaded nickel silver containing 12 to 18% Ni.

Group 3. Alloys Machinable with Difficulty. This group includes nonleaded coppers, nickel silvers and phosphor bronzes, as well as cupro-nickel and beryllium copper. When machined, these alloys usually produce long, tough, stringy turnings.

These ratings of machinability are arbitrary values to be considered only as an approximate indication. They are a reasonable guide to relative tool life and to the amount of power required for cutting.

Turning. On copper alloys the larger portion of "form" turning operations are performed by circular, dovetail or flat tools that reduce diameters and produce shaped contours by feeding toward the axis of a rotating rod or blank in a "plunge cut". This type of tool often performs its function simultaneously with a drilling or reaming operation. The tool should have the shape shown in Fig. 1 for the various groups. The materials in Group 1 require very little or no rake, but ductile materials usually require a com-

Chromium copper	99.50 max	....	(0.40 Cr min)	...	(0.10 Si or Zn)	20	1.046

(a) Approximate relative machinability rating (Free-cutting brass = 100)
(b) Weight conversion factor (Free-cutting brass = 1.000 based on a density of 0.307 lb per cu in.)

paratively steep rake. The moderate rake angles suggested for use on alloys in Group 1 reduce the tendency of the tool to "hog" into the work piece. More pronounced rakes are used for the alloys of Group 2 and 3 to provide a free flow of chip.

When parts that have a small diameter are made from the alloys in Group 1, they are usually machined at the highest practical spindle speed; the feeds are adjusted to suit such conditions as depth of cut, available power, coolants and finish requirements.

Turning Speeds and Feeds for Use with High Speed Steel Cutters

(When carbon steel cutters are used, the suggested speeds should be reduced by approximately 50%.)

	Surface Speed, fpm	Roughing Feed, inch	Finishing Feed, inch
Group 1	300 to 700	0.006 to 0.020	0.003 to 0.015[a]
Group 2	150 to 300	0.015 to 0.035	0.005 to 0.015[a]
Group 3	75 to 150	0.015 to 0.040	0.005 to 0.020

(a) An 8 to 15-deg end cutting edge angle should prove satisfactory for most rough and finish turning operations. When the end cutting edge of a finishing tool is ground with a drag or parallel with the axis, considerably heavier feeds may be employed on light finishing cuts. Tools should be ground and set so that the tool point is on center, with the effective rake angles in correct relation to the center line of the work.

Form tools are usually of two types, circular and dovetail (Fig. 2). The circular form tool is used to best advantage in automatic screw machines. In general, the speeds and feeds used with form tools are controlled to a considerable extent by the width of the tool in relation to diameter of the work piece, the amount of overhang and the contour. It is good practice to adjust only the cutting speed to the alloy that is being machined and to maintain a light feed of 0.001 to 0.003 in. for roughing operations and 0.0005 to 0.002 in. for finishing operations.

Cutting speeds and feeds for carbide-tipped tools (Fig. 3), as for other types of cutting tools, will vary over a wide range, depending on the material to be cut, the available power and rigidity of the machine, the diameter of the work piece, the desired finish, tolerances and other such factors. Roughing cuts of ¼ in. or more are frequently used, producing a satisfactory finish. The following suggested cutting speeds and feeds are typical for copper and copper alloys and are based on a depth of cut of approximately 0.045 to 0.125 in. for roughing, and 0.015 to 0.030 in. for finishing. A starting point may be taken as halfway between the limits given, adjusting the speed upward or downward until the best results are obtained.

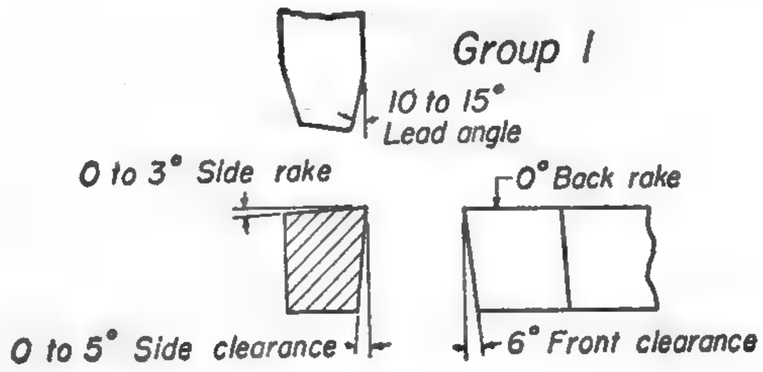
Turning Speeds and Feeds with Carbide-Tipped Tools

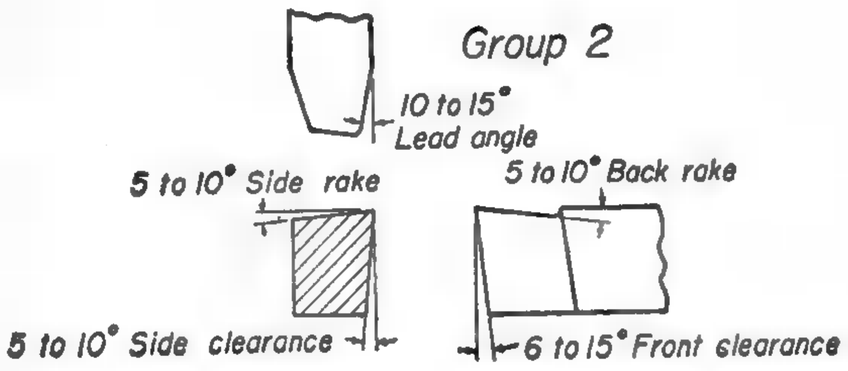
Group 1
- Roughing surface speed, from 400 to 800 fpm
- Roughing feed, 0.015 to 0.025 in.
- Finishing surface speed, from 500 to 1000 fpm
- Finishing feed, 0.005 to 0.015 in.

Group 2
- Roughing surface speed, from 300 to 500 fpm
- Roughing feed, 0.015 to 0.030 in.
- Finishing surface speed, from 400 to 600 fpm
- Finishing feed, 0.005 to 0.015 in.

Group 3
- Roughing surface speed, from 250 to 600 fpm
- Roughing feed, 0.015 to 0.030 in.
- Finishing surface speed, from 300 to 800 fpm
- Finishing feed, 0.008 to 0.015 in.

Milling. Copper alloys can be milled at very high speeds. Because of rapid removal of metal, coarse-tooth cutters are desirable and, if they are even moderately wide, they should





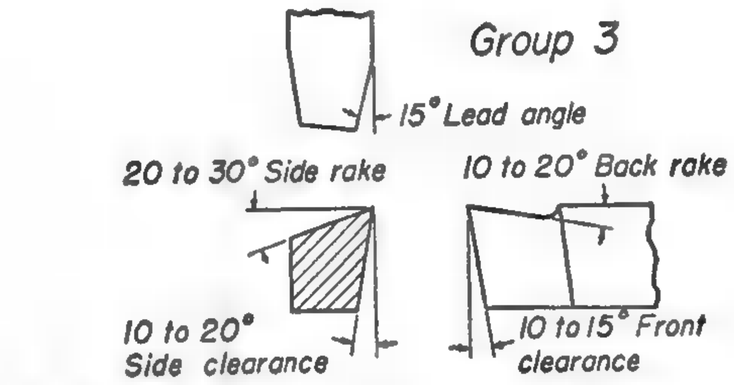


Fig. 1 Carbon and high speed steel lathe turning tools. An angle of 8 to 15 deg at the end cutting edge should prove satisfactory for most rough and finish turning operations. When the end cutting edge of a finishing tool is ground with a drag, or parallel with the axis, considerably heavier feeds may be employed on light finishing cuts. Tools should be ground and set so that the tool point is on center with the effective rake angles in correct relation to the center line of the work.

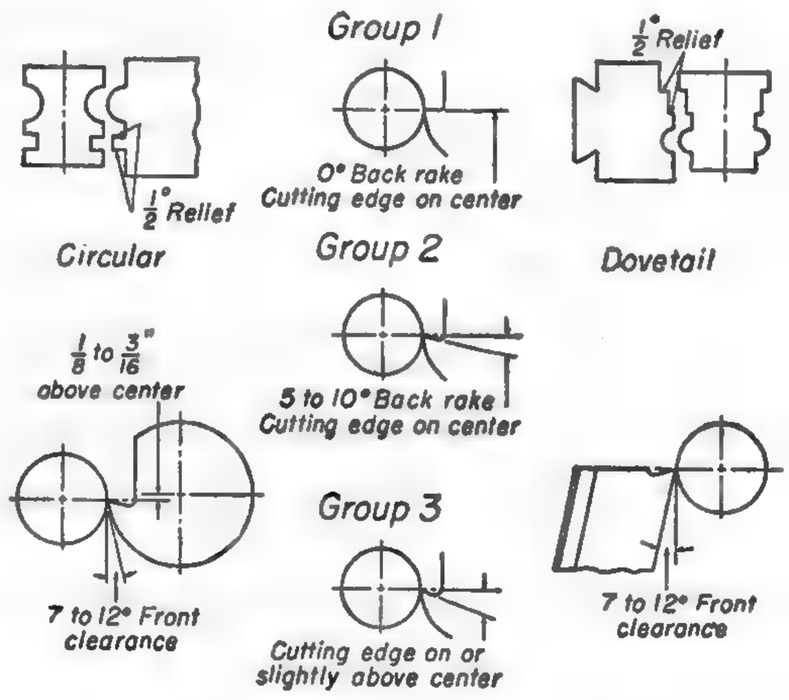

Fig. 2 Circular and dovetail forming tools

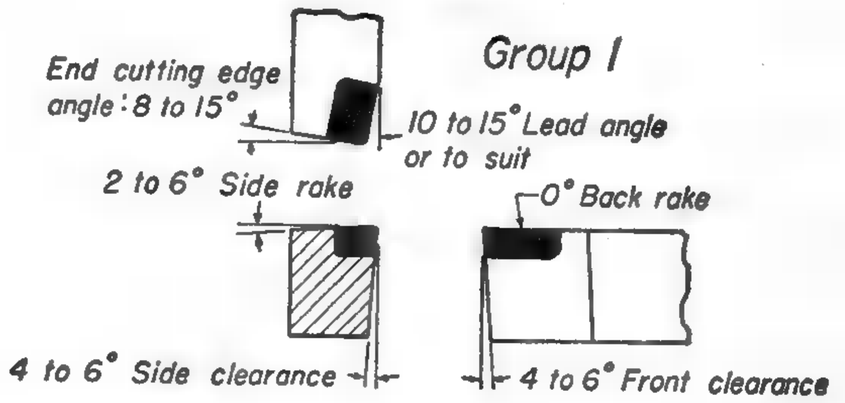
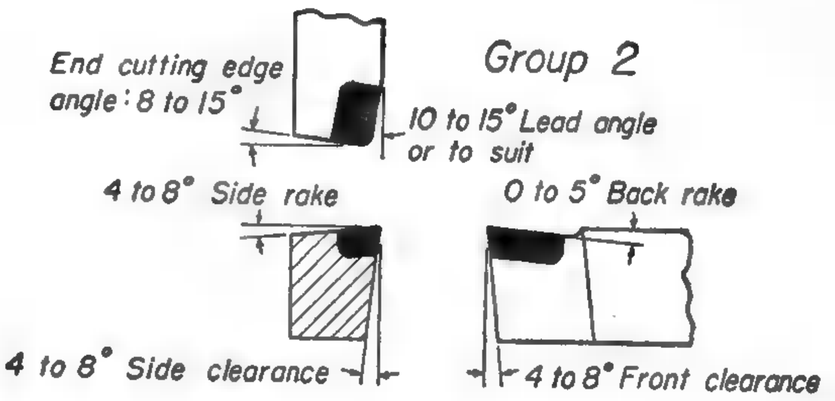
be spiral. High speed steel cutters are commonly used, and cutters having inserted teeth of cemented carbide are efficient for large tools and heavy cuts. Combined cutters are inefficient, unless they have interlocking teeth, since rapid production of chips wedges fine chips between the cutters. Conditions of milling are listed in Table II.

Leaded brasses are readily machined dry and with no hook on teeth, but Groups 2 and 3 require a coolant and hooked teeth. Cutting edges and sides must be especially smooth to avoid a "plating" or "loading" action.

For straight-blade and circular cutoff tools, see Fig. 4.





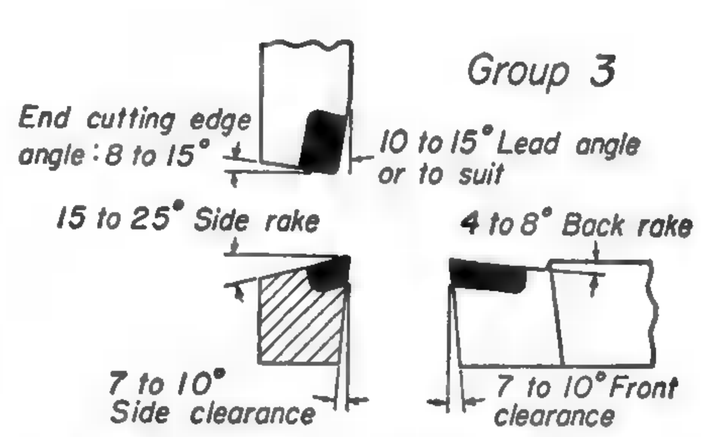


Fig. 3 Carbide-tipped lathe turning tools. For establishing rake angles, the tool shank should be set parallel with the center line of the work and with the tool point on center. Placing the tool point above or below center will change the effective rake angles appreciably, particularly on work of small diameter. On a setup where the tool holder is not parallel with the center line, the rake angles should be ground so that, when the tool is mounted, they are in correct relation.

Table II. Milling

Many variables enter into milling practice but, in general, conditions are determined by the finish desired. The high tooth of the cutter will always leave a series of parallel ridges. For finish cuts the following conditions are advisable.

	Group 1
Rake angle, degrees	0 to 10
Clearance angle, cutters more than 3 in. in diam	10 to 12
cutters less than 3 in. in diam	6 to 7.5
Feed, fpm	1 to 2
Speed, fpm[a]	150 to 200
Depth of cut may vary between wide limits	0.010 to 0.250
For very rough cuts on heavy slabs—cutters 6 in. in diam	
Rake angle, degrees	0
Clearance angle, degrees	8 to 12
Feed, fpm	15 to 20
Speed, fpm	1100

(a) Actually governed by finish desired.

At high speeds the greater the helix and the feed, the greater should be the clearance.

Use of a coolant is recommended.

Engraving tools Class I; diameter < ⅜ in.; surface speed 400 fpm.

Drilling. For free-cutting brass rod, the conventional twist drills are ordinarily used, although some work pieces require straight-flute, slow or fast spiral, gun or standard drills. Where the volume of production does not warrant the use of special drills, standard carbon or high speed steel drills are satisfactory for Group 1. It is often helpful to thin the web at the point to reduce pressure at the end, and for metals of Group 3 the cutting edge may be notched to split the chips.

The slow spiral with wide polished flutes and a thin web provides larger chip clearance with a decreased rake angle and is often used for drilling deep holes.

Alloys of Group 1 are occasionally drilled dry but can be drilled to better advantage when conditions permit the use of a suitable lubricant. On alloys of Groups 2 and 3 a lubricant should always be used. The drill should be kept cutting without interruption as long as the chips are being ejected. In holes that are deep in relation to the diameter of the drill, a depth no greater than five diameters can be drilled satisfactorily without relief or chip clearance.

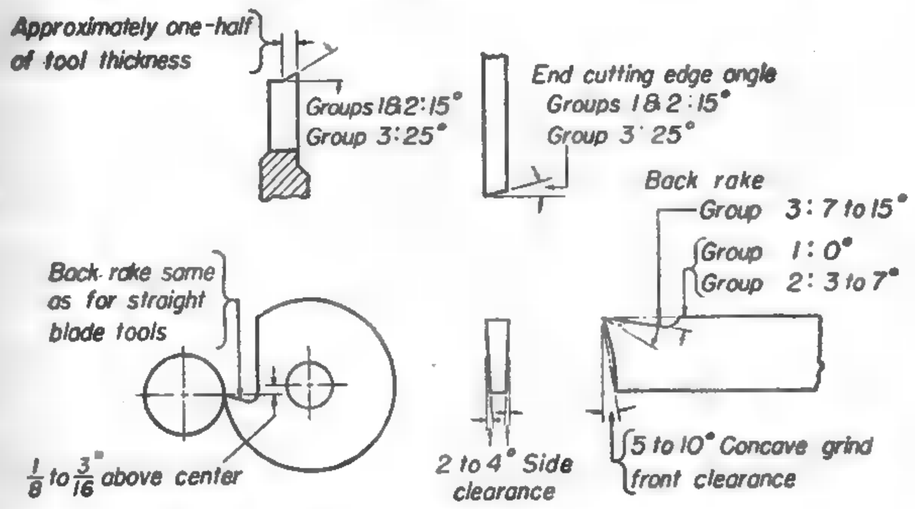

Fig. 4 Straight-blade and circular cutoff tools

Many factors control the speed and feed of drilling operations, depending on the diameter of the drill, the wall thickness of the work and the depth of the hole. Drill point and clearance angles are shown in Fig. 5 and Table III.

Threading and Tapping. This operation is probably more severe than that of any other cutter. Because copper alloys are easy to machine, the operation is inexpensive compared with similar operations on metals that necessitate milling

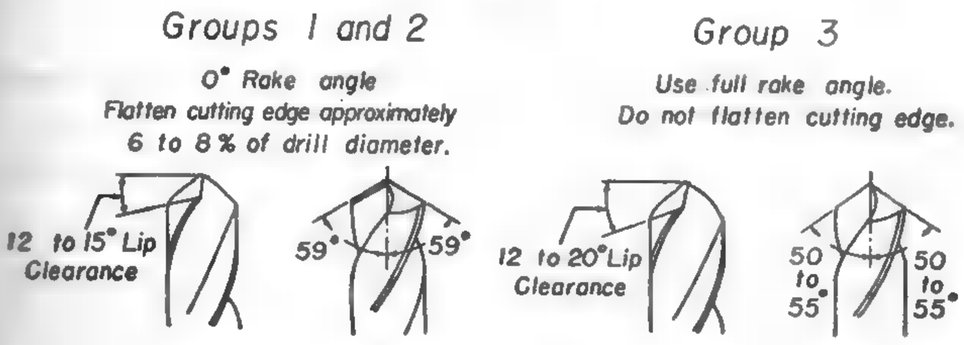

Fig. 5 Drill point and clearance angles for twist drills

or rough and finishing operations. The cutting action is unfavorable for any tool, since the tap or chaser must often have a short lead and must produce a smooth, commercially full thread to close tolerances in one cut. As compared with using a self-opening die or tap, it is slow and expensive to mill threads by rotating a multitooth hob and the work piece. Ground thread-chasers and taps made of high speed steel are conventional tools for copper alloys. The milled

Table III. Drilling

	Group 1
Helix angle, degrees	24 to 40[a]
Clearance angle, degrees	12 to 15
Web to edge angle, degrees	135
Included point angle, degrees	118
Speed fpm for depths as great as 10 diam	350 to 700
For small diameters (less than 0.080 in.)	200 to 300
Lubricant	Dry, or paraffin oil

(a) For quick removal of chips, but it tends to "pull" into work.

type of chaser is used for Group 1 and the hobbed type for tough alloys and tubular sections that have a thin wall. Three-flute or four-flute taps are ordinarily used. However, a greater number of flutes is advisable on sections that have a thin wall and a large diameter. Alloys in Group 3 often require a slight back taper on deep holes. Tools should be smooth, not too keen-edged and with no rake for Group 1, but sharp and hooked for Group 3.

The cutting speeds suggested are for threads of moderate pitch; for coarse threads, speeds in the lower range should be used. On automatic screw machines working Group 1 alloys, the maximum spindle speed is frequently used when threading work pieces that have small diameter or thread of fine pitch.

Threading Speeds:

Group 1, from 100 to 150 fpm
Groups 2 and 3, from 50 to 90 fpm

When automatic screw machines are working on Group 1 alloys, maximum spindle speed is frequently used when tapped holes are of relatively small size or when the thread has a fine pitch.

Tapping Speeds:

Group 1, from 150 to 250 fpm
Group 2, from 60 to 150 fpm
Group 3, from 30 to 60 fpm

Knurling and Thread Rolling. There are two methods of producing knurls on brass parts and differing results are produced with different tooling and alloys. One method is by "ploughing" from the end, and the other is by "butting" or plunge-feeding from the side. Neither of these methods will produce an especially clean knurl from leaded brass, because leaded brass will stand only a limited amount of upsetting without "roughening". High-copper and non-leaded alloys will produce a cleaner job. However, knurling as produced on leaded alloys is generally acceptable.

Thread rolling is produced by "butting" against a diameter that approximates the pitch diameter of the thread. A much better thread will result from low-leaded brass. It is important that a suitable temper of leaded brass be used when that alloy is required for knurling.

Sawing. Saws that have a large number of cutting edges can rotate at very high speeds, especially on leaded brass. Thinner high-speed saws or blades can be used on copper alloys than on other metals, because of the smaller frictional heat developed. Because of rapid removal of chips, coarse-tooth saws are best with no hook for leaded alloys and with hook increasing with copper content. Usually no coolant is required for leaded brass. Naturally, the contact with the part should be at a minimum; a rectangular shape should be sawed through its thinnest section. If finish is required, metal-slitting saws should be used with side chip clearance that minimizes "rubbing" and "chip wash". Tooth shapes for circular saws are illustrated in Fig. 6. Other data are listed in Table IV.

Carbide-tipped blades are efficiently used in automatic sawing machines.

Lubricants and Coolants. Some machining operations on copper alloys, particularly turning and drilling, are performed dry when the quantity and other considerations do not justify the use of cutting fluids. However, higher speeds and feeds may be used and a finer finish obtained where the use of a coolant or lubricant is practicable.

The functions of a cutting fluid are threefold: (1) As a coolant, it reduces the temperature of the cutting tool and

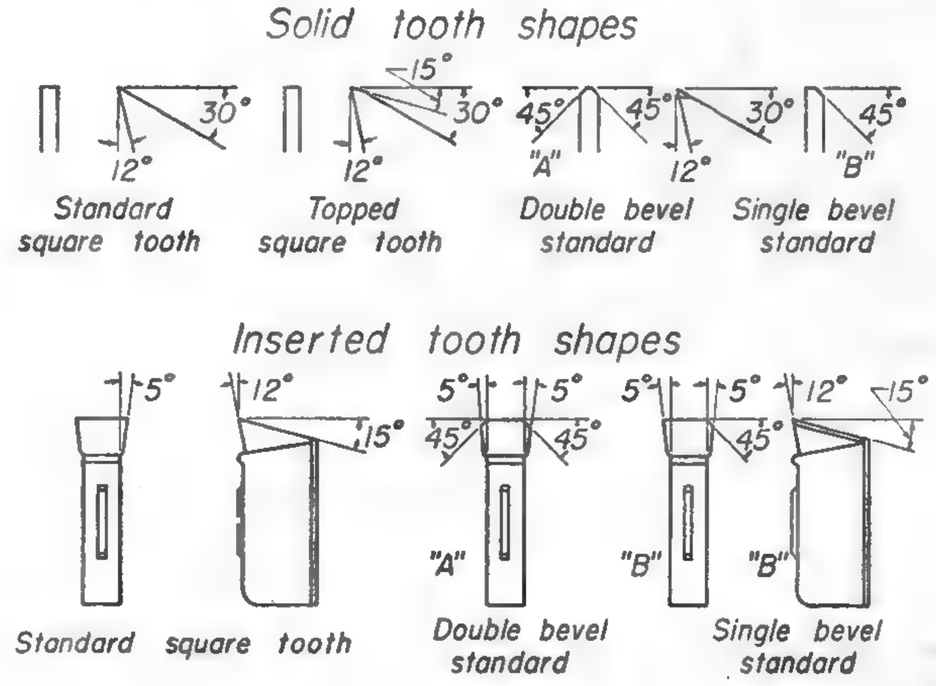

Fig. 6 Solid and insert tooth shapes for circular saws

thereby preserves the hardness and prolongs tool life. (2) As a lubricant, it provides a film of oil between the work piece and cutting tool, thereby reducing abrasion and erosion. (3) As an anti-weld agent, where some elements such as sulfur are added to the cutting fluid to minimize or eliminate the deposit built up on the cutting edge by high cutting pressures and temperatures.

Table IV. Sawing with Circular Saws

Form and Size	Alloy Class	Grade Steel[a]	Tooth[b] Type	Diam, inches	Thickness, inch	No. Teeth	Hook Angle, deg	Rim Speed, fpm	Feed, ipm	Lubricant[c]	Rockwell C Hardness	Chromium Plated 0.002 in. per side	Hollow Ground Taper per in.

(a) SHSS is a trade designation for semihigh speed steel saw and HSS for high speed steel saw.
(b) See Fig. 6 for tooth types.
(c) Compound made up as water emulsion of soluble oil. Use 10% oil by volume and 1 lb heavy soap per 20 gal of compound.

Because of the many considerations that govern cutting operations, it is impossible to make specific recommendations. The following suggestions may serve as a guide.

Group 1. For the free-cutting alloys included in this group, a light mineral oil, frequently called "paraffin oil", is used in large quantities on automatic and hand screw machines and is directed at the cutting edge of the tools. Unblended light mineral oil is particularly desirable when machining alloys of this group at high speed, light feed and moderate depth of cut. An inexpensive cutting compound with good coolant properties may also be used, consisting of 20 parts water to 1 part soluble oil.

Group 2. The soluble coolant compound mentioned under Group 1 may also be used for this group. A mineral oil base, fortified with 5 to 15% lard oil, will be likely to prove more satisfactory as both lubricant and coolant; the higher percentage of lard oil is used on those alloys producing tough, stringy chips.

Group 3. A cutting fluid frequently used for this group of alloys is a mineral oil base with 10 to 20% lard oil. For copper and the alloys that have a high nickel content, sulfurized mineral oil, or sulfurized mineral–lard-oil compounds have given excellent results. When a sulfurized compound is used on copper alloys, the parts should be cleaned as soon as possible after machining, to avoid discoloration. This tarnish can be removed by immersion for 20 minutes in a 10% sodium cyanide solution.

Finishing of Copper and Copper Alloys

BY THE SUBCOMMITTEE ON FINISHING COPPER ALLOYS*

THIS ARTICLE outlines methods and practices used in industry for preparing the surface of copper and copper alloys for subsequent fabricating, and for finishing the surface of completely fabricated products. Unless otherwise stated, the procedures will apply to the following metals: copper, brasses, special brasses, aluminum bronzes, silicon bronzes, phosphor bronzes, manganese bronzes, nickel silvers and copper-nickel alloys.

* The members of this subcommittee are R. W. Belfit, *Chairman* (Scovill Manufacturing Co.), Wm. E. Baulieu (Bridgeport Brass Co.), E. W. Lovering (Seymour Manufacturing Co.) and B. H. McGar (Chase Brass & Copper Co.).

Mechanical Cleaning and Surface Conditioning*

Barrel Deburring. Small cut parts, such as disks, eyelets, cups and the like, often have a sharp edge with a burr that would interfere with subsequent operations.

* *See also* the article on page 301 of this Handbook.

Small articles are deburred inexpensively by tumbling in a barrel. Two distinct types of barrel are used—an open-end oblique barrel that may be tilted for unloading, and a cast-iron horizontal, polygonal barrel with removable tight-fitting cover. The tilting barrels, made of copper-silicon alloy, iron or stainless steel, have four or more ribs inside to aid in the desired rolling action.

The deburring procedure varies considerably for different sizes, weights and shapes of work pieces. Experiments must be conducted to determine the preferred size of the load in the barrel, the speed of rotation, the length of time in the barrel, and the abrasives and chemicals that may be used. Generally, copper alloy parts will be received in the rolling room with oil still on them from the previous mechanical operation, so a typical deburring procedure will start with cleaning.

Cleaning and Deburring Small Copper Alloy Articles. *Equipment.* A horizontal, octagonal cast-iron barrel or an obliquely tilting steel barrel with narrowed mouth and centrifugal dryer.

Materials. Caustic soda flakes (sodium hydroxide), sodium cyanide eggs, No. 2 pumice, sea sand, soapbark, and cream of tartar or a substitute.

Procedure. 1 Add hot water to cover 50 to 250 lb of work; add approximately 5 lb of caustic soda and 4 oz of sodium cyanide (*poison*).

2 To remove oil, roll for 10 min at a speed of approximately 30 rpm.

3 With water piped to the mouth of the barrel, wash the parts until they are free from alkalies, that is, until red litmus paper no longer turns quickly blue. (Operators sometimes judge by elimination of the slippery feel.) In oblique barrels, the parts are washed during rotation.

4 Add 3 lb of No. 2 pumice and 6 lb of sea sand (screened through 40-mesh) with a cover of water.

5 Roll until burrs are removed from work pieces. The time may vary from ▪ to 24 hr.

6 Dump the work into a perforated centrifuge basket and wash free from abrasive.

7 Dry the work in a centrifuge equipped with a hot air blast. Work will have a smooth, dull matte finish.

Remarks. The abrasive used may be different grades of pumice, rottenstone, sea sand, silex, emery, aluminum oxides, silicon carbides, or similar materials. Sometimes when the work pieces are heavy, satisfactory deburring is accomplished simply by rolling the parts in an oblique barrel with water only. Also, the oil may be removed by other alkaline cleaners.

Bright or Water Rolling. *Equipment.* Obliquely tilting steel barrel with narrowed mouth and centrifugal dryer.

Materials. Caustic soda, sodium cyanide, and cream of tartar or a substitute.

Procedure. Operations 1, 2 and 3 for bright rolling are similar to those for deburring, or the work pieces may have been deburred already.

4 Add about 6 oz of cream of tartar to 20 gal of water and roll at 30 to 40 rpm until the desired bright finish is obtained. It is usually necessary to replace the dirty solution with clean water and more cream of tartar.

5 Rinse the work with running water for 5 to 10 min while the barrel is rotating.

6 Dump the work into ▪ perforated centrifuge basket, place in heated centrifuge and dry.

Ball Burnishing. *Equipment.* Horizontal barrel made of wood, steel with wood lining or steel with brass lining; or oblique, tilting stainless steel barrel.

Materials. "Neutral" soap, cream of tartar or a substitute, and soapbark.

Procedure. 1 Work should have been deburred or bright rolled, then treated by "bright acid dipping", before being placed in the barrel for ball burnishing.

2 For each volume of work material, add two volumes of steel burnishing balls, 1/16 in. to ½ in. in diam.

3 If using the preferred horizontal barrel, fill it with water to within a few inches of the cover and add approximately 2 oz of soap for each gallon. If the water is hard, add a water softener first or a proprietary mixture that includes a wetting agent.

4 Roll at approximately 30 rpm for 6 to 48 hr, depending on the luster required and the kind of work pieces.

5 Dump the entire contents of the barrel and riddle out the balls from the work parts while washing the parts.

6 Dry the work by rolling it for about 20 min in a horizontal wooden barrel that contains sawdust slightly moistened with Stoddard solvent to prevent fine sawdust from adhering to the work material.

7 Riddle sawdust from the work.

Remarks. Ball burnishing produces the highest luster that can be obtained in bulk finishing. Such burnishing may be applied to copper alloys before plating or lacquering, or may be used after plating to improve the luster. In ball burnishing, the soap acts as a lubricant, so the metal surface is rubbed (peened) by the hardened steel balls that are marketed for that specific use. When balls are not in use, they should be kept in a soap solution or other alkaline solution to prevent rusting.

Steel shapes other than balls, such as cones, pins and slugs, are sometimes used with balls for special-shaped items, since balls cannot reach into sharp corners.

Wheel Polishing. *Equipment.* A buffing lathe and glue pot with temperature controlled at about 160 F.

Material. Cotton cloth buff sections (18 in. in diam), felt or sheepskin leather wheels, high-gel-strength hide glue, and emery or aluminum oxide (80 to 220-grain).

Procedure. 1 Glue together 8 to 12 sections of the cloth wheel (20 pieces of cloth to each section). Brush glue solution all over one side of each section and stack the sections while they are centered by a temporary 1-in. arbor. Compress the sections beneath about 20 lb of weights and allow 12 hr or more for setting. The cutting face of the wheel will be 1 to 1½ in. thick.

2 Mount the wheel on the spindle where it is to be used, and dress the wheel with a well-worn hacksaw blade.

3 Size the cutting face of the wheel with a solution of approximately 25% hot hide glue, and dry at least ½ hr.

4 Apply glue solution at 160 F to the face of wheel.

5 Roll the wheel in the abrasive until it has picked up all the grain it will hold. Then dry for 1 hr.

6 Repeat operations 4 and 5 but allow overnight drying.

7 True the wheel with a file sharpened to a chisel edge.

8 Crack the wheelhead by striking the wheelface lightly with a round bar at about a 45-deg angle. This should be repeated around the wheel so that "X" series of cracks are formed. These cracks make the wheel more flexible and retain the grease better, making possible a more uniform and higher polish.

9 The wheel is ready for polishing at ▪ speed of approx 2500 rpm. A stick of polishing tallow should be used on the wheel to lubricate the cutting.

Remarks. The most popular abrasive is the 150-grain. Similarly, wheels may be set up with abrasives and glue applied on wool felt or sheepskin leather. Since the felt wheels are much more costly, they are generally used only where a shaped wheel or bob (for inside polishing) is desired. The sheepskin wheels are used on parts that are round and irregular, if a more flexible wheel is required.

Light polishing and deburring are also accomplished by the use of a cotton cloth wheel and a greaseless composition. This type of composition, with glue as the essential binder of various abrasives, is sold in stick form in a moisture-resistant cardboard or lead container. When the stick is placed in contact with the revolving wheel, some of the compound coats the cutting surface and may be used almost immediately. For polishing effects, the most suitable speeds are 4300 to 5700 surface ft per min, that is, 1800 rpm, with a wheel 9 to 12 in. in diam.

Belt Polishing. Many polishing operations are performed on endless canvas or leather belts set up with abrasives and glue. In one method, the abrasive is sprinkled onto a belt that has previously been brushed with hot glue. Another method requires making a thick paste of the hot glue and abrasive and then spreading it on the belt with a brush, knife or trowel. Factory-coated abrasive belts are preferred because of the uniformity of abrasive coating. Polishing belts are run at 4500 to 6000 surface ft per min.

Scratch Brushing. Most scratch brushing is now done with a greaseless composition on a cotton cloth wheel. The chief advantage of this method is that it eliminates both a buffing and a cleaning operation that were necessary after the use of grease-bound, scratch-brush compositions.

Before being scratch brushed, the work should be clean (often, "bright dipped" in acid). Various finenesses of scratch are obtained by means of sharp or mild abrasives of different grain sizes and by variation in the packing of the wheel and its speed. The wheel packing will be discussed under Buffing. Some scratch brushing on surfaces is done with a wire or tampico wheel, wet or dry, with a little soapy water and 0 ½ pumice.

Wheel Buffing. The highest luster on copper alloys is produced by wheel buffing.

Equipment. Either a buffing lathe of variable speed or lathes run at different speeds, 1200 to 3600 rpm. Buffing wheels may be incorporated into semiautomatic or fully automatic machines.

Materials. Cotton cloth (rag) wheels; different finenesses of tripoli composition; lime composition; and red rouge (iron oxide) composition. The abrasives are in bar form, and are bound with a grease mixture that contains a considerable amount of double-pressed stearic acid.

Procedure. 1 Usually start with at least 12-in. sections of cotton cloth buffs that are mounted on a spindle.

2 As the wheel revolves, rake it by means of a strong stick through which nails have been driven so as to protrude about 1 in. apart each way.

3 Apply selected buffing composition to the wheel as needed, taking care not to use too much composition.

4 Buff a work part by holding it up to the face of the wheel. After buffing, withdraw the part in the direction of rotation of the wheel, which is downward. The operator should be careful that a sharp corner does not catch in the wheel and snap the material out of his hands. Small work pieces are often held in a revolving chuck so that a piece will spin as it is held against the wheel.

Remarks. Operators sometimes pack buff wheels differently for the same work. To soften a wheel, "spacers" are used in packing. Spacers are small buff sections that have been worn down and are placed between full-size sections. The larger the percentage of spacers, the softer the wheel. Judicious use of spacers often permits "cutting down" and "coloring" on the same spindle, by packing one side of the wheel hard and the other side soft. For "cutting down", a tripoli composition is used on the rag wheel, while for coloring, a white lime or red oxide rouge (iron oxide) is generally used. The cutting-down operation removes polishing lines and light metal imperfections; the coloring operation develops the ultimate luster.

All operations with a buffing wheel should be adequately ventilated to protect the operator from the dust.

Buffing is a relatively expensive operation, but often costs can be reduced considerably by close co-operation among the designing, buffing and processing departments. The metal should have the minimum grain size consistent with the working operations in order to buff smooth.

Belt Buffing. For some intricate shapes, such as the inside surfaces of an S-bend trap, a woven cotton belt driven at 6000 ft per min, may be used advantageously. The tripoli or other composition is applied to the belt.

Sandblasting. Sandblasting is the process of removing material from the surface of metal by forcibly impinging sand, steel grit or shot onto the surface. The abrasive is introduced into an air stream at air pressures of 25 to 100 psi and the blast is directed over the surface until the desired finish is obtained. The objective may be to produce a dull, rough finish for appearance; to prepare a surface that affords excellent adhesion to enamels and other decorative coatings; or to create designs on the surface.

Chemical and Electrochemical Cleaning

During the course of processing and fabricating, copper alloys may become coated with lubricating oils, drawing compounds, greases, oxides, dirt, metallic particles, or abrasives, which must be removed by cleaning. The type of cleaning employed will depend on the type of lubricant and other materials to be removed, the equipment available and the degree of cleanliness required. The nature and size of the pieces also influence the selection of the equipment or process to be employed.

Mechanical scrubbing, accomplished by turbulent boiling, pressure spraying, or agitating, where permissible, helps in the removal of any substances not too adherent, and thus aids in cleaning. Occasionally, hand brushing may be used, but production requires mechanical methods.

Lubricants made from animal or vegetable oils or greases, such as tallow, lard oil, palm oil and olive oil, can usually be removed by saponification, which is accomplished by immersing the parts in an alkaline solution where the oil reacts with the alkali to form water-soluble soap compounds.

Mineral oils that are not saponifiable, such as kerosene, machine oil, cylinder oil and general lubricating oils, are usually removed from the metal by an emulsification process. Soap is the wetting agent and dispersing medium.

Dirt particles, abrasives, metal dust and inert materials are generally removed by one or both of these processes. To bring about the removal of undesirable materials by saponification, emulsification or similar means, it is necessary to use certain chemicals or combinations of chemicals. A number of cleaning methods employ available chemicals for the removal of lubricants and other materials. The common methods are discussed below.

Solvent Cleaning. This type of cleaning is used for removing the greater portion of oils from coated pieces by immersing them in a solvent, such as Stoddard's solvent, which is a low-boiling fraction of mineral oil, with a minimum flash point of 100 F and no lasting odor. Centrifuging, after the last immersion, removes excess solvent; the pieces are then virtually free from oil. Solvent cleaning is often used for screw-machine work. After a short period of service, the solvent will become contaminated by the materials that it is removing. It is often advantageous to set up a series of interconnected iron tanks leading to and from a still. The still removes the accumulated oil and returns the solvent to the first of the series of tanks, which overflows into the adjacent tank, which in turn overflows into the next one, and so on. The last tank in the cycle feeds the still. The final rinse is nearly clean solvent.

Degreasing. Degreasing, or vapor cleaning, is used when oil must be removed quickly. For cleaning, the metal part is placed in a container where solvent vapors can condense on it. Condensate washes away the oily coating and leaves the piece clean and dry. Degreasing machines with two or three compartments are preferred. The work pieces are immersed in the first compartment, which contains a boiling solution of solvent; they are then dipped into the second section, which contains clean cold solvent; and finally, they are held in the third section, where only clean vapors condense on the work and wash over it. The degreasing unit is usually self-purifying; oils and wastes accumulate in the bottom of the third section. If the quantity of oils removed should justify the expense, this unit may be equipped with an auxiliary still in order to ensure that sufficient clean solvent is returned to the proper section. The solvent used is generally inhibited trichlorethylene.

Alkaline Scouring. Alkaline cleaning baths are used primarily for the removal of oils, greases, solid particles of dirt, and metal particles, by immersing the work in a hot alkaline solution. The chemicals saponify, or make soap of vegetable and animal oils and fats, and emulsify mineral oils and greases, suspending the solid materials. Either the dirt is removed from the metal surface, or its tendency to cling is greatly reduced. The essentials here are a combination of a sufficient quantity of active chemicals and agitation when possible. Soap is used as a direct addition to the cleaning bath, or is formed by the saponification of vegetable or animal fats and oils present.

The following are satisfactory cleaning formulas:

Formula 1	*Formula 2*
85% sodium orthosilicate	46% sodium carbonate (anhydrous)
10% sodium carbonate	32% trisodium phosphate
5% sodium resinate	16% sodium hydroxide
	6% rosin

These formulas are from the Joint Army-Navy Specification JAN-P-116, "Methods of Preservation, Packaging and Packing for Overseas Shipment".

Caustic soda and soda ash are the cheapest and most direct means of producing alkalinity in the bath. However, as a general rule such materials possess less surface activity than materials of more complex chemical structure. Sodium metasilicate, trisodium phosphate and similar salts, with the addition of suitable wetting agents, are often used to obtain alkalinity in a solution.

To be effective, the alkaline cleaners should exhibit the following characteristics:

1 They should wet the surface of the material, which is usually accomplished by lowering the interfacial surface tension.
2 They should have the ability to penetrate the layers of dirt.
3 They should have good emulsification and deflocculation or suspending properties.
4 They should be "free rinsing".
5 They should saponify animal and vegetable oils.
6 They should have the ability to remove mineral oils by the mechanism of wetting, emulsification and deflocculation.

To accomplish the above objectives, the essential requirements for a good alkaline cleaner are that it should be a source of available alkali, should have a buffer to control alkalinity, should be readily soluble, operate at optimum cleaning temperature, be stable, and have good detergent ability and rinsing qualities. Various temperatures and concentrations are permissible. The range of temperature may be from 120 to 200 F and the concentration from 3 to 8 oz per gal, depending on the requirements of cleaning. These characteristics are listed to indicate the need for using a type of cleaner that is compounded for a specific purpose.

For alkaline cleaning, steel tanks where work can be put into baskets or on racks and raised from and lowered into a solution, are the simplest and least expensive to install. The more highly mechanized units consist of belt conveyers where work material passes over and under sprays; and also of spiral drum cleaning units, where alkaline cleaner is scooped up and thrown over the pieces, which are rinsed and dried farther on.

Emulsion Scrubbing. For emulsion scrubbing, a number of proprietary preparations are used. They consist of an emulsifying agent that acts to disperse organic solvents in water solutions. These emulsifiable cleaners, miscible with oils, can be washed off with water, although a slight film of oil may remain on the work, necessitating a subsequent alkaline cleaning. Drag-out costs are fairly high. Parts carrying oils or other substances to be removed are immersed in this type of cleaner. The cleaning agents penetrate and unite with the oils and dirt on the surfaces of the articles, and during subsequent immersion in water solution, both the emulsion cleaner and the oil and dirt that it has wet, are washed away. Steel tanks are usually suitable for holding these materials.

Electrolytic Cleaning. Alkaline solutions are used in electrolytic cleaning, which is performed before plating. Work pieces are usually placed on racks. The tanks are equipped with bus bars, and these in turn are connected to a generator. When work is put on a cathode bar, the procedure is termed "direct cleaning"; when on an anode bar, "reverse cleaning". The bath is maintained at the boiling point or as near the boiling point as is permissible without excessive tarnishing, and the gas evolved, because of the work being made an electrode, tends to lift off the soil, providing a clean surface for subsequent operations. The usual procedure in electrocleaning is to make the work the cathode. The purpose of this is to obtain as high an evolution of gas as possible although, in some present processes, only anodic treatment is employed. The merits of one, as against another, depend on what, specifically, is to be accomplished, and the nature and type of work and chemicals employed. Many formulas are available for electrocleaning, but the one used will depend on the material to be cleaned and the amount of tarnish permissible. Electrolytic cleaning is often as satisfactory as hand scrubbing. It also makes possible the cleaning of many parts for which hand scrubbing would be impracticable or too costly.

Removal of Tarnish. Brass and copper articles often become discolored or tarnished while standing, or during the course of alkaline cleaning. This tarnish can be removed when the work material is free from oil or grease, by immersing the parts in a water solution containing 4 to 8 oz of sodium cyanide per gal. After discoloration has been removed (usually a matter of seconds), the pieces should be rinsed thoroughly. Sodium cyanide is *very poisonous* and extreme care must be used in handling it. When parts are cleaned in alkali, the alkali should be completely removed, because if alkali and cyanide are mixed and allowed to stand, ammonia may be developed. Care must be taken also not to allow any cyanide to come in contact with acid, because of liberation of lethal hydrocyanic acid gas. Even though the above precautions must be carefully observed, many gallons of cyanide solution are used daily, particularly in plating cycles. Steel tanks are suitable for holding the solution.

Tarnish can also be removed by immersing the work pieces in dilute hydrochloric (muriatic) acid or in dilute sulfuric acid solution; usually 5 to 10% by volume is sufficient for this purpose. The hydrochloric acid should be poured into rubber-lined containers or vitrified crocks. The sulfuric acid is usually put into a lead-lined tank or a crock. After the acid treatment the pieces should be rinsed thoroughly with water, so that no acid will remain on the work.

Summary. The fundamentals essential to cleaning that have been considered here, are the reduction of affinity or adhesion of substances to a metal surface, and the equipment required for this reduction.

When the practical application of cleaning cycles is considered, the kind of equipment that can be obtained, that is available or that is required for performing a process, will determine what type of cleaning should be or can be employed. Cleaning equipment may be very simple; however, the fully automatic equipment is not.

The nature and size of the pieces to be cleaned also determine the kind of equipment or process to be employed. Very small pieces are handled in baskets or in bulk. Large, highly polished pieces are handled individually or are placed on racks where there is no chance for one piece to come in contact with another. Oils or other materials should be removed without darkening the metal, since when this occurs, further treatment may be required to restore the original color and luster.

In planning the production of a new article, it proves advantageous to consider the kind of lubricants to be used in manufacturing and processing operations, with particular reference to the ease of removing these substances later, with the cleaning equipment available.

Pickling and Bright Dipping

When copper and copper alloys are annealed in an oxidizing atmosphere, they are discolored by the formation of surface oxides, which can be removed by an acid treatment called "pickling". This treatment leaves the surface free from oxides but without a bright color. A treatment that gives an absolutely clean, bright, lustrous surface is termed "bright dipping" and is always preceded by a pickling operation.

A pickling or bright-dipping solution depends on the action of suitable acids (usually nitric or sulfuric) to dissolve the oxides by chemical reaction. In certain instances oxidizing agents are added to convert lower oxides, which may be insoluble in the acid, to higher oxides that can be dissolved readily.

Pickling Equipment. Pickling tubs, tanks, racks and auxiliary equipment must be resistant to strong acids. Tanks may be made of or lined with stainless steel, lead, ceramics, glass or rubber. Racks or baskets are ordinarily made of stainless steel, monel or nichrome.

Automatic pickling machines are now in common use, carrying the work on trays and belts, and in rotating drums, through the pickling solution. Such machines for volume work have automatic control of the temperature of the solution and wash waters and of the speed at which the parts travel. A uniform pickling is thus assured, as well as a thorough rinsing and drying. For small or intermittent volume work, however, tanks or tubs are generally used with excellent results.

Pickling of Copper and Copper Alloys (including the tin bronzes, phosphor bronzes, manganese bronzes, naval

brasses and aluminum brasses). These alloys, with scale consisting largely of cupric oxide, cuprous oxide, and zinc oxide, are generally pickled in dilute sulfuric acid of the following composition: concentrated sulfuric acid (H_2SO_4, sp gr 1.83) 5 to 10% by vol; the rest, water.

This solution is used from room temperature to between 125 and 150 F. Heating to higher temperatures increases the amount of objectionable fuming and corrosion of equipment without substantially increasing the speed of pickling. The strength and temperature of the solution, as well as the duration of immersion, vary with the alloy being cleaned and the amount of oxides present. A small amount (less than 1%) of copper sulfate may be added to the fresh solution to increase the initial speed of reaction.

Cuprous oxide (sometimes called "red oxide") is only slightly soluble in sulfuric acid; consequently, after pickling in dilute sulfuric acid, brasses may have red stains caused by such undissolved oxide. A stain of similar appearance may also result from a film of copper deposited galvanically, or from localized superficial dezincification. These stains may be eliminated by immersion of the metal in the following solution:

Concentrated sulfuric acid (H_2SO_4, sp gr 1.83) 4 to 10% by volume
Sodium bichromate ($Na_2Cr_2O_7$, commercial) 4 to 8 oz per gal of solution
Water, remainder

This solution is operated at temperatures from 80 to 120 F. The articles should first be pickled in sulfuric acid and then immersed in the bichromate solution to remove red stains. The duration of immersion is determined best by trial; too brief an immersion leaves stains and too long a dip etches the metal.

Commercial ferric sulfate may be used instead of sodium bichromate. About 10 to 25 oz per gal of ferric sulfate is used in a solution containing 4 to 10% by volume of sulfuric acid at temperatures up to 150 F. The ferric sulfate should be dissolved completely before being used. It has been found that this solution has less tendency than the bichromate to etch the metal, although the finish and color are not exactly the same as obtained with the bichromate solution.

Great care should be taken to rinse the metal thoroughly after treating with the above solutions. Generally several water washes, both hot and cold, are used, and sometimes a hot solution of 1 to 2 oz per gal of soap, which neutralizes any residual acid remaining on the metal. The parts should then be dried completely, in hot air, sawdust or by other means to avoid water stain.

Bright and Matte Dipping. When a bright lustrous finish is desired, the metal should first be pickled in the sulfuric acid pickle, and then given a "scale" dip, and finally a bright dip. The pickling removes oxides and the scale dip prepares the surface for the bright dip that follows. Scale dips and bright dips consist of sulfuric and nitric acids, in proportions that vary greatly from plant to plant. In general, nitric acid will speed up the action of the dip, and sulfuric acid will slow it down. The following dips are typical:

Scale Dip

	A	*B*
Concentrated nitric acid (HNO_3, sp gr 1.40)	40%	50% by volume
Concentrated sulfuric acid (H_2SO_4, sp gr 1.83)	30%	....
Concentrated hydrochloric acid (HCl, sp gr 1.16)	0.5%	....
Water	29.5%	50%

Bright Dip

Concentrated nitric acid (HNO_3, sp gr 1.40)	25% by volume
Concentrated sulfuric acid (H_2SO_4, sp gr 1.83)	60% by volume
Concentrated hydrochloric acid (HCl, sp gr 1.16)	0.2% by volume
Water	Remainder

These solutions are used at room temperature. Parts are immersed in the scale dip, are rinsed in water, are immersed in the bright dip and rinsed immediately in cold running water; then they are rinsed in a sodium cyanide solution (2 to 4 oz of sodium cyanide per gal) to remove any acid stains, are rinsed in water again and dried. Care must be taken to clean off the acid completely before dipping the work material in the cyanide; otherwise, deadly hydrocyanic acid gas may form.

In some plants, it is customary to add wood soot to the bright dip to ensure uniformity of brightness on the surface of the dipped articles. The soot is stirred in and then skimmed off, a procedure that is said to overcome the effect of too much hydrochloric acid, which results in irregular brightness.

A matte surface can be obtained after bright dipping, rinsing and drying, by using the following typical solution, which should be agitated occasionally:

Concentrated nitric acid (HNO_3, sp gr 1.40)	65% by volume
Concentrated sulfuric acid (H_2SO_4, sp gr 1.83)	35% by volume
Zinc sulfate ($ZnSO_4$, commercial)	1 lb per gal of solution

This dip is used at 180 F. The parts are dipped, rinsed and dried in the usual manner.

All the above solutions should be provided with an adequate ventilating system.

Pickling of Aluminum Bronzes. Since aluminum bronzes are very difficult to pickle and dip because of the presence of aluminum oxide, it is recommended that they be annealed in a nonoxidizing atmosphere. Alloys that contain up to 7% Al are pickled in a sulfuric acid solution, such as that used for brass. This treatment leaves the metal clean but dull in color, because aluminum oxide is not soluble in sulfuric acid. A solution containing approximately 3% by volume of sulfuric acid and 3 to 4 oz per gal of sodium bichromate, may be used. A bright finish is obtained only by mechanical cleaning, and alloys with more than 7% Al must have a mechanical treatment in order to remove any oxides that are present.

Pickling and Bright Dipping of Silicon Bronzes. Because of the refractory nature of silicon oxide and the insolubility of it in any acid except hydrofluoric, it is advisable to anneal silicon bronzes in a protective atmosphere. However, if the metal has been subjected to an oxidizing atmosphere, a sulfuric acid pickle (5 to 10% of H_2SO_4 by volume) is sometimes used in order to remove copper oxide from the metal, although the silicon oxide is unattacked and the metal is left with a dull finish. Where a clean bright surface is required, the following dip is used after a sulfuric acid pickle:

Concentrated sulfuric acid (H_2SO_4, sp gr 1.83)	5% to 10% by volume
Concentrated nitric acid (HNO_3, sp gr 1.54)	10% to 20% by volume
Commercial hydrofluoric acid (HF, 52%)	3% to 5% by volume
Water	Remainder

Great care should be taken when using this dip. Metal or ceramic tanks are not suitable, because they are attacked by the solution. A wax or carbon-base lining material must be used and the tank should be provided with a hood and an exhaust to remove dangerous acid fumes. The dip should be employed at room temperature, and parts should be rinsed carefully after they have been removed from the solution. This solution is extremely powerful and workmen should be protected carefully from any contact with the fumes or the liquid.

Pickling and Bright Dipping of Nickel Silvers and Cupro-Nickels. The nickel silvers may be pickled and bright dipped with the same solutions as brass and copper.

Cupro-nickels may be pickled in a bichromate bath of the kind used for brass, or in a ferric sulfate bath that contains up to 25% ferric sulfate in a 5 to 10% sulfuric acid solution at temperatures up to 150 F. Cupro-nickels may be bright dipped in the usual solution employed for brass.

Defects from Pickling. By far the most common defect encountered in pickling is the presence of red stain on the metal. It has been mentioned that, when caused by cuprous oxide, this defect may be removed in a bichromate or ferric sulfate pickle. However, red stains may also result from the presence of metallic iron or steel in the pickling solution, causing copper to plate out on the parts because iron is anodic to copper. Great care must be taken to prevent any stray pieces of iron, such as nails or tools, from entering the pickling solution.

Oil and lubricants remaining on formed metal are a source of much trouble in pickling and dipping. If formed material is to be bright dipped directly after having been pressed, it should be degreased because otherwise the

lubricant remaining will prevent the dip from being effective. Also if the work is to be annealed and pickled, it should be degreased (usually a hot water rinse is sufficient) since the oil may cause excess cuprous oxide to form during annealing, with unwanted red staining as a result. In extreme instances, the more volatile constituents of the oil burn off readily, leaving a carboniferous deposit that cannot be removed except mechanically.

Acid stains will appear on the metal if it is not thoroughly rinsed and cleansed of all remaining acid after pickling or dipping. At least two separate washings in water or one thorough running-water wash should be used before drying. A dip in a soap solution or buffered salt solution will neutralize traces of acid.

The metal will be etched or pitted if it is immersed for too long in a pickling solution or dip, or if the solution is too strong or too hot. The proper conditions for operation may be found quickly by a trial of time, temperature, and concentration of solution.

Surface Preservation and Decoration

Immediately before the final assembly of small manufactured articles, the surface finish is often protected by application of a clear transparent lacquer or is decorated by a type of colored enamel. The coating should be adhesive, tough, highly resistant to abrasion and perspiration, and relatively impervious to sulfur fumes.

Often it is desired to preserve the natural colors of copper alloys. In such instances clear finishes are applied, such as air-drying lacquers or synthetic ones of the baking type. The actual selection of the finishing material will be affected by the conditions of use of the product, the number of parts to be finished, the size and shape of the parts, the cost and method of application.

An operator should wear soft cotton gloves when handling the material after the cleaning operation and before lacquering. Enamels or lacquers should not be applied to metals that are even a little dirty. Work pieces should be lacquered promptly after cleaning.

Methods of Application for Lacquers or Enamels. *Hand Brushing.* A soft, firm bristle or camel's-hair brush is used, and the finish should be flowed on with little or no rebrushing.

Hand Spraying. The material is finely atomized in a spray gun by means of compressed air. Striping can be effected with a small spray gun; the other extreme is a fan spray of 15 in. A good smooth coat requires an experienced sprayer. A single coat may be from 0.0002 to 0.002 in. thick.

Automatic Machine Spraying. This method is suited to large-volume production, since the atomizing gun is mechanically operated as the work passes by it.

Dipping by Machine. The work material is mechanically withdrawn, slowly and uniformly, with little or no vibration, from the clear cellulose or synthetic lacquer. This method produces a uniform film, except on edges, and is economical of material. Sometimes this process is limited by the shape of the product.

Basket Bulk Dipping. The work material is placed in screen baskets, is immersed in the clear lacquer and withdrawn; the excess is allowed to drain off while the baskets are revolving slowly in an oblique frame; then the work pieces are dried in an oven, where they are rotated manually or mechanically in order to prevent them from sticking together. This can be the least costly lacquering procedure when protection until use is all that is required. Parts that nest together, or flat pieces, are not adaptable to bulk lacquering.

Centrifuging. The work material in screen baskets is immersed in the clear lacquer and withdrawn; the excess lacquer is allowed to drain back into the container; and then the basket is placed in a centrifuge and whirled for 30 sec in one direction, and for 30 sec in the opposite direction. The pieces are transferred to an oven and dried, after shaking once or twice to prevent sticking.

Barrel Tumbling. Small, lightweight pieces that cannot nest are placed in an oblique, wide-mouth barrel (made of brass, stainless steel or monel) revolving at about 30 rpm. A small quantity of lacquer (for instance, 2 oz) is applied to the inside of the barrel, whence it is transferred to about 25 lb of work, coating only the outside of the shells that have a cup shape. The parts are dried in an oven, with periodic agitation, and are then baked to polymerize the film. One coat of lacquer is not sufficient to give a continuous film, so barrel tumbling is used only with baking finishes that enable the application of several coats.

An orifice type of viscosity cup is desirable for checking the viscosity of the lacquers or enamels in order to maintain uniformity.

Characteristics of the seven methods of application are summarized in Table I.

Table I. Characteristics of Methods of Application for Lacquers or Enamels

Method	Optimum Appearance of Finish	Optimum Durability of Finish	Material Consumption	Relative Labor Cost
Hand brushing	Fair	Fair	Low	High
Hand spraying	Excellent	Excellent	High	High
Automatic machine spraying	Excellent	Excellent	Very high[a]	Very low
Machine dipping	Excellent	Excellent	Low	Low
Basket bulk dipping..	Fair	Fair	Low	Very low
Centrifuging	Good	Good	Low	Very low
Barrel tumbling.....	Good	Excellent	Low	Low

(a) May be reduced by the use of electrostatic equipment.
NOTE. Containers may be made of 18% nickel silver, chromium-plated or silver-plated brass or ceramic.

Enamels. Enamels are essentially clear lacquers, air-drying or baking, in which pigments and plasticizers have been incorporated. They may have a high luster or a dull finish. Because of differences in characteristics of the available pigments, coverage, tendency to "bleed", and light fastness will vary for different colors.

With the use of stencils to blank off areas, enamels of air-drying or baking types are often employed to decorate a brass article with attractive designs. The air-drying types are always soluble in the solvents in which they were originally mixed; after baking, the baking types are not soluble in their original solvents, since baking polymerizes the coating to an insoluble condition. Ingenious mechanical devices have been constructed to apply enamels in patterns, by roller coating, screen stenciling and printing.

Some products are made with depressed designs in the metal, so that after clear lacquering or enameling, these designs can be filled in with colors. The process involves hand painting the parts with a quick-drying oil paint, drying them, and wiping off excess paint with a rag.

For most articles, more than one type of lacquer or enamel will be satisfactory. If ovens that circulate hot air with automatically controlled temperatures or infrared heat, are not available for baking the finish, an air-dry lacquer or enamel should be used. If equipment for baking is available, a baked finish can be the least expensive, because of reduction in the number of coats necessary to obtain the same thickness of film. Baking enamels may be sprayed with a total content of solids of 50%; 25% is high for this content in an air-drying nitrocellulose lacquer enamel.

In the coating of copper alloys, it is not necessary for the first coat of enamel to contain a passivating pigment, as is often desired with steel, in order to prevent rusting. Sometimes it is desirable to use for the first coat an enamel and lacquer with especially good adhering qualities, and in special instances it is desirable to roughen the surface by sandblasting or by dipping in acid to attain superior adhesion.

Tables II and III list factors relating to the lacquer finishes that are used most extensively at present.

All solvents used in lacquers and enamels, are toxic to some extent if breathed in regularly. Therefore, positive ventilation by suction should be provided to protect the operator. All solvents have two fundamental properties that should govern any design for ventilation: (*a*) When *cold*, every solvent is heavier than air and naturally flows downward. (*b*) When solvents are *hot*, convection currents more than offset gravity, so hot solvents rise.

Table II. Air-Drying Lacquers and Enamels (Thermoplastic)

Chief Ingredients	Outstanding Good Characteristics	Important Limitations
Nitrocellulose-resin	Compatibility with resins and solvents; nearly colorless, cheap, quick drying	Temperature, 180 F
Cellulose acetate-resin	Better resistance to heat and light than nitrocellulose	Few solvents available, few resins compatible
Cellulose acetate-butyrate resin	Outdoor durability	Few resins compatible, cost high
Ethyl cellulose-resin	Good resistance to alkalies	Ready solubility in many solvents
Polyvinyl-resin	Resistance to acids and alkalies	Ready solubility in ketones and chlorinated solvents
Natural resins (as shellac)	Excellent adhesion	Easily scratched
Methacrylates	Clarity	High cost

NOTES. The nitrocellulose-resin mixtures are the most widely used. "Blushing" is a term applied to whitening caused in the lacquer film when moisture condenses in the wet coating. This is a result of the cooling effect from the rapid evaporation of the solvents in an atmosphere of high humidity. Blushing may be corrected by the addition of up to 10% of solvents that evaporate slowly. Air-conditioned rooms eliminate this atmospheric problem.

Paste wax of the rubbing type may be used to advantage over a lacquer or enamel. Wax will ordinarily increase substantially the durability of a finish to be used outdoors. It can also be employed to advantage on indoor applications, such as railings that are subjected to considerable perspiration from continual handling. In such instances, regular waxing with a moist rag will remove most of the deleterious perspiration, while maintaining a wax coat that protects the lacquer.

Cleaning and Electroplating

The process of cleaning fabricated parts made of copper and copper alloys, in preparation for electroplating and lacquering, is comparatively simple, presenting fewer difficulties than are found with various other metals and alloys. Adequate cleaning is very important because it is essential that oil, grease, dirt, and buffing composition be entirely removed; otherwise, results of the subsequent operations will be unsatisfactory.

Metals such as gold, silver, nickel and chromium are electrodeposited on copper and copper alloys, primarily for decorative purposes and for preventing tarnish. A light deposit will give satisfactory protection, whereas a much heavier coating is needed on some other metals.

Coloring and Chemical Dipping

Immersion Plating of Copper and Copper Alloys. All articles must be thoroughly cleaned and bright dipped before being treated in the following solutions in order to obtain the desired coatings. A short immersion is all that is required in either the gold or the silver solution. After removal from any of the following baths, articles should be rinsed in cold water, then in hot water, and dried.

Silver

Silver nitrate ..... 1.25 oz per gal
Sodium cyanide ..... 2 oz per gal

Use a stoneware or agateware receptacle. Temperature should be approximately 110 F.

Gold

Sodium gold cyanide ..... 0.5 oz per gal
Sodium cyanide ..... 2.5 oz per gal
Sodium carbonate ..... 2 oz per gal

Use a stoneware or agateware receptacle. Temperature should be approximately 180 F.

Tin

Stannous chloride ..... 4 oz per gal
Caustic soda ..... 8 oz per gal

Use a steel tank and operate the bath at approximately 195 F. The fabricated articles must be spread out on steel mesh and covered with strips or sheets of perforated tin for about 2 hr.

Table III. Baking Lacquers and Enamels (Thermosetting)

Chief Ingredients	Outstanding Good Characteristics	Important Limitations
Urea-formaldehyde	Hard, colorless; resistant to chemicals	Temperature, 300 F
Melamine	Colorless, resistant to alkalies and high temp	High cost
Alkyds (glycerol-phthallic acid)	Outdoor durability, excellent adhesion	Slightly yellow; not so hard as urea-formaldehyde
Phenol-formaldehyde	Resistant to chemicals	Darkens in light
Polyvinyl-resin	Highly resistant to acids and alkalies	High cost

NOTES. The urea-formaldehyde, alkyds and phenol-formaldehyde mixtures are the most extensively used. The different kinds are often combined in order to obtain the required characteristics in the finished product. The baking schedules are for 5 to 60 min at temperatures from 250 to 350 F.

Coloring of Copper or Copper Alloys Containing 85% Cu or More. Yellow brass articles are often copper-plated and treated as copper in the following solutions:

Reddish Bronze to Dark Brown (Statuary Bronze). Either of the following solutions may be used:

Solution A

"Liquid sulfur" ..... 1 oz
or
Potassium sulfuret (liver of sulfur) ..... 2 oz
Aqua ammonia (sp gr 0.89) ..... ¼ oz
Water ..... 1 gal

Use solution at room temperature.

Solution B

Potassium sulfuret (liver of sulfur) ..... 2 oz
Caustic soda ..... 3 oz
Water ..... 1 gal

Use solution at approximately 170 F.

The depth of the shade can be controlled by the strength of the solution and the duration of immersion. After the articles have been removed from the bath they should be rinsed thoroughly in cold water, then in hot water, and dried either in hot sawdust or with an air blast. The desired finish is obtained by dry scratch-brushing on a fine wire wheel, and then finally by lacquering.

Steel Black.

Arsenious oxide (white arsenic) ..... 4 oz
Hydrochloric acid (sp gr 1.16) ..... 8 fluid oz
Water ..... 1 gal

Use solution at approximately 180 F. Immerse the articles in the above solution until a uniform color is obtained. Scratch-brush while wet, then dry and lacquer.

Black. Several proprietary processes are available for producing a satisfactory black finish on copper and copper alloys.

Coloring of Brass. All articles should be cleaned thoroughly and bright dipped before they are placed in the following solutions.

Black. Place a suitable quantity of brass articles in an oblique tumbling barrel made of stainless steel, and cover them with warm water; usually 3 to 5 gal is sufficient. Dissolve 3 oz of copper sulfate and 6 oz of sodium thiosulfate in warm water in a separate container, and add to the contents of the barrel. Tumble the articles for 15 to 30 min to obtain the desired black finish. Drain the solution from the barrel and wash the articles thoroughly with clean water. Remove articles from the barrel, dry them in sawdust or with an air blast, and lacquer them if desired.

Blue Black.

Copper carbonate ..... 1 lb
Ammonium hydroxide (sp gr 0.89) ..... 1 qt
Water ..... 3 qt

Mix the copper carbonate thoroughly with the ammonium hydroxide, and then add the water. This solution should be used at approximately 175 F. It is desirable to have an excess of copper carbonate present. Immerse the work pieces until the proper color is obtained, which should be in about one minute. Remove the pieces, rinse them in warm water, and immerse in a hot cleaning solution made by adding 2 to 4 oz of alkaline cleaner per gal of water. Rinse the articles thoroughly, first in cold water, then in hot water, dry, and lacquer.

Black Anodizing *

Caustic soda ..... 16 oz
Water ..... 1 gal

Use the solution in ■ steel tank, and operate at 180 to 210 F with adequate ventilation. Cathodes may be steel, carbon or graphite, and the brass articles serve as anodes. Anode to cathode ratio, approximately 1:1. Current density, ■ to 10 amp per sq ft at 6 v. Plating cycle, 45 to 225 sec. After the articles have been anodized, wash them in hot and cold water, and then rinse them in clean hot water. Dry, buff lightly with a soft cloth wheel, and lacquer if desired.

*McLean and Young, Metal Finishing, June 1945

Brown

Solution A

Copper sulfate	4 oz
Potassium chlorate	8 oz
Water	1 gal

Solution B

"Liquid sulfur"	1 oz

or

Liver of sulfur	2 oz
Water	1 gal

First immerse the articles in Solution *A* for approximately one minute. Then without rinsing, immerse in Solution *B* for a short time. The articles should then be rinsed in cold water, and the dipping operation should be repeated in both solutions until the desired color is obtained. Finally, rinse the work in hot water, dry in hot sawdust or with an air blast, scratch-brush with a fine wire wheel, and lacquer.

Old English Finish (Light Brown)

Solution A

"Liquid sulfur"	½ oz

or

Liver of sulfur	1 oz
Water	1 gal

Solution B

Copper sulfate	2 oz
Water	1 gal

Immerse the articles in Solution *A* and, without rinsing them, immerse in Solution *B*. Then rinse them in cold water, and repeat the dipping operations until a light color is produced. For a uniform finish, scratch-brush and then repeat the dipping operations, first in Solution *A* and then Solution *B*, until the desired color is obtained. Finally, rinse the pieces thoroughly in cold and hot water, dry them in sawdust, scratch-brush on a fine wire wheel, and lacquer. A great variety of colors can be imparted to the surface of copper and copper alloys by the electrocoloring method.

The Resistance of Copper and Wrought Copper Alloys to Corrosion

BY THE SUBCOMMITTEE ON CORROSION OF COPPER*

SINCE ancient times, many of the applications of copper and of copper alloys have been based on high resistance to corrosion. Copper is highly resistant to the atmosphere, to naturally occurring waters, both fresh and salt, and to alkaline solutions, except those that are distinctly ammoniacal. The behavior of copper in contact with acids depends largely on oxidizing conditions, which affect it adversely. Copper has good resistance to many saline solutions but offers low resistance to sulfur and sulfur compounds, which produce a corrosion product of copper sulfide. When such solutions as sea water and brine move at high velocities against copper, they can damage it seriously.

The commercial copper alloys cover a wide range of composition and accordingly display considerable variation in resistance to corrosion. Many of these alloys overcome deficiencies of the parent metal and may offer further improvements in physical or mechanical properties. Other alloys may have certain superior characteristics at the expense of some resistance to more aggressive exposures.

Through the years, experience has suggested many uses for which the copper alloys are suitable and superior to other obtainable materials. These uses include:

1 Roofing, insect screen cloth, window frames, hardware, and other products that must withstand atmospheric exposure.
2 Fresh-water supply lines requiring superior resistance to corrosion by various types of water and sometimes to corrosion by soil.
3 Equipment used in contact with sea water—usually water supply lines and heat exchangers, including condensers; also shafting and marine hardware.
4 Heat exchangers and condensers in general, subject to certain limitations at higher temperatures.
5 Equipment for industrial and chemical plants, involving exposure to a wide variety of materials, including acid, alkaline or saline solutions.

* The members of this subcommittee are H. L. Burghoff, *Chairman* (Chase Brass & Copper Co.), F. M. Barry (Scovill Manufacturing Company), C. L. Bulow (Bridgeport Brass Company), Wilson Lynes (Revere Copper and Brass Inc.) and A. W. Tracy (The American Brass Company).

The comprehensive tests conducted under the supervision of the American Society for Testing Materials[1,2] have confirmed the general excellence of copper and copper alloys for atmospheric exposures. Other prolonged tests[3] have indicated that there is little or no difference among the several available brands of copper with regard to behavior in the atmosphere. Copper and many copper alloys are well suited to resist all but the most corrosive soils, a fact that has been demonstrated by experience and by the extensive tests conducted by the National Bureau of Standards.[4,5]

Types and Causes of Corrosion. *General or Uniform Thinning.* Under many conditions of service, exposed surfaces of copper and copper alloys corrode uniformly. In indoor exposures or in contact with outdoor rural, industrial and marine atmospheres, the rate of attack is extremely slow. Duration of service is often measured in hundreds of years. The surface of the metal may be only slightly tarnished in very mildly corrosive environments, or may gradually acquire a thin adherent brown or black coating of corrosion product or, in many instances, a green patina.

Corrosion of copper and many alloys of copper is usually general or uniform when it results from long contact with fresh, brackish or salt waters, many types of soil, neutral, alkaline or acid salts, organic acids, sugar juices or other chemicals. The rate of corrosion will vary in such services, depending not only on the corroding mediums but also on the degree of aeration, the presence of oxidizing materials, temperature, velocity of the mediums flowing over the surfaces, and other factors. It is not unusual to measure the duration of service in such applications in periods of 20 to 30 years or longer.

Copper alloys corrode uniformly but more rapidly in contact with mediums that do not permit the formation of protective films or that continually dissolve any films

that do form over the metal surfaces. Thus, oxidizing salts and acids, or salts and acids in the presence of oxygen or an oxidizing agent generally attack the metal in such a way that uniform thinning of the metal results. Both aqueous ammonia and solutions of cyanides cause uniform thinning also. Copper alloys may be entirely unsuitable for use under certain conditions where the above corrodents are present; but, in other applications, copper or alloys of copper have been employed to a considerable extent when the uniform thinning of the material is sufficiently retarded to assure a reasonably long period of usefulness. The use of the copper alloys under such conditions requires a complete study of all factors affecting each individual application, supplemented in many instances by field and laboratory tests.

Pitting. The copper alloys, in common with all commercial metals and alloys, undergo corrosion of the pitting type when exposed to some conditions of service. Sometimes pitting may be general over the entire exposed area; then the metal has an irregular and roughened appearance. In other instances, the metal may be pitted in relatively few areas. Pitting is usually associated with one of the following basic causes: (1) an incomplete protective film or corrosion product or a nonprotective deposit of scale, corrosion product or both over the metal surface; or (2) extraneous deposits that lodge against metal surfaces for considerable periods of time.

In technical publications, the pitting of copper and copper alloys has been described by various terms, such as "deposit attack", "erosion-corrosion", "impingement attack", and "concentration-cell action". The pitting action may be considered electrochemical in character, resulting from the formation of local cells at the metal surface. The term "deposit attack" is usually limited to a pitting action that occurs, under certain service conditions, in the immediate vicinity of foreign deposits, such as sand, stone, wood or clinkers, on the metal surface. Erosion-corrosion action or impingement attack is generally experienced where gases, vapors or liquids impinge on the metal surfaces at relatively high velocities. The erosive action removes protective films from localized areas at the metal surface, thereby contributing to the formation of differential cells at such areas and to localized pitting of the anodic points of the cells. These specialized examples of pitting, as well as other types of pitting initiated by scales or corrosion products of a porous, friable, unprotective type, may all be classified as forms of concentration-cell or solution-cell action.

The pitting of copper and the copper alloys is not sufficiently serious to interfere with the economical use of these materials in most applications. Probably pitting occurs most frequently when the metal is in contact with mediums that contain lower compounds of sulfur, or in contact with polluted or contaminated waters that are salty and brackish. It is often possible to prevent or minimize severe corrosion of the pitting type by proper choice of alloy, by changes in design, by filtering or screening mediums that contact the metal, by frequent cleaning of metal surfaces or by other methods indicated after an inspection.

Dezincification. Certain copper-zinc alloys and, less frequently, aluminum bronze and cupro-nickel, undergo corrosion of a type that, in the copper-zinc alloy, is termed "dezincification". The initial corrosion in this type of attack is followed by a secondary reaction in which copper, in the corrosion product, is redeposited in a porous, friable and weak mass on the metal surface. Corrosion of a similar nature continues beneath the primary deposit of copper, resulting in the gradual replacement of sound metal by brittle, porous copper. Action of this kind, unless arrested, eventually penetrates the cross section of the metal, weakening it structurally and resulting in leakage through the porous copper layer in conduits for conducting liquids. Dezincification that occurs at localized areas on the metal surface is termed "plug-type dezincification". The dezincification of brasses usually occurs in contact with sea water or with fresh waters that have a high content of oxygen and carbon dioxide. Dezincification is particularly active at elevated temperatures.

At present the dezincification of brasses is not a serious corrosion problem, since copper, red brass or several yellow brasses, containing inhibitors of dezincification, can be used in applications where dezincification has been experienced or is anticipated.

*Stress-Corrosion Cracking (Season Cracking).** Under certain specific corrosive conditions, brasses and some other copper alloys that are stressed as a result of cold working or that are stressed by loads externally applied in service, sometimes fail as a result of stress-corrosion cracking or season cracking. In addition to the primary factors of stress and corrosion that influence failures of this type, time and temperature of exposure are also important controlling factors. Ammonia or some ammonium compounds are the special corrosive agents that contribute to such failures. There is evidence that oxygen, carbon dioxide and moisture also influence the action. Contact with mercury and mercury compounds will induce cracking of susceptible materials. The stresses responsible for cracking are high constant tensile stresses acting at the surface of the metal. Failures from stress-corrosion cracking are primarily intercrystalline; however, cracks may pass through grains if no grain boundaries are suitably oriented.

The stress-corrosion cracking of brasses may be overcome by various means, the most important of which may be listed as follows: (1) selection of alloys known to have high resistance to failures of this type; (2) thermal stress-relieving where stresses are residual or have resulted from cold working operations; (3) the use of protective coatings over the metal surfaces, such as electroplates, lacquering or painting; (4) improvement of the environment.

Corrosion-Fatigue Cracking. The combined action of corrosion, usually of the pitting type, and cycle stressing of copper and copper alloys may result in corrosion-fatigue cracking of the material. Cracking of this type is predominantly transcrystalline and is characterized by the localized nature and abruptness of the failure, with very little distortion of the part as a whole. Cracks generally take a direction at right angles to the maximum tensile stress in the affected region. The combination of alternating stress and corrosion, acting simultaneously, is considerably more damaging than either one acting alone. Besides resisting corrosion effectively, copper and the copper alloys also offer very good resistance to failures of the corrosion-fatigue type in the many applications of copper materials that involve repeated stressing and corrosion. These applications include such parts as springs, switches, diaphragms, bellows of the sylphon type, piping and tubing in gasoline and oil lines of aircraft and automobiles, tubing for condensers and heat exchangers, and Fourdrinier wire in the paper industry. Obviously those alloys of copper that have a high endurance limit and that offer high resistance to corrosion under any specific condition, will be most serviceable in applications involving repeated stress and corrosion. Some of the alloys frequently used for service of this kind include beryllium copper, phosphor bronze, aluminum bronze and cupro-nickel.

Intercrystalline Corrosion. Another manifestation of intercrystalline attack, perhaps allied with stress-corrosion cracking, is best referred to simply as "intercrystalline corrosion or solution". In this type of attack, the metal is penetrated along grain boundaries and mechanical stress is apparently not a factor. The attack may be noted under the microscope to a depth of several grains, distinguishing it from ordinary surface roughening where intercrystalline penetration, one or two grains in depth, is sometimes noted. Apparently only a very few alloy compositions are susceptible to this more serious general intercrystalline corrosion, observed rather infrequently.

Galvanic Corrosion. Copper rarely suffers galvanic corrosion as a result of contact with other metals. The reason for this is apparent from examination of the electromotive series of elements, listed in Table I. Copper is cathodic to the commonly encountered metals—iron, zinc, aluminum, magnesium, lead and tin. Of course there are many conditions in which galvanic corrosion does not proceed in accordance with the common electromotive series. The potential differences between dissimilar metals vary, depending on the nature of the corrosive environment.

*** For a more detailed discussion of the stress corrosion of copper alloys, the reader may refer to the article on page 231 of this Handbook.**

Table II lists the potentials that have been observed between couples of copper and several copper alloys when immersed as freshly abraded specimens in a dilute synthetic solution of sea water. Potential differences observed for couples of copper-base materials with other common metals, under similar conditions, are qualitatively similar to the arrangement of the electromotive series of Table I, in that aluminum, iron, lead, nickel, tin and zinc are anodic to the copper-base materials. Laboratory corrosion tests of couples in this same type of solution have shown

Table I. Electromotive Series of the Common Metals[a]

Metal	Ion	Normal Electrode Potential, volts[b]
Gold	Au^{+++}	+1.36
Platinum	Pt^{+++}	+0.86
Mercury	Hg^{++}	+0.799
Silver	Ag^{+}	+0.798
Copper	Cu^{++}	+0.344
Hydrogen (atm)	H^{+}	0.000
Lead	Pb^{++}	−0.12
Tin	Sn^{++}	−0.14
Nickel	Ni^{++}	−0.23
Cadmium	Cd^{++}	−0.40
Iron	Fe^{++}	−0.44
Chromium	Cr^{++}	−0.56
Zinc	Zn^{++}	−0.762
Aluminum	Al^{+++}	−1.33
Magnesium	Mg^{++}	−1.55

(b) Potential in salt solution of normal ionic activity relative to the normal hydrogen electrode as an arbitrarily chosen zero point

that the use of steel, wrought iron, aluminum, zinc and lead, in combination with copper alloys in water solutions, is likely to result in severe corrosion of the noncopper alloy. Similar tests have indicated that, despite any contrary expectation based on the measurements of potential, nickel, monel metal, tin and stainless steel may usually be coupled with copper alloys with satisfactory results.

Table II. Potential Differences (in volts) Between Various Copper Alloys in Dilute Synthetic Sea Water[a] [b]

	Red Brass	70–30 Brass	Muntz Metal	Aluminum Bronze	30% Cupro-Nickel	Aluminum Brass

(b) Solution one-sixth the usual strength of sea water

With regard to couples of two different copper-zinc alloys, it will be noted that the more anodic materials are the ones of higher zinc content, although even in such combinations the differences in potential are not great. These data accord with experience that galvanic corrosion of copper alloy couples is uncommon. Laboratory corrosion tests in the same series mentioned above indicated that there was virtually no acceleration of corrosion as a result of contact between any two copper alloys. Occasional examples have been observed of the failure by dezincification of Muntz metal nipples used in red brass (85% Cu, 15% Zn) plumbing lines. Failure in such instances may have been hastened by galvanic action, but this is not certain, because it is known that Muntz metal is far inferior to red brass in resistance to naturally occurring waters and that it dezincifies quite readily even when not in contact with other metals.

LaQue and Cox,[7] who determined the potentials of a number of copper alloys and other alloys in sea water, noted only slight differences among the copper alloys.

Effect of Alloy Composition. *The Brasses.* The copper-zinc alloys or brasses range from 55 to 100% Cu, with the remainder essentially zinc. The alloys that contain 55 to 80% Cu are susceptible to dezincification in many natural fresh waters, sea water and numerous aqueous solutions. An increase in copper content to approximately 85% or more renders the alloys virtually immune to dezincification in these mediums. The 85% Cu—15% Zn alloy, red brass, is considered to have the best general resistance to corrosion among the brasses.

In other mediums, the resistance to corrosion of the copper-zinc alloys may improve with a decrease in copper content. In sulfide-bearing solutions and vapors, the 60% Cu—40% Zn alloy, Muntz metal, may corrode at a rate 1/100 as rapid as that of copper or red brass.

Brasses containing more than 80% Cu are highly resistant to stress-corrosion cracking, but those containing 80% Cu or less are highly susceptible to this type of cracking.

Some elements such as lead, tellurium, selenium, beryllium and manganese, as found in certain common commercial coppers and copper alloys, have no significant effect on resistance to corrosion.

Tin-Bearing Brasses. The addition of ¾% Sn to Muntz metal results in the familiar naval brass, 60% Cu, 39¼% Zn, ¾% Sn. In this alloy tin serves chiefly as an inhibitor that lessens the possibility of dezincification under service conditions. Naval brass, however, does not resist dezincification very effectively. The addition of 1% Sn to the 70% Cu—30% Zn alloy to produce admiralty metal (71% Cu, 28% Zn, 1% Sn) lessens the possibilities of rapid dezincification. The further addition of a dezincification inhibitor, such as arsenic, antimony or phosphorus, reduces still further the possibility of this type of attack.

Aluminum Brass. The addition of aluminum to the copper-zinc alloys leads to a marked increase in resistance to impingement corrosion; that is, the resulting alloy exhibits greatly improved resistance to rapidly flowing, turbulent sea water. For example, 2 to 2.25% Al is added to the 60% Cu—40% Zn alloy in the production of propeller bronze, and to the 75% Cu—25% Zn alloy in the production of aluminum brass tubing for condensers. The aluminum brass, however, is still susceptible to dezincification. This weakness is reduced by the use of an inhibitor of dezincification, such as arsenic, antimony or phosphorus.

Arsenic, Antimony and Phosphorus in Brasses. The addition of such elements as arsenic, antimony and phosphorus has been found to prevent or to minimize dezincification in admiralty metal and aluminum brass under a number of conditions. Concentrations of 0.02 to 0.05% As, Sb or P have been found effective in these alloys. These inhibiting elements are used also in certain other brasses containing less than about 85% Cu; the actual amounts vary with the alloy.

Copper-Tin Alloys. The addition of tin to copper to produce the phosphor bronzes, which may also contain as much as 0.35% P, improves resistance to corrosion from contact with flowing sea water and most acids, except hydrochloric acid. In general, very uniform corrosion takes place in the wrought bronzes that contain from 5 to 10% Sn. This group of alloys is much less susceptible than brass to stress-corrosion cracking.

Copper-Nickel Alloys. The most common copper-nickel alloys are 70% Cu—30% Ni and 80% Cu—20% Ni. The 70% Cu—30% Ni alloy is widely used in the form of condenser tubing for the construction of marine condensers, because of its high resistance to attack by rapidly flowing sea water. The addition of approximately ½% Fe definitely improves the resistance of the 70% Cu—30% Ni alloy to impingement corrosion caused by sea water.

The 70% Cu—30% Ni alloy also resists effectively corrosion caused by alkalies and for this reason is widely used for storing and conveying alkaline solutions in chemical plants. This alloy is generally regarded as the best of the copper alloys now available for such applications.

The resistance of 70% Cu—30% Ni to corrosion by sulfide-bearing solutions and vapors appears approximately equal to that of red brass and, therefore, this alloy is less satisfactory than admiralty metal or Muntz metal. The 70% Cu—30% Ni alloy is apparently immune to the stress-corrosion type of failure.

Copper-Nickel-Zinc Alloys. The two most common nickel silvers contain 65 and 55% Cu, 18% Ni and the remainder zinc. The nickel silvers have good resistance to corrosion by fresh and salt waters. In saline solutions the resist-

Table III. Corrosion Ratings for Copper and Wrought Copper Alloys in Various Corrosive Mediums

This table is intended to serve only as a general guide concerning the behavior of copper and copper alloys in corrosive environments. It is impossible to cover in a simple tabulation the performance of a material for all possible variations of temperature, concentration, velocity, impurities, degree of aeration, and stress. It should be emphasized strongly that the table should be used with caution. The ratings shown in the tabulation are based on general performance.

The letters **a**, **b** and **c** have the following significance:

a The metal should be suitable under most conditions of use.

b Corrosion may be expected but the metal should be suitable under some conditions.

c Corrosion rates will usually be too high for successful use.

* The column includes cartridge brass, yellow brass, Muntz metal, forging brass and architectural bronze.

(1) Containers having more than 65% Cu should not be used for acetylene because of the danger of the formation of explosive acetylides.

(2) When copper or copper alloys are used in contact with foodstuffs or beverages, the metal should be tin-coated or otherwise protected to prevent the pickup of copper ions, which may affect the color or the taste of the food products.

ance to corrosion is usually appreciably higher than that of brasses of the same copper content, because the large amount of nickel inhibits dezincification.

The 80% Cu—20% Ni alloy is sometimes modified by the addition of 5% Zn. The resulting alloy has approximately the same corrosion resistance as the original alloy.

Copper-Silicon Alloys. In general, the resistance to corrosion of the commercial copper-silicon alloys is similar to that of copper. When copper-silicon is chosen by the product designer in preference to copper, selection is usually based on the relatively high mechanical properties of the silicon bronze alloys, in conjunction with their ready weldability. Examples of usage include tanks, bolts, screws, connectors, fastenings, gears, shafts and pinions.

When the alloys containing 3% Si or more are used in contact with steam under pressure, the possibility of intergranular corrosion should be recognized.

Copper-Aluminum Alloys. As with the copper-silicon alloys, selection of the copper-aluminum alloys, rather than copper, is frequently based on properties other than resistance to corrosion, such as superior resistance to wear and oxidation, and superior mechanical properties at room and elevated temperatures. However, aluminum bronze resists corrosion more effectively than copper under a number of environmental conditions. Aluminum bronze condenser tubes, containing 5% Al, have been used successfully with contaminated brackish cooling water. The aluminum bronzes are more resistant than copper to corrosion by sea water moving at high velocity.

Aluminum bronze is used for beater bars and blades of wood-pulping machines because of the ability of the alloy to withstand mechanical abrasion as well as chemical attack by sulfite solutions and other bleaching compounds; it is used also in sewage equipment.

Amounts of aluminum larger than about 5% sometimes induce selective corrosion, in which aluminum is removed by an action similar to the dezincification of brasses.

Nickel, manganese and iron are sometimes added to aluminum bronze. In the small amounts usually added, these elements have no significant effect on resistance to corrosion, although nickel is sometimes credited with increasing this resistance. Similarly, the addition of 2% Si to aluminum bronze has no significant effect on resistance to corrosion.

Protective Coatings. The relatively high resistance to corrosion of copper and copper alloys in many kinds of environment, is a result of the protective coatings developed by converting the surface metal into one or more compounds.

For various uses, this resistance may be increased by the preapplication of protective coatings. For convenience, these coatings may be divided into two groups, metallic and organic. Provided the coating material is able to resist corrosion adequately, success in service may depend on impermeability, continuity, and adhesion to the base metal. In metallic coatings, the electropotential relationship of the metal to the base may be important.

Tin, lead, and solder, used extensively as coatings, are ordinarily applied by hot dipping. Tin-coated copper is used for dairy and refrigeration equipment, as well as for containers and conveyers of foods and beverages. Tin-coated copper tubing is useful for handling natural fresh waters that are very soft or that contain large percentages of dissolved carbon dioxide and oxygen. As a coating on copper conductor wire and cable, tin arrests corrosion caused by sulfur in rubber insulation. Lead-coated copper is used chiefly for roofing, for other construction materials, and for applications requiring contact with flue gases or other products that contain dilute sulfuric acid. Tin or lead coatings are sometimes applied to copper that is intended for atmospheric exposure; however, these coatings serve primarily for architectural effects, since the atmospheric resistance of bare copper is excellent. Likewise, chromium plate is used not for protection from corrosion but for decoration, improvement of wear resistance, or reflectivity. Electroplated nickel is used commonly as protective underplating for chromium. Processes have been developed for coating copper with tin or black cupric oxide by immersion.

Clear lacquer is used to delay tarnish of copper and brass during indoor exposure. For more corrosive conditions, many new synthetic resins have been developed, such as phenolic, vinyl and acrylic. Thermosetting types of coatings have certain advantages over the thermoplastic or air-drying types; for instance, greater stability and a higher limit for temperatures that can be withstood in service.

Selection of Materials. Operating experience, in the form of careful records properly interpreted, is the most reliable guide (although costly and imperfect) in the selection of a suitable alloy. Instead of service data, or in conjunction with them, various considerations or tests aid in the choice of material.

Resistance to corrosion alone is an inadequate criterion for selection. The original cost of material, the costs of installation, maintenance, shutdowns and obsolescence should be considered. On occasion, some resistance to corrosion will have to be sacrificed in order to fulfill minimum requirements for such properties as formability, weldability, yield strength, and electrical conductivity.

Sometimes the economical solution of a corrosion problem will consist in appropriate changes in the design of the product or in treatment of the environment, rather than in a change of alloy.

Laboratory corrosion tests can furnish valuable information concerning the length of service to be expected, but only if the operating conditions can be defined precisely and simulated faithfully in all important respects in the laboratory. In the past, many laboratory tests have been inadequate because investigators have failed to realize the importance of taking into account operating factors such as stress, velocity, effects of galvanic couples and concentration cells, effect of surface condition, size of metal specimen and contamination of the solution. When test conditions are intensified to accelerate the test, there is considerable danger of distorting the results.

Erroneous conclusions based on laboratory tests may be reached not only by making the test improperly but by measuring inaccurately the damage from corrosion. If damage is in the form of pitting, intergranular corrosion, or deposition of metal (for example, dezincification), a measurement of corrosion rate based on loss or gain in weight may be misleading. Other methods of measurement should be used, such as loss of tensile strength, microscopic examination, or measurement of pit depth.

Much valuable information has been obtained from field tests wherein many different metals, alloys and coatings are tested for long periods of time in different types of atmospheres and natural waters. The corrosion testing station at Kure Beach, N. C., is a well-known example. Another type of testing requires the insertion of a group of test specimens of varying alloys, often in the form of tensile specimens, into operating equipment—for example, into the shell of a heat exchanger where major corrosion damage is on the shell side. In some instances, a test specimen is inserted as an integral part of the equipment.

The corrosion ratings of copper and copper alloys as shown in Table III may be helpful in the selection of materials.

The Metallography of Copper and Copper Alloys

BY THE SUBCOMMITTEE ON METALLOGRAPHY OF COPPER ALLOYS*

THE SELECTION and preparation of a metallographic specimen is fundamental, because improper choice of section, mounting technique or polishing technique can not only destroy a valuable sample, but can result in misleading interpretations of the structure. The paragraphs below include basic principles together with certain precautions.

Mechanical Preparation. *Sectioning.* The following rules are suggested.

1 Castings are sectioned, depending on size and design, adjacent to risers and through extremely heavy or thin sections, to reveal shrinkage voids, porosity and cold shuts.

2 Forgings are sectioned to include all changes in direction of flow. The edges should be kept sharp to reveal cold shuts and other surface defects.

3 Manufactured articles fabricated from wrought mill products should be sectioned longitudinally to reveal, if possible, the original grain size in unworked sections and the degree of deformation in worked sections.

4 Fabricated articles that have failed in service should be sectioned both in the region of failure and adjacent to it, to reveal the maximum information.

5 The determinations of grain size and structure for wrought and annealed wire, rod, tube and other drawn products, should be made on a complete longitudinal section or from the center to the surface.

6 For determinations of average grain size on flat products thicker than about 0.1-in. gage, a longitudinal section is recommended. On lighter gages, an area below and parallel to the surface is acceptable if desired for purposes of convenience.

7 Distribution of defects, such as shrinkage, seams, porosity, pipe, cracks and laminations in wrought products, is revealed best by a transverse section.

8 Thickness of plating on electroplated objects should be determined from the average of at least three transverse sections, after deposition of a protective plate of a different metal.

Normally, small, well-selected, representative longitudinal and transverse sections give the most information.

Mounting, Grinding, Polishing. For a detailed general discussion of mounting, grinding and polishing, the reader may refer to the article on "Metallographic Polishing", page 159 in this Handbook.

The following additional recommendations have been suggested for copper and copper alloys.

1 Multiple mounting of relatively light-gage stock for routine determinations of grain size, can be accomplished in several ways:

(*a*) For examination of longitudinal or transverse sections, specimens of light-gage strip can be stacked and held together with clamps, or mounted in solder or a plastic medium under pressure.
(*b*) Specimens of light-gage strip or wire can be laid on a plate at the bottom of a mold and mounted in a suitable medium. Molten sulfur or plastics molded under pressure are recommended.
(*c*) For heavier gage stock up to about ⅜ in., solder is recommended for method (*b*).

For method (*a*), strip and wire specimens can be held together in a vise. The projecting ends are then bent over and soldered.

2 To avoid tearing the polishing cloths, the edges of the mount or of the unmounted specimen should be beveled.

3 For preservation of edge sharpness, when cloth wheels are used for polishing, the specimen may be nickel-plated or sandwiched between harder material in brass clamps. Hand polishing toward the edge in question, using metallographic papers 0, 00, 000, 0000 on plate glass, is also recommended for preservation of the edge in a mounted sample, and for good flatness. Each successive operation should be carried out at an angle to the preceding operation.

4 To prevent staining, caused by seepage of etchant from a crack, void, or any space subject to capillary action, the specimen can be warmed sufficiently to allow penetration by beeswax before the preliminary facing operation.

5 Grinding on a belt surfacer, using 30-grit, 50-grit and 100-grit successively, has been found to be adequate preparation for polishing. Finer grits may be used if desired.

6 The following polishing cycle has proved adequate for routine preparation of most copper alloys when rotating cloth-covered disks are used at suitable speeds. Other abrasives and cloths are commonly used in different laboratories with equal success.

(*a*) 8 to 12-oz canvas duck.....220-mesh emery
(*b*) felt .....FF Turkish emery
(*c*) wool broadcloth.....SF6X Turkish emery
(*d*) velvet, or "kitten's ear".....levigated alumina (re-levigated as desired)

Step (*d*) is sometimes omitted for rapid routine work.

7 For detailed microexamination and photomicrography, hand polishing on plate glass with metallographic papers 0, 00, 000, and 0000 successively, is recommended. Two or three polishing cycles should follow, using increasingly finer levigated alumina and low wheel speeds (200 to 500 rpm).

8 Preparation of surfaces for macroexamination depends on the size of the section. For as-cast bars, cakes, or billets, a very smooth machined surface (preferably planed by using a single-tooth cutter) is adequate for macroexamination. For sections such as small forgings, cartridge cases or castings, the surface to be etched may be machined smooth or prepared on a belt surfacer using 30-grit, 50-grit and 100-grit successively.

Chemical Etching of Copper and Copper Alloys. *Macrostructures.* Sections that have been cut from castings, cakes, bars, billets, forgings, rod, extrusions, strip or coarse wire, and prepared according to the directions of the preceding section, may be placed in a shallow container, where weight and size permit, and the etchant may be poured over and flowed back and forth by raising and lowering one side of the container. When the structure has developed sufficiently, the section is rinsed first with water, then with alcohol, and is then dried as promptly as possible. On larger units, the etchant may be applied with a large swab, followed immediately by rinsing in water—preferably hot water—and drying rapidly.

To preserve the surface temporarily for photographing, the specimen may be covered with a thin film of colorless mineral oil or glycerin, or, for permanent preservation, with clear thin lacquer.

Etchants that have been used successfully are nitric acid with and without dilution, 20% ferric chloride solution acidified with hydrochloric acid, chromic acid solution, and potassium bichromate solution acidified with sulfuric acid, as listed in Table I. Concentrated nitric acid is desirable for large units because of the speed of reaction. The etching is done customarily at room temperature.

To minimize staining caused by seepage, it may be advisable to freshen the surface with etchant, replace with acidified water or alcohol, and photograph the specimen in the tray under a thin layer of the liquid.

Microstructures. Suitable etchants for microstructures are listed in Tables I and II. The technique of good etching is an art to be learned through a great deal of experience. Metallographers have produced equally good results by techniques that differ in the application of etchants—by swabbing, immersion or agitation. It is frequently advisable to follow the progressive attack of the reagent with the microscope. Not infrequently, even the careful metallographer fails to develop the full measure of structural delineation, and therefore, it is sometimes worth while to overetch experimentally in order to determine the limit of suitable etching.

Specimens finished on 0000 emery paper can often be etched in concentrated nitric acid and chromic anhydride with entirely satisfactory results.

* The members of this subcommittee are F. H. Wilson, *Chairman* (The American Brass Company), W. D. France (Scovill Manufacturing Company), H. B. Pulsifer (Deceased) and P. A. Leichtle (Chase Brass & Copper Co.).

Electrolytic Polishing and Etching. The polishing of metallographic specimens by electrolytic methods, following the introduction and development of the idea by P. Jacquet, has provided a technique for obtaining a highly polished surface, free from mechanical distortion. According to requirements, two major techniques may be applied to copper alloys. The first, where quality of polish is paramount, has been the subject of the greater amount of published information. This technique—an excellent tool for the research metallographer—involves mechanical polishing followed by electrolytic polishing, with rather careful control of current density and voltage. The second technique, where saving time is paramount, has received comparatively little attention in technical publications. Methods of rapid electrolytic polishing have been developed for copper alloys, and polishes adequate for determinations of grain size can be developed from ground surfaces in a minute or less. In this limited space, representative techniques for each purpose are presented on the assumption that every investigator will adapt the most suitable technique to his specific purpose. Various modifications have been described in technical publications.

Table I. Etchants Used in Routine Examination of Copper and Copper Alloys

No.	Etchant			Remarks
1	NH_4OH	5 parts		Fresh solution made up just before use
	H_2O_2 (3%)	2 to 5 parts		
	with or without	5 parts H_2O		
2	NH_4OH	10 ml		KOH prevents oxide film. Fresh solution made up just before use
	H_2O_2 (3%)	4 ml		
	KOH (20%)	1 ml		
	H_2O	▮ ml		
3	Electrolytic			Can also be used following 1 or 5 for coloring copper and high-copper alloys. Circuit includes dry cell, a platinum wire cathode and the specimen as anode. The polished surface is dipped just under the surface.
	$FeSO_4$	30 g		
	NaOH	4 g		
	H_2SO_4 (conc)	100 ml		
	H_2O	1900 ml		
4	CrO_3	40 g		Also used for macrostructure. The degree of contrast can be modified by adding a few drops of HNO_3 or H_2SO_4 to the etching bath as desired.
	NH_4Cl	7.5 g		
	HNO_3 (conc)	50 ml		
	H_2SO_4 (conc)	50 ml		
	H_2O to make 1 liter	900 ml		
5	$K_2Cr_2O_7$	2 g		Also used for macrostructure.
	NaCl	1.5 g		
	H_2SO_4 (conc)	8 ml		
	H_2O	100 ml		
6	HNO_3 (conc)	75 ml		Also used for macrostructure. Fresh solution is made up just before use. Specimen should be dry.
	Glacial acetic acid	25 ml		
		(a)	*(b)*	
7	$FeCl_3$	5 g	10 g	Also used for macrostructure.
	HCl	10 ml	25 ml	
	H_2O	100 ml	100 ml	
8	HNO_3	various conc		For macrostructure. Trace of $AgNO_3$ gives brilliance.
9	$(NH_4)_2S_2O_8$ 10% solution			Follows 8, for improving contrast.

Table II. Etchants Used for Various Copper Alloys

Alloy[a]	Etchant[b]	Remarks
Copper and dilute copper alloys	4 or 5	.....
Brass, alpha, 85 to 100%	4, 5 or 1 then 7	7 follows 1 to develop contrast
Brass, alpha, 65 to 85%	1	.....
Brass, alpha-beta	1 or 1 then 7	7 follows 1 to darken beta
Phosphor (tin) bronze	4, 5 or 1	.....
Tin brass	1	.....
Silicon brass	4 or 1	.....
Silicon bronze	4 or 5	.....
Aluminum bronze, alpha	5 or 4	.....
Aluminum bronze, alpha-beta	1 or 1 then 7	7 follows 1 to darken beta
Aluminum-silicon bronze	2 or 5	.....
Manganese bronze	1 or 1 then 7	7 follows 1 to darken beta
Nickel silver	4, 5 or 6	.....
Cupro-nickel	3, 4 or 5	3 minimizes appearance of coring
Beryllium bronze	5 or 1	1 used for detecting small quantities of beta

(a) For leaded alloys, use the etchant recommended for matrix.
(b) Numbers, given in order of preference, refer to the etchants listed in Table I.
NOTE. These etchants are commonly used for ordinary examination. When other etchants are sought for special purposes, reference can be made to ASTM Tentative Method E 3-46T.

Research Method. The electrolyte consists fundamentally of phosphoric acid. Various concentrations and diluents are employed, according to the alloy to be polished. The specimen, which has been given a preliminary mechanical polish up to 0000 emery paper, serves as the anode, and a cathode of much greater area can consist of copper, lead, stainless steel or such. The freshly made solution is not agitated; the polished surface is held in a horizontal position with the cathode above and about ½ in. from the surface to be polished. A low-voltage d-c source, such as a battery, is adequate and the voltage across the cell is controlled with a rheostat. As the voltage is increased with rheostat adjustment above 1 volt, the current increases with it for a while and then decreases. With the rheostat left stationary, the surface becomes polished, while the voltage increases and the current decreases gradually. After several minutes of polishing, the specimen is transferred to a rinse quickly, and preferably without opening the circuit, if etching is to be avoided; or etching can be accomplished by shifting the rheostat for applying a lower voltage. If slight staining occurs, it can be removed by dipping the specimen in a fresh solution of 5% orthophosphoric acid.

For copper, 1.5 to 1.8 volts, giving a current density of 6 to 8 amp per sq dm, in an electrolyte of 400 to 500 ■ per liter of pyrophosphoric acid, will produce a good polish in 10 to 15 min at 15 to 25 C. Under similar conditions, copper alloys have been polished, and it is probable that modifications of conditions can be found for polishing all single-phase copper alloys. Duplex alloys are more difficult, but alpha-beta brass has been polished adequately for metallographic purposes. P. Jacquet has presented a recent review and bibliography of this field.[1]

Rapid Method. Under some circumstances the use of electrolytic polishing can be adapted so as to accelerate the preparation of metallographic specimens for the determination of grain size. H. E. Brown[2] has reported a rapid method for polishing most copper alloys by the use of an electrolyte that consists of two parts methyl alcohol to one part concentrated nitric acid. The constituents of this electrolyte react exothermally and can develop a violent reaction unless the electrolyte is kept cool. Another rapid method, suggested by DeSy and Haemers for iron and steel specimens, has been adapted to other metals including copper alloys.[3] This method uses high voltage and high current densities with an electrolyte of perchloric acid, water, alcohol and ether. The perchloric acid introduces a serious hazard, since explosive reactions can result from contact with organic substances.

A safer rapid method has been developed that employs relatively dilute phosphoric acid, high voltages and high current densities.[4] It has been found that if the specimen is agitated in the solution, a good polish can be developed by the application of about 30 volts. By this means, roughly ground specimens can be given an adequate polish in one minute. For usual anode areas, ⅛ sq in. or more, the necessary current densities demand voltages as high and resistances in the electrolyte as low as these. Thus a high-capacity source of d-c power is required.

The following specific procedure is described with the realization that numerous modifications can probably give adequate results. The output of an autotransformer attached to the 110-volt a-c line is given full-wave rectification with a copper oxide rectifier. The specimen or specimens, serving as anode, are held in an insulating holder that is rotated by a stirrer motor, giving the specimens a circular path in the electrolyte. The electrolyte, consisting of orthophosphoric acid diluted to a specific gravity of 1.04, is cooled in a bath of running water. Voltage and current are controlled entirely by the autotransformer. For polishing, the voltage is controlled and the current passing may be 10 to 20 amp; for etcning, amperage is controlled.

An initially flat surface is produced on copper and brass specimens by grinding with 180-grit on a belt sander. They are polished electrolytically in one minute, using 30 volts, after which the voltage is decreased for etching purposes. Brass specimens develop a film of copper that disappears

quickly during the etching. Cartridge brass (70% Cu) is etched with a current of 2 amp for 15 sec and copper is etched with 1 amp for 75 sec; for intermediate alloys, intermediate times and currents are used. After etching, the specimens are rinsed quickly and dipped for a few seconds in a solution of copper ammonium sulfate (30 g Cu $SO_4 \cdot 5H_2O$, 70 ml H_2O, and 21 ml conc NH_4OH, filtered); 10% ammonium persulfate, 10% ferric chloride or dilute nitric acid may also be used. These solutions improve the grain contrast. Specimens are then rinsed in water and alcohol and dried.

The chief disadvantage of this method is the necessity for the high-capacity d-c power source. More concentrated electrolytes, with lower voltages and currents, result in longer times for polishing. The method has not yet been extended to alloys other than the brasses, but it is quite probable that it can be applied more widely with proper modifications.

With adequate precautions, the nitric acid–methyl alcohol method may be preferred, since it has been used successfully with other copper alloys, including tin bronzes. Moreover, when the samples polished by this method are small enough, adequate current densities can be obtained by the comparatively simple arrangement of a grid-controlled tube rectifier in conjunction with a small transformer and with resistances.

Because electrolytic polishing affords a distinct improvement over other methods in providing surfaces totally free from scratches and distorted metal, this method has an important place in metallography. The technique is easily mastered. The chief disadvantage of electrolytic polishing is that this method may exaggerate discontinuities. It is ideal for homogeneous structures, but the differences in electrolytic potential between phases of heterogeneous structures lead to uneven or pitted surfaces, although some duplex structures have been polished satisfactorily.

Factors That Determine the Applications of Copper

By the Subcommittee on Applications of Copper*

COPPER has certain valuable properties that, individually and in combination, determine what fields of application are suitable for the metal. The properties of major significance are electrical conductivity, thermal conductivity, resistance to corrosion, malleability, formability and strength. In addition, copper has a pleasing color, is nonmagnetic and is easily finished by plating or lacquering. Copper can also be welded, brazed and soldered satisfactorily. When it is desirable to improve certain of these basic properties and when such an improvement can be effected with the sacrifice of no other properties except those of limited significance in the intended application, alloying often solves the problem, and such widely used commercial materials as the brasses, bronzes, copper-nickel alloys and nickel silvers have been developed in consequence.

Copper is a moderately expensive metal of high density and, in about 90% of its applications, serves satisfactorily where ferrous materials or the light metals could not, and where lead, zinc and tin would be unsuitable. In possibly 10% of the applications copper products are in direct price competition with other materials.

The greatest single field of use for copper results from the high electrical conductivity of the metal. The reasons for the use of copper for electrical conductors and in the manufacture of all types of electrical equipment are so commonly understood that a detailed discussion is unnecessary. However, it is of interest to note that even in the electrical industry high conductivity alone does not give copper great economic value; it is rather the combination of this property with high resistance to corrosion and ease of formability. Even with very high electrical conductivity, a refractory material, unable to be drawn or fabricated with ease, or subject to rapid corrosion when exposed to normal atmospheric conditions, would not be practical in the electrical industry.

In applications where resistance to corrosion is the primary attribute—for instance, in the use of copper for roofing, sheathing, construction of large vessels and chemical engineering equipment—it is again found that not corrosion resistance alone, but corrosion resistance in conjunction with workability and formability, renders the metal commercially valuable in widespread application.

The same considerations govern when the high thermal conductivity of the material is of prime importance. If this property were not accompanied by high resistance to corrosion, the utility of the metal as a conductor of heat would be decreased or nullified in many instances; for example, copper would be unsuitable for use in the construction of heat-exchange or heat-transfer equipment.

An automobile radiator is typical of a structure with performance depending on many attributes of copper, rather than on a single property. In such a radiator very light gages of metal are used, approximately 0.005 in. thick. Obviously resistance to corrosion must be sufficient to prevent various waters from penetrating the thin sections of metal over a period of many years of service. In addition, moderately high thermal conductivity is desirable in order to dissipate heat, since cooling is the primary function of the radiator. High ductility and formability and ease of joining the material are factors of major importance in manufacturing.

Electrical and thermal conductivities of copper *alloys* are of secondary importance, if significant at all. When alloying elements are added to copper these properties are deliberately sacrificed for the purpose of improving other characteristics that are more important in the articles for which alloys are used.

When copper is alloyed with zinc, the tensile properties are improved without much sacrifice of resistance to corrosion and tarnish. The properties are retained that lead to ease in buffing, finishing and plating, and hence qualify the base metal for a wide variety of stamped, spun, drawn and other formed parts that can be made into highly finished and plated products. By the substitution of nickel for some of the copper in various brasses, a series of alloys is obtained in which the color is changed in order to make a more suitable base for silver-plated flatware and hollow ware, without sacrifice of strength, ductility, formability or ease of finishing.

When high rates of production are desired, as for screw-machine parts, and when resistance to tarnish or corrosion is desirable in the finished part, then lead is added to brass for the purpose of improving machinability—a purpose achieved by this means with no other substantial modification of the properties of the brass.

It is unnecessary to list here the numerous applications of copper; it should suffice to reiterate that some combination of properties frequently suggests the use of copper or copper alloys in sound engineering design.

PROPERTIES OF COPPER AND COPPER ALLOYS

Pure Copper*

COMPILED BY J. S. SMART, JR.*

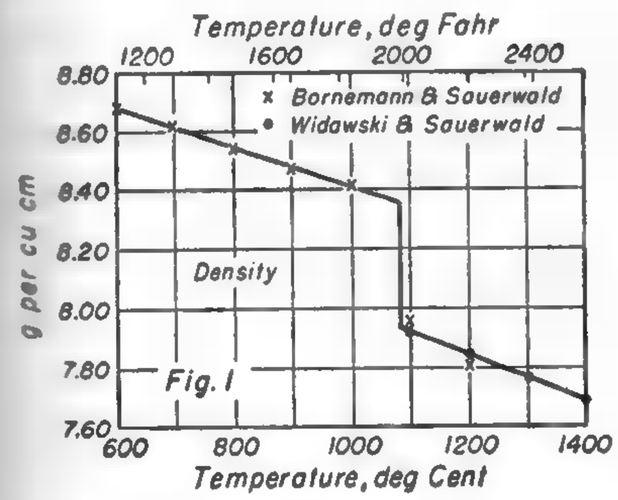
C *1 Density* at 20 C (68 F).[1] 8.96 ■ per cu cm (0.324 lb per cu in.) *Density versus temperature. See* Fig. 1.
4 Density versus percentage deformation.[1] 0.028% decrease in density for a reduction of 50% by drawing
5 Solidification shrinkage. 4.92%

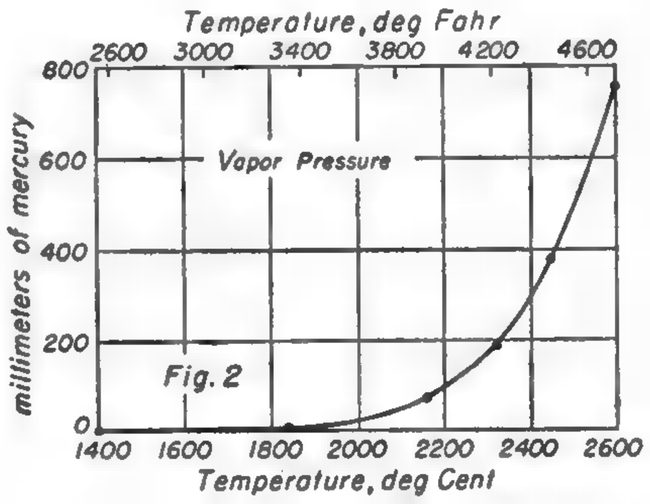
D *1 Melting point.*[5] 1083.0 ± 0.1 C (1981.4 ± 0.2 F)
4 Boiling point.[32] 2595 C (4703 F)
Vapor pressure versus temperature.[32] *See* Fig. 2.
6 Thermal expansion at 20 C.[31] 0.0000165 per °C
[0 to 300 C (32 to 572 F)][7]
$L_t = L_0 [1 + (16.23t + 0.00483t^2) \times 10^{-6}]$
[0 to 1000 C (32 to 1832 F)][8]
$L_t = L_0 [1 + (16.733t + 0.002626t^2 + 0.00000091t^3) \times 10^{-6}]$
For data on instantaneous coefficient of expansion between minus 23 C and minus 223 C, see Fig. 3.[9,10,11]
11 Specific heat at 20 C (68 F).[41] 0.092 cal per ■
12 Specific heat vs temperature.[10,12–14,16–23] *See* Fig. 4 and 5.
13 Latent heat of fusion.[42] 50.6 cal per ■
16 Thermal conductivity at 20 C (68 F).[26] 0.941 ± 0.005 cal/sq cm/cm/°C/sec
17 Thermal conductivity vs temperature. See Fig. 6.[27,35–39]
19 Recrystallization diagram.[1] *See* Fig. 7.

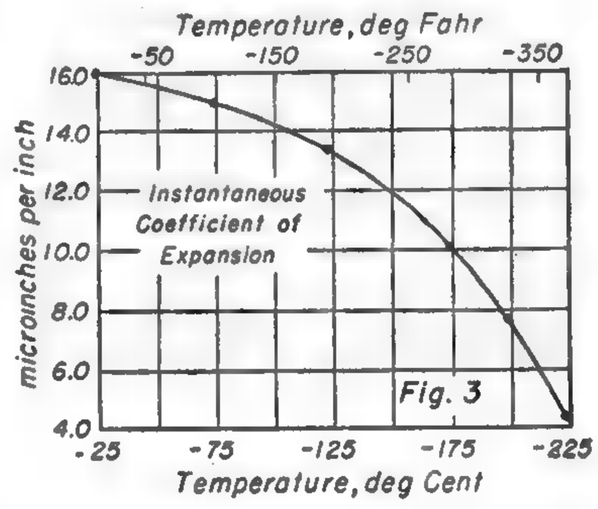
E *1 Volume conductivity* referred to std copper.[1] 103.06%
Mass conductivity referred to std copper. 102.3%
2 Electrical resistivity at 20 C (68 F).[1] 0.14983 ohms per meter-gram or 1.6730 microhm-cm
4 Electrical resistivity (liquid). See Fig. 6.[27,35–39]
5 Temperature coefficient of electrical resistivity at 20 C (68 F).[26] 0.0068 microhm-cm per °C or 0.00060 ohms per meter-gram per °C
Electrical resistivity vs temperature. See Fig. 6.[27,35–39]

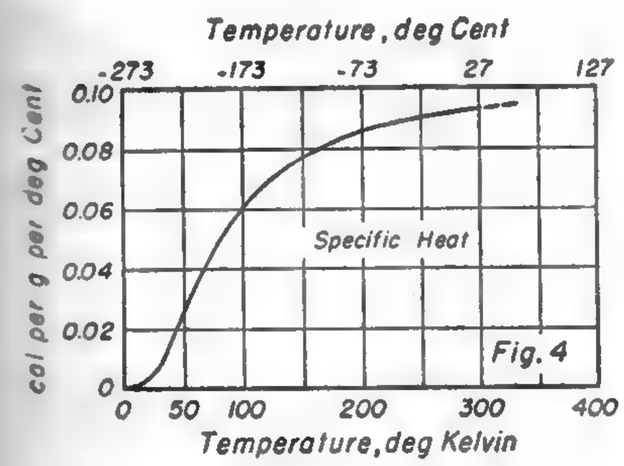
* The properties marked with reference numbers 1, 2, 3, 4 and 5 were determined on spectrographically pure copper, as reported in the cited articles. Other values were measured on various coppers of purity equal to or greater than that of commercial electrolytic copper.

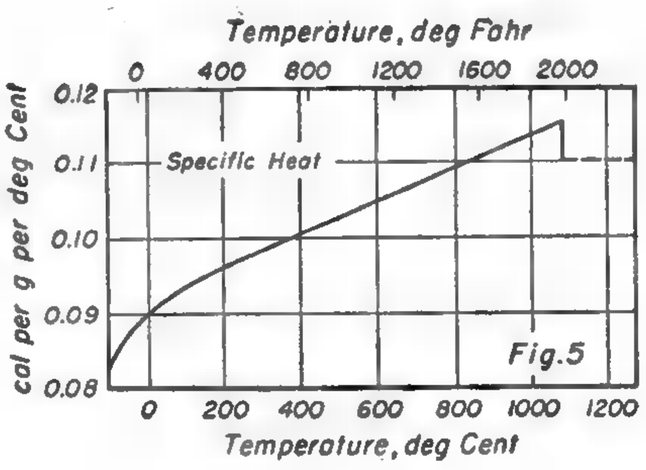
* Research Department, American Smelting and Refining Company, Barber, N. J.

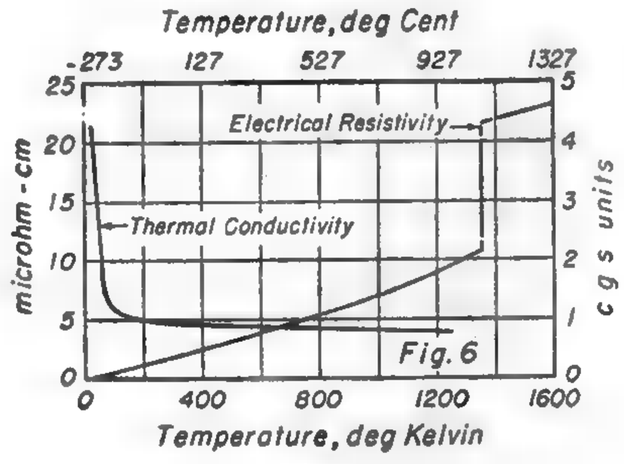


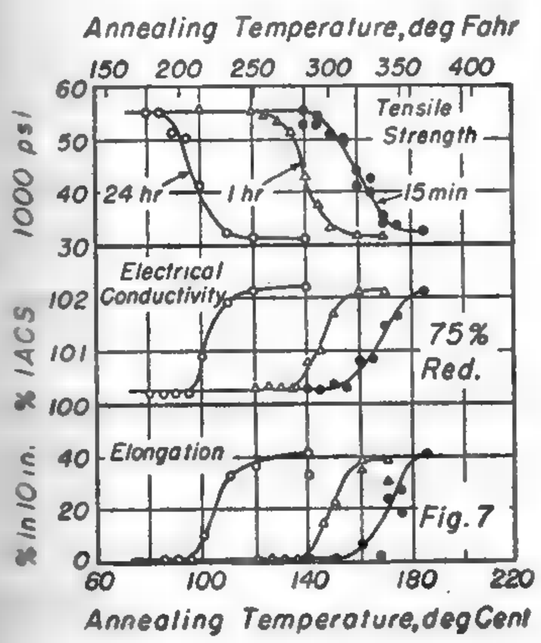


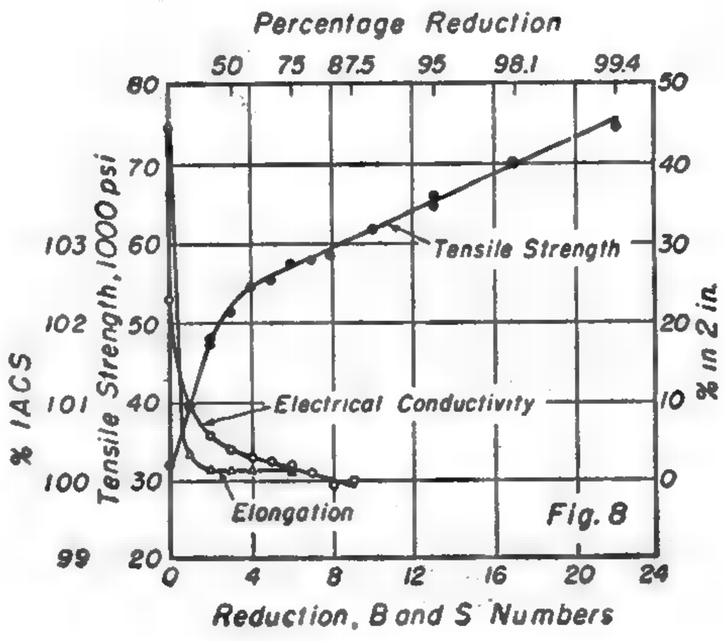


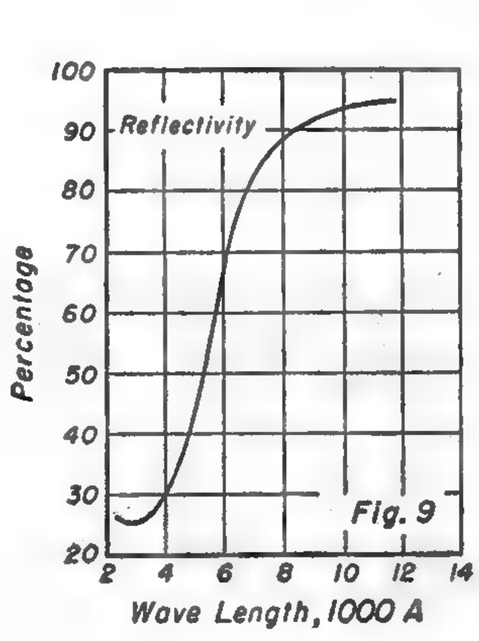












8 Electrical conductivity versus plastic deformation at 20 C (68 F).[1] *See* Fig. 8.

10 Electrochemical equivalent.
0.3294 mg per coulomb for Cu^{++}
0.6588 mg per coulomb for Cu^{+}

15 Hall effect.[34] minus 5.24×10^{-4} volts; 3000 to 8116 gausses

F *1 Reflectivity versus wave length.*[33] *See* Fig. 9.

5 Emissivity.[40]

Wave length, A	7000	6500	6000	5500	5000
% Emissivity at 1000 C (1832 F)	8.7	11.2	18.5	31.3	40.4
% Emissivity at 1125 C (2057 F)	11.8	14.8	20.5	29.3	38.7

G *1 Influence of treatments.* The magnetic susceptibility of copper is determined largely by the quantity of iron present as an impurity. If the copper is free from oxygen, the iron is present in solid solution and has but a small effect. The presence of oxygen results in the precipitation of Fe_3O_4 and a greater effect on magnetic properties. The measurements below were probably made on oxygen-bearing coppers.

2 Magnetic susceptibility.
at 18 C (64 F). minus 0.086×10^{-6} cgs[28,29]
at 1080 C (1976 F). minus 0.077×10^{-6} cgs[30]
at 1090 C (1994 F). minus 0.054×10^{-6} cgs[30]
minus 259 to minus 253 C (−434 to −423 F). minus 0.097×10^{-6} cgs

J *1 Crystal structure.* Face-centered cubic; $a = 3.6080$ kX

2 Slip plane (primary). (111)

3 Twinning plane. (111)

5 Minimum interatomic distance. 2.551 kX

K *Mechanical properties. See* Fig. 7 and 8.

M *Composition limits.* Continuously cast, high-purity copper (⅜-in. rod), *impurities:* 0.0005% Fe max; 0.0001% Sb max; 0.00005% Pb max; 0.00005% Sn max; 0.0001% Ni max; 0.0001% Bi max; 0.00003% Ag max; 0.0001% As max; 0.0001% Te max; 0.0001% Se max; 0.0001% S max; 0.0008% C max; nil O_2.

2 Consequences of exceeding impurity limits. Effects of impurities are discussed in detail in references 3, 4, 5 and 15. *See also* "Electrolytic Tough Pitch Copper".

B *1 Typical uses.* Architectural: building fronts, downspouts, flashing, gutters, roofing, screening, spouting; automotive: gaskets, radiators; electrical: bus bars, conductivity wire, contacts, radio parts, switches, terminals; hardware: ball floats, burrs, cotter pins, nails, rivets, soldering coppers, tacks; miscellaneous: anodes, chemical process equipment, kettles, pans, printing rolls, rotating bands, road-bed expansion plates, vats.

C *1 Density* at 20 C (68 F). 8.89 to 8.94 ■ per cu cm (0.321 to 0.323 lb per cu in.)
Density at 1083 C (1981 F).[1]
(solid). 8.32 g per cu cm
(liquid). 7.93 ■ per cu cm

3 Density versus pressure (compressibility). Volume compressibility is given by

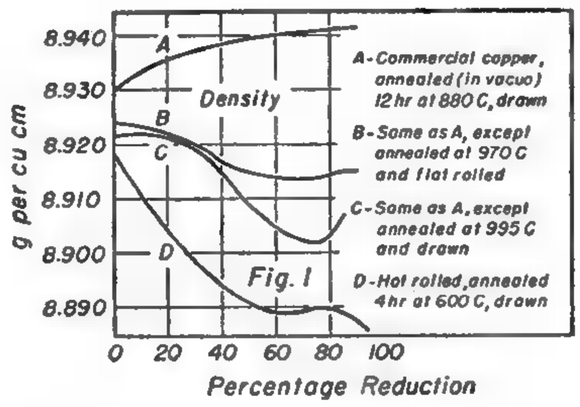
$$\Delta V/V_0 = 10^{-7} P (7.32 - 2.7 \times 10^{-5} P)$$

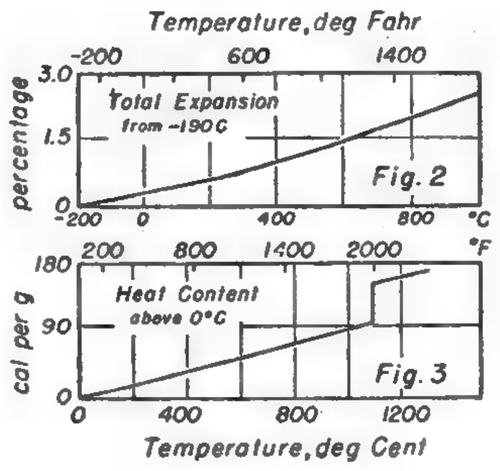
(P = pressure in kg per sq cm). For a pressure of 10,000 atm, this means a volume shrinkage of about 0.7%, or an increase in density of about the same amount.[2,3]

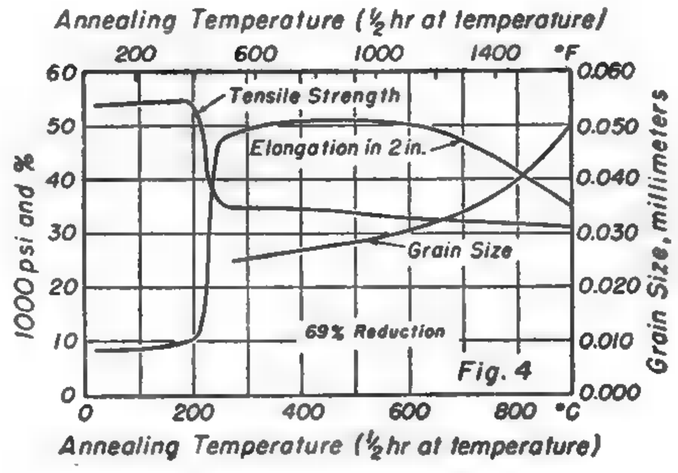
4 Density versus percentage deformation. See Fig. 1. It is generally considered that cold working decreases density. Maier[4] states density changes in cold work

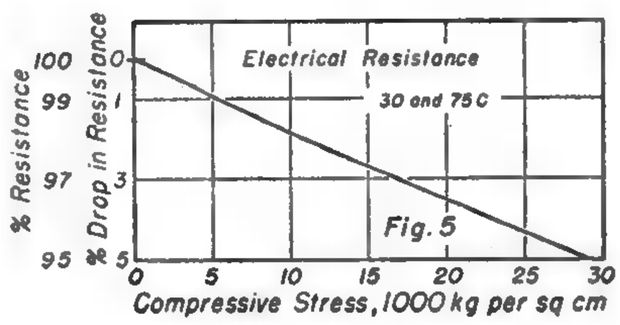
* Compiled by the Copper & Brass Research Association and the American Brass Company

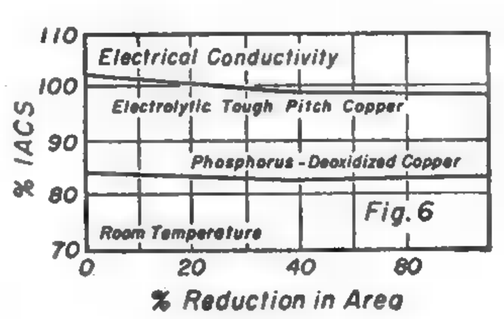
* Most of the physical properties listed here were measured on laboratory coppers that contained various amounts of oxygen. However, the values listed are generally applicable to electrolytic tough pitch copper. For the properties of higher-purity material, see the data sheet on "Pure Copper".

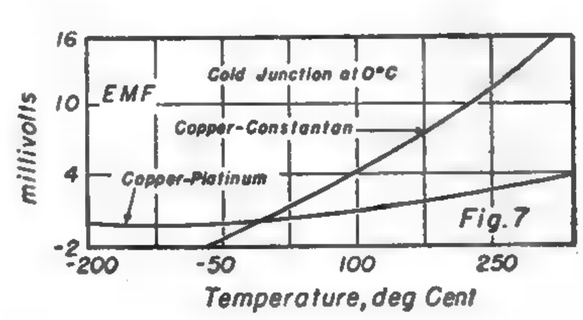


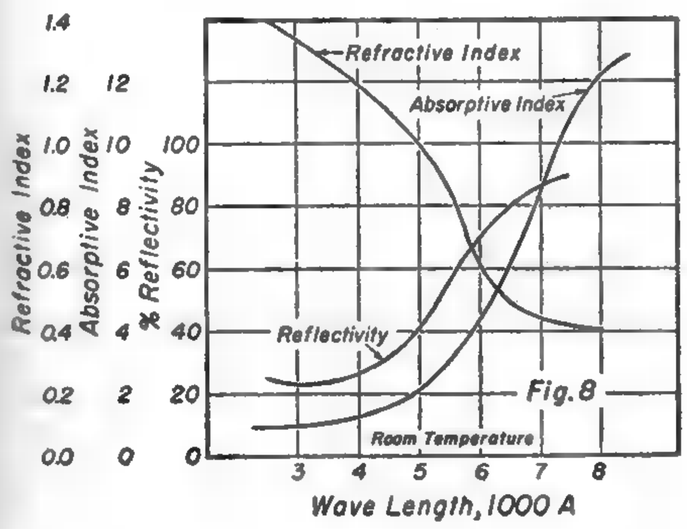


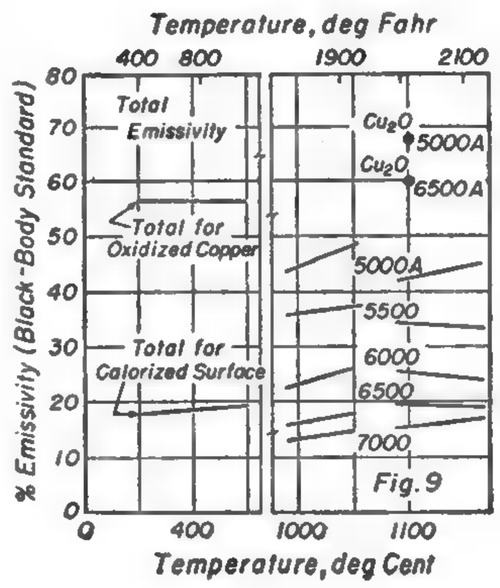


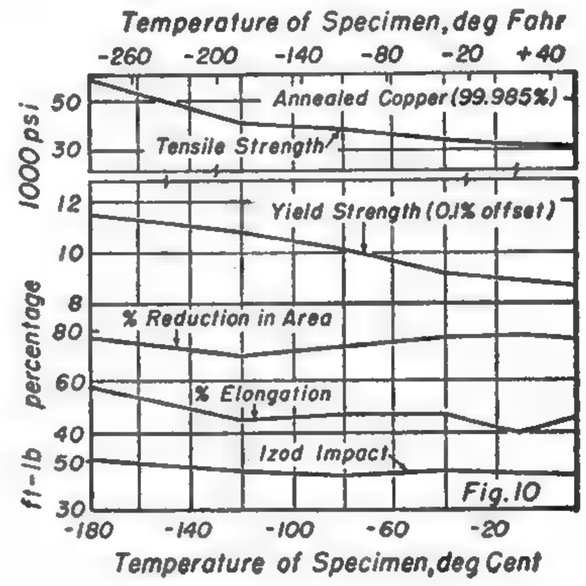












may be positive or negative depending on the type of cold work and the conditions of annealing.

5 *Solidification shrinkage.* Ideal casting condition for tough pitch copper is a "level set", such that liberation of gas counteracts the normal shrinkage.

D 1 *Liquidus temperature.* 1083 C (1981 F)

2 *Solidus temperature.* 1065 C (1949 F)

6 *Thermal expansion* 20 to 300 C (68 to 572 F).[6] 0.0000177 per °C

$L_t = L_0 [1 + (1623 \times 10^{-8}t + 483 \times 10^{-11}t^2)]$ *See* Fig. 2

10 *Volume thermal expansion* (liquid) 1083 to 1295 C (1981 to 2363 F).[12] 0.00019 per °C

11 *Specific heat* at 20 C (68 F). 0.092 cal per g per °C

12 *Specific heat versus temperature. See* Pure Copper. *Heat content versus temperature. See* Fig. 3.

13 *Latent heat of fusion.*[1] 50.6 cal per ■

15 *Latent heat of vaporization.*[12] 1755 cal per ■

16 *Thermal conductivity* at 20 C (68 F). 0.934 cal/sq cm/cm/°C/sec (adjusted to correspond to an electrical conductivity of 101%)

17 *Thermal conductivity versus temperature. See* Pure Copper and Deoxidized Copper.

18 *Heat of combustion.*[13] Cu_2O 279 cal per g
CuO 438 cal per g

19 *Recrystallization temperature.*[14] About 225 C (435 F) for 69% reduction and 0.030-mm initial grain size (nominal 0.5-hr anneal). *See* Fig. 4.
Recrystallization diagram. See Fig. 4.

E 1 *Volume conductivity* referred to standard copper. 101% at 20 C, annealed

2 *Electrical resistivity* at 20 C (68 F). 1.71 microhm-cm, annealed

4 *Electrical resistivity (liquid)* at 1100 C (2012 F). 21.52 microhm-cm

5 *Temperature coefficient of electrical resistivity* at 20 C (68 F). 0.00392 per °C.
Electrical resistivity versus temperature. See Pure Copper and Deoxidized Copper.

7 *Pressure coefficient of electrical resistivity. See* Fig. 5.

8 *Electrical conductivity versus plastic deformation* at 20 C (68 F).[21] *See* Fig. 6.

9 *Contact potential. See* Fig. 7.

10 *Electrochemical equivalent. See* Pure Copper.

11 *Electrolytic solution potential versus hydrogen.*
Cu^{++} minus 0.344 volts
Cu^{+} minus 0.470 volts

13 *Temperature coefficient of solution potential* versus hydrogen, between 20 and 50 C.[45] minus 0.01 millivolts per °C

14 *Hydrogen overvoltage.*[46] 0.23 (dilute H_2SO_4) Varies with current density.

15 *Hall effect.*[24] R = minus 0.52×10^{-12} volt-cm per ampere-gauss. Experimental figures vary from minus 0.428 to minus 0.547×10^{-12}.

F 1 *Reflectivity.*[25]
32.7%, at $\lambda = 4200$ A
43.7%, at $\lambda = 5000$ A
71.8%, at $\lambda = 6000$ A
83.4%, at $\lambda = 7000$ A
Values given here are for polished surfaces, which vary considerably according to polish.
Reflectivity versus wave length. See Fig. 8.

2 *Refractive index. See* Fig. 8.

3 *Absorptive index. See* Fig. 8.

5 *Emissivity versus temperature. See* Fig. 9.

G *Magnetic properties. See* Pure Copper.

H 1 *Velocity of sound.*[28] 12,700 ft per sec at 20 C (68 F)

J *Structure. See* Pure Copper.

Plate, cold rolled 50%	9	sample transverse to rolling

Mechanical properties at low temperatures. All wrought copper alloys are alike in that the effect of temperatures lower than normal is to improve all useful mechanical properties.[34] *See* Fig. 10.

2 *Directional properties.* The most pronounced differences are found with heavy reductions followed by high anneals. Earing generally takes place at angles of 0 and 90 deg to the rolling direction, in contrast to brass. *See* Table II.

6 *Minimum creep rate* at 204 C (400 F). (annealed) (by interpolation)[37]

5000 psi, 0.042% per 1000 hr
6700 psi, 0.10% per 1000 hr
9000 psi, 0.21% per 1000 hr

7 *Viscosity* at 1145 C (2093 F).[1] 0.0341 cgs units

8 *Surface tension* at 1150 C (2102 F).[1] 1104 dynes per cm

9 *Specific damping capacity.* The damping capacity of copper and brasses depends on the amplitude and, under certain conditions, on the frequency of vibration; it is also affected by the condition of the metal. A specific damping capacity of 0.00005 has been recorded for single-crystal, annealed copper.[38] Up to a point damping capacity increases with cold working (increase is reported for reduction as large as 60% for a 70-30 brass).[31] Under torsional stress, brass and copper have relatively high damping capacity.[39] Under the same conditions, copper has a higher damping capacity than alpha brasses (*see* graphs, page 910).

M *Composition limits* (ASTM Specification B 5-43). Electrolytic wire bars, cakes, slabs, billets, ingots and ingot bars. All the following forms specify copper (silver being counted as copper) at 99.9%: chill cast, sheet, wire, extrusions, forgings, and deep drawings. By

Table II. Directional Properties of Tough Pitch Lake Copper[35]
(Within specification purity for electrolytic tough pitch copper)

Treatment	Tensile Strength, psi: Parallel to rolling	Tensile Strength, psi: 45 deg to rolling	Tensile Strength, psi: 90 deg to rolling	Elongation in 2 in., percentage: Parallel to rolling	Elongation in 2 in., percentage: 45 deg to rolling	Elongation in 2 in., percentage: 90 deg to rolling
Cold rolled 50%	51,300	50,100	53,700	6.2	6.2	4.8
Cold rolled 50%, annealed at 600 C	31,375	31,400	31,750	52.5	54.8	57.5
Cold rolled 50%, annealed at 800 C	30,750	30,225	30,750	51.0	57.3	53.6
Cold rolled 89.8%	62,750	60,450	64,600	5.	4.5	4.
Annealed at 600 C	29,900	29,250	29,250	49.3	64.2	48.5
Annealed at 800 C	26,200	26,950	26,250	41.2	76.5	42.

agreement between manufacturer and purchaser, additions of silver up to 30 ounces per ton (0.102%) may be considered within the specification, silver being counted as copper in the chemical analysis.

2 *Consequences of exceeding impurity limits.*

Nominal *oxygen* content about 0.04% (range 0.01 to 0.07%).

Sulfur causes spewing and unsoundness, and is kept below 0.003% in ordinary refinery practice.

Selenium and *tellurium* are usually considered undesirable impurities but may be added to improve machinability.

Bismuth creates brittleness in amounts greater than 0.001%. Bismuth is rarely detected in American copper.

Silver has little effect on mechanical and electrical properties, but does raise the recrystallization temperature and tends to "fine" the grain.[1, 41, 42, 43]

Iron, as present in commercial copper, has no effect on mechanical properties, but even traces of iron may cause ferromagnetism.[47]

Lead should not be present in amounts greater than 0.005% if copper is to be hot rolled.

Cadmium is rarely present; its effect is to toughen copper without much loss in conductivity.

Arsenic decreases the conductivity of copper noticeably, although it is often added intentionally to copper not used in electrical service, because it increases the toughness and heat resistance of the metal.

Antimony is sometimes added to copper when high recrystallization temperature is desired.

N 1 *Melting and casting temperature range.* 1083 to 1150 C (1981 to 2102 F)

5 *Type of flux.* Melt under charcoal.

6 *Precautions in melting.* Pour into dry mold. Oxygen content should be kept within good working limits.

7 *Hot working temperature range.* 750 to 875 C (1400 to 1600 F)

9 *Annealing temperature.* 375 to 650 C (700 to 1200 F)

10 *Maximum cold reduction between anneals* is about 90%. It may be higher in strip.

11 *Suited to forming* by blanking, coining, coppersmithing, drawing, heading and upsetting, hot forging and pressing, impact extrusion, piercing and punching, roll threading and knurling, shearing, spinning, squeezing and swaging, and stamping.

12 *Precautions in forming.* Avoid annealing in a reducing atmosphere.

17 *Joining.*

Rivet composition. Copper

Soft solder with all grades solder; commercial solder fluxes or rosin.

Silver solder with all grades solder; proprietary flux; all types of flame.

Braze with Cu-P or Cu-Zn alloy; commercial brazing flux; all types of flame.

Oxyacetylene welding is not recommended.

Carbon-arc welding is not recommended.

Resistance welding is not satisfactory, except as butt welding of rod and wire.

Pipes	B 42	99.90	....	0.04	....

(a) Silver is counted as copper. *See note* on silver for Electrolytic Copper.

2 Consequences of exceeding impurity limits.

Phosphorus lowers electrical and thermal conductivity; "toughens" the copper.

Remarks on electrolytic copper relative to the harmful effects of bismuth and lead apply to deoxidized copper.

Presence of arsenic in commercial amounts does not appreciably affect the impact strength of deoxidized copper.[7]

N *1 Casting temperature.* 1083 to 1150 C (1981 to 2102 F)

3 Alloying. 15% P-Cu cake is added in the ladle just before pouring.

5 Type of flux. Melt under charcoal.

6 Precautions in melting. Pour into oil-dressed mold.

7 Hot working temperature. 750 to 875 C (1400 to 1600 F)

9 Annealing temperature. 375 to 650 C (700 to 1200 F)

10 Maximum reduction between anneals. 95% is possible.

11 Suited to forming by blanking, coining, coppersmithing, drawing, forming and bending, hot forging and pressing, piercing and punching, shearing, spinning, squeezing and swaging, and stamping. Excellent hot and cold working properties.

17 Joining.
Soft solder with all grades solder; commercial solder fluxes or rosin.
Silver solder with all grades solder; proprietary flux; all types of flame.
Braze with Cu-P or Cu-Zn alloy; commercial brazing flux; all types of flame.
Oxyacetylene welding with special copper rods; commercial brazing flux; oxyacetylene flame.
Carbon-arc welding with phosphor bronze, no flux; or with copper-silicon alloy and a flux.
Resistance welding is not satisfactory, except for butt welding of rod and wire.

Table I. Mechanical Properties of Deoxidized Copper

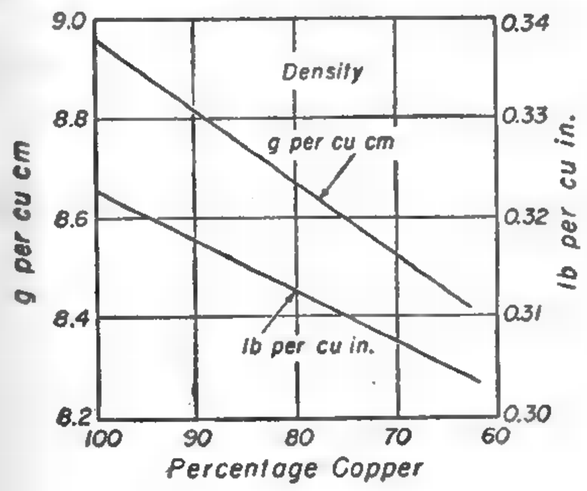
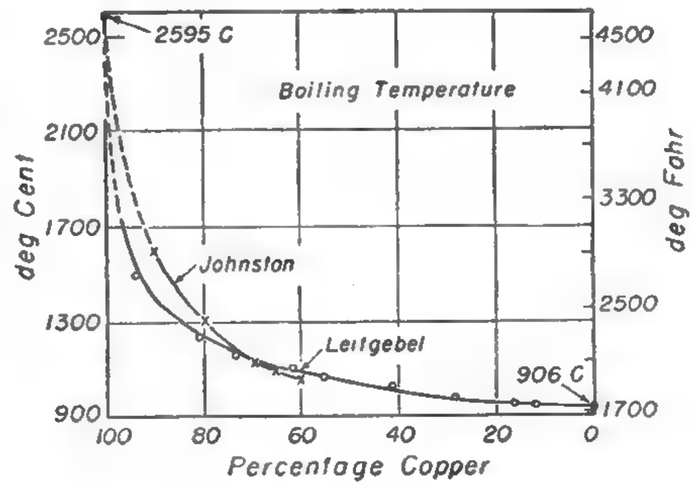
WROUGHT ALLOYS

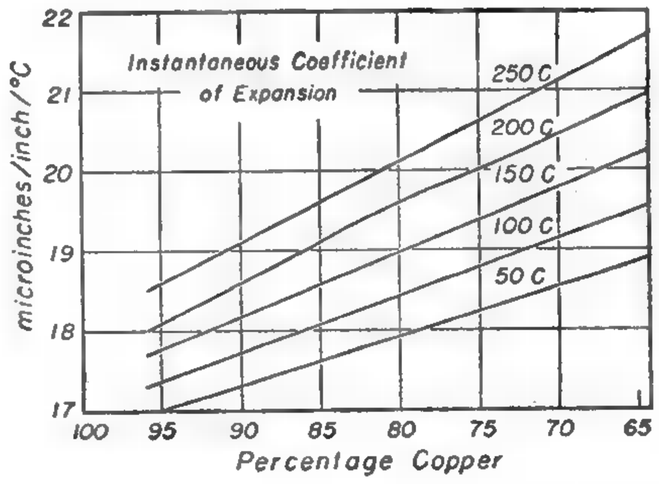
Some Properties of Copper-Zinc Alloys*

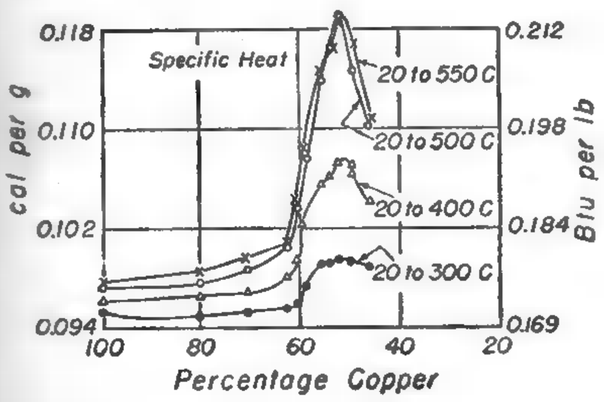
THIS COMPILATION summarizes graphically the effect of composition on some of the physical and mechanical properties of binary copper-zinc alloys. More specific information concerning the properties of particular alloys in this series may be found in the data sheets for the seven standard wrought copper-zinc alloys that contain 95, 90, 85, 80, 70, 65 and 60% Cu. These data sheets are given on pages 910 to 917, immediately following this compilation.

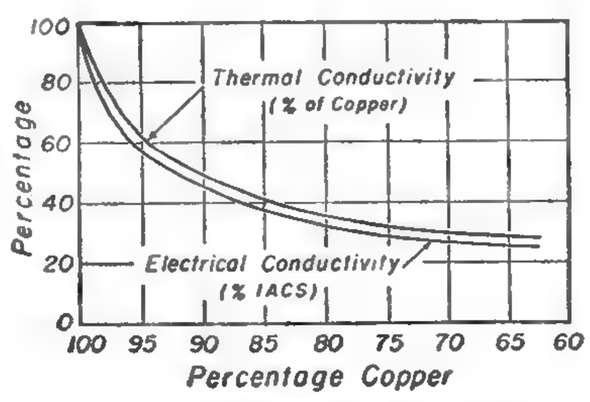
* Compiled by The American Brass Company

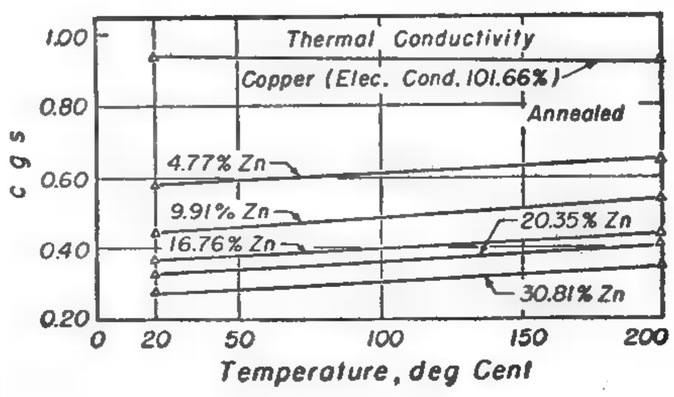






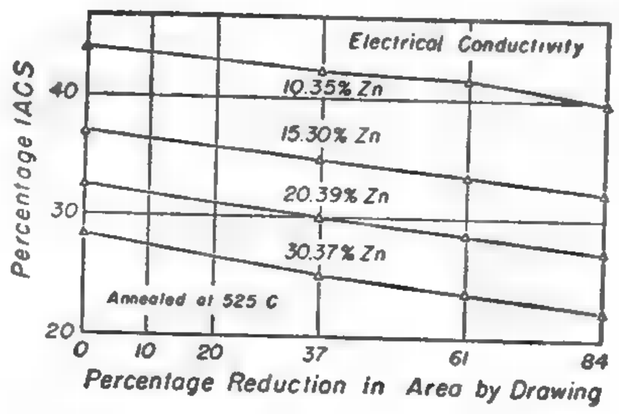




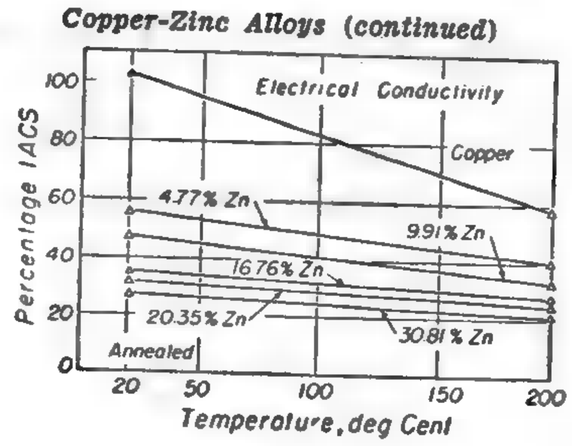


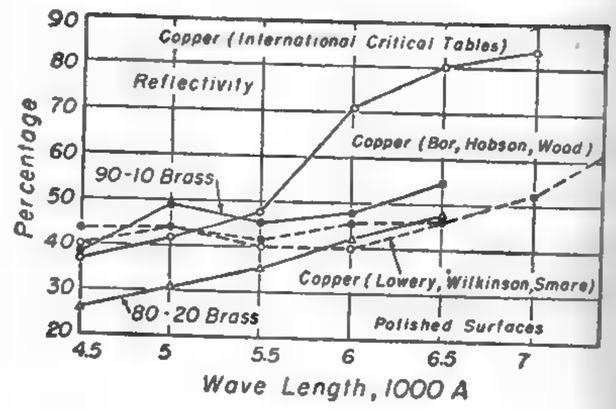
(continued on the next page)

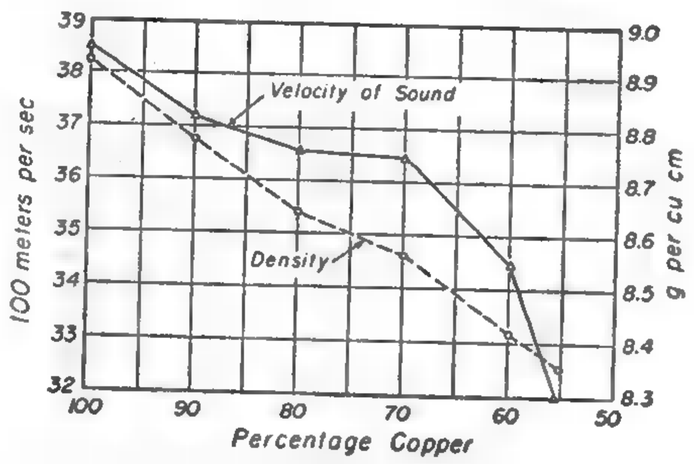
Properties of Gilding Metal

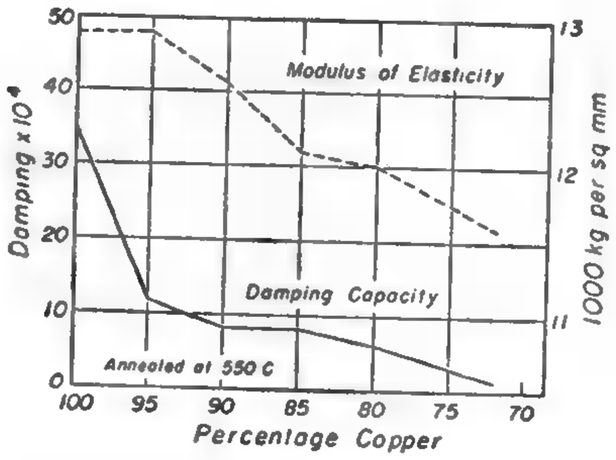


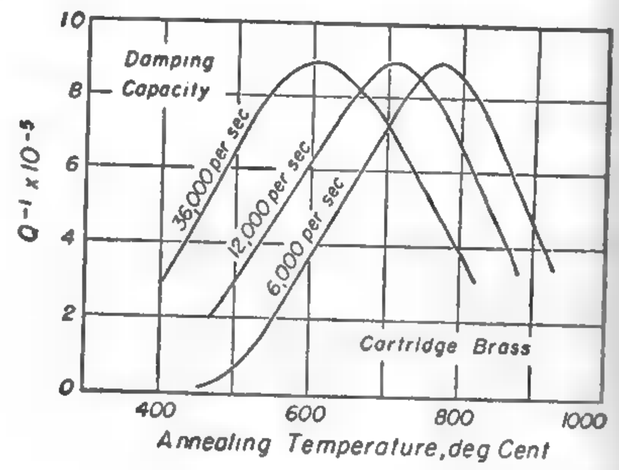
Copper-Zinc Alloys (continued)

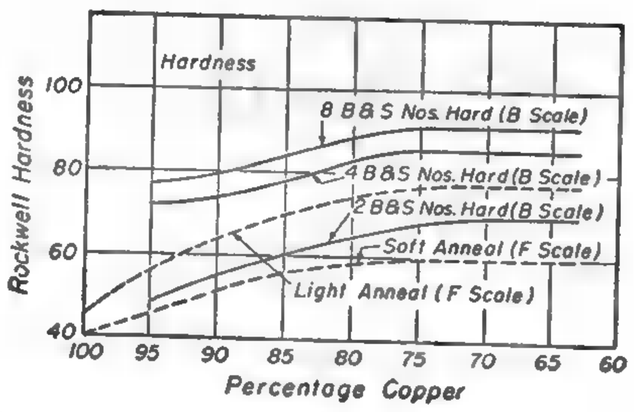


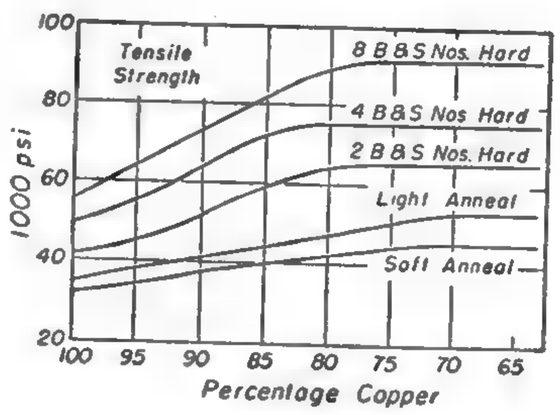


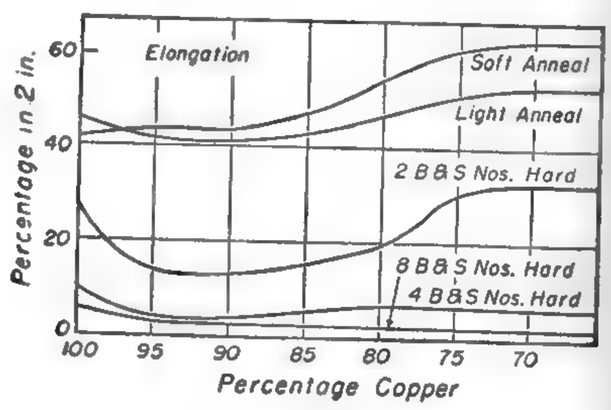












95 Cu – 5 Zn*

A *1 Common name.* **Gilding Metal**

3 ASTM number.
Rolled flat products: B 36, No. 1; B 134, No. 1
Drawn flat products: B 134, No. 1
Wire: B 134, No. 1

4 Government number. Army 57-171-2

B *1 Typical uses.* Coinage: coins, medals and tokens; munitions: bullet jackets, firing-pin supports, shells, fuse caps and primers; novelties: emblems, jewelry, plaques; miscellaneous: base for gold plate, base for vitreous enamel, etched articles.

C *1 Density* at 20 C. 8.86 ■ per cu cm (0.320 lb per cu in.)

D *1 Liquidus temperature.* 1065 C (1950 F)

2 Solidus temperature. 1050 C (1920 F)

4 Boiling point at 760 mm Hg.[1] About 1600 C (2910 F)

6 Thermal expansion 25 to 300 C (77 to 572 F).[2] 0.0000181 per °C (0.0000100 per °F), cold rolled

$L_t = L_0\ [1 + (16.81t + 0.00389t^2) \times 10^{-6}]$ cold rolled

$L_t = L_0\ [1 + (16.87t + 0.00356t^2) \times 10^{-6}]$ cast (avg of 4)

11 Specific heat at 20 C (68 F). 0.09 cal per ■ per °C

16 Thermal conductivity at 20 C (68 F). 0.56 cal/sq cm/cm/°C/sec (135 Btu/sq ft/ft/hr/°F)

17 Thermal conductivity versus temperature. See "Some Properties of Copper-Zinc Alloys".

19 Recrystallization temperature.[4] About 370 C (700 F) for 50% reduction and 0.015 to 0.070-mm initial grain size. *See* Fig. 1.

E *1 Volume conductivity* referred to standard copper. 56% at 20 C (68 F), annealed

2 Electrical resistivity at 20 C (68 F). 3.1 microhm-cm (18.5 ohms per mil-ft), annealed

4 Electrical resistivity (liquid).[5]
at 1100 C (2010 F). 24.4 microhm-cm
at 1300 C (2370 F). 26.6 microhm-cm

5 Temperature coefficient of electrical resistivity at 20 C (68 F).[6] 0.00231 per °C

Electrical resistivity versus temperature. See "Some Properties of Copper-Zinc Alloys".

F *1 Reflectivity.*[7] 90% at $\lambda = 5780$ A

G *2 Magnetic susceptibility.*[8] minus 0.086 $> \chi >$ minus 1.00×10^{-6} cgs

H *1 Velocity of sound.*[9] Approx 12,400 ft per sec at 20 C (68 F) (by interpolation)

J *1 Crystal structure.* Face-centered cubic alpha; lattice parameter. 3.620 kX

5 Minimum interatomic distance. 2.559 kX

K *Mechanical properties.* See Fig. 1.

Temper	Tensile Strength, psi	Yield Strength, psi	Elongation in 2 in., percentage[a]	Rockwell Hardness 30-T	Shear Strength, psi
Rolled strip, 0.040-in. section

½ hard	48,000	40,000	12	B 52	34,000
Hard	56,000	50,000	5	B 64	37,000
Extra hard	61,000	55,000	4	B 70	39,000
Spring	64,000	58,000	4	B 73	40,000

(a) 0.5% extension under load

Modulus of elasticity (tension). 17,000,000 psi

4 Machinability index (free-cutting brass = 100). 20

M *Composition limits.* See Table I.

2 Consequences of exceeding impurity limits. See remarks for 70 Cu – 30 Zn concerning the effects of lead

* Compiled by the Copper & Brass Research Association and the American Brass Company

Table I. Composition Limits of 95 Cu – 5 Zn

Form	ASTM Designation	Components: Cu min	Cu max	Zn min	Zn max	Impurities: Pb max	Fe max
Sheet	B 36	94.0	96.0	remainder		0.03	0.05
Wire	B 134	94.0	96.0	remainder		0.05	0.05

and of iron. Lead in the amounts specified above has little effect on tensile properties.

N 1 *Melting and chill casting temperature range.* 1275 to 1300 C (2327 to 2372 F)

3 *Alloying.* Zinc is added just before pouring.

5 *Type of flux.* Melt under charcoal.

6 *Precautions in melting.* The temperatures above may not be exact. The right pouring temperature is indicated by "zinc shine" on the melt. "Zinc boiling" at higher temperatures is to be avoided. The melt should be poured into an oil-dressed mold.

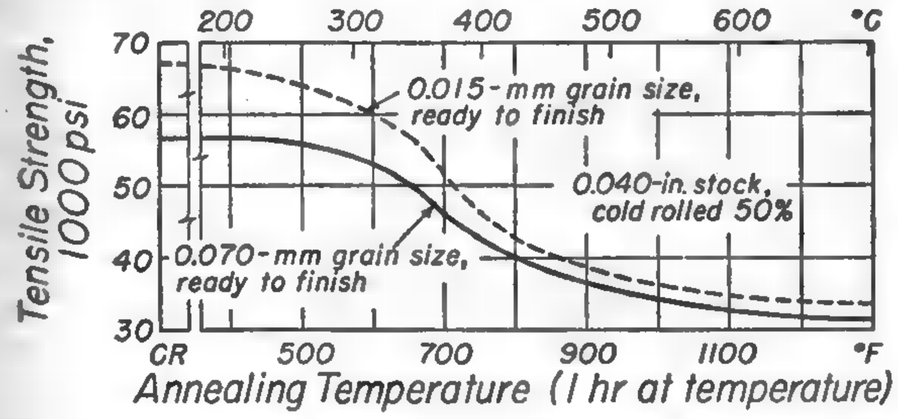

Fig. 1 Recrystallization diagram for gilding metal (Wilkins and Bunn[4])

7 *Hot working temperature.* 750 to 875 C (1400 to 1600 F)

9 *Annealing temperature.* 425 to 800 C (800 to 1450 F)

10 *Maximum reduction between anneals.* Almost as high as copper

11 *Suited to forming* by blanking, coining, drawing, forming and bending, piercing and punching, shearing, spinning, squeezing and swaging, and stamping. Excellent cold working properties, good hot working properties.

17 *Joining.*

Soft solder with all grades solder, commercial solder fluxes or rosin.

Silver solder with all grades solder, proprietary flux, all types of flame.

Braze with P-Cu, or copper-zinc alloy, commercial brazing flux, all types of flame.

Oxyacetylene welding with bronze welding rods, commercial brazing flux, and oxyacetylene flame.

Carbon-arc welding is fair.

Resistance welding is unsatisfactory except for butt welding of rod and wire.

90 Cu – 10 Zn*

A 1 *Common name.* **Commercial Bronze**

3 *ASTM number.*
Rolled flat products: B 36, No. 2; B 130, B 134, No. 2
Drawn flat products: B 134, No. 2
Wire: B 134, No. 2
Bullet jacket cups: B 131

4 *Government numbers.*
Sheet, strip and coil for small-arms ammunition: Army 57–171–1B
Bullet jacket cups: Army 57–171–3A
Wire, spraying: AN–W–20 (Army-Navy Aeronautical)
Blanks for projectile rotating bands: Army 50–27–1B, class B

B 1 *Typical uses.* Architectural: etching bronze, grillwork, screen cloth, weather stripping; hardware: escutcheons, kick plates, line clamps, marine hardware, rivets, screws, screw shells; munitions: primer caps, rotating bands; miscellaneous: compacts, lipstick cases, costume jewelry, ornamental trim, screen wire, base for vitreous enamel.

C 1 *Density* at 20 C. 8.80 g per cu cm (0.318 lb per cu in.)

D 1 *Liquidus temperature.* 1045 C (1910 F)

2 *Solidus temperature.* 1020 C (1870 F)

4 *Boiling point* at 760 mm Hg. About 1400 C (2550 F)

6 *Thermal expansion* 25 to 300 C (77 to 572 F).[3] 0.0000182 per °C (0.0000101 per °F), cold rolled

$L_t = L_0\ [1 + (17.01t + 0.00379t^2) \times 10^{-6}]$, cold rolled

11 *Specific heat* at 20 C (68 F). 0.09 cal per g per °C

16 *Thermal conductivity* at 20 C (68 F). 0.45 cal/sq cm/cm/°C/sec (109 Btu/sq ft/ft/hr/°F)

17 *Thermal conductivity versus temperature.* See "Some Properties of Copper-Zinc Alloys".

19 *Recrystallization temperature.*[4] About 370 C (700 F) for 37% reduction and 0.050-mm initial grain size. *See* Fig. 1.

E 1 *Volume conductivity* referred to standard copper. 44% at 20 C (68 F), annealed

2 *Electrical resistivity* at 20 C (68 F). 3.9 microhm-cm (23.5 ohms per mil-ft), annealed

4 *Electrical resistivity (liquid)* at 1100 C (2012 F).[5] 27.2 microhm-cm

5 *Temperature coefficient of electrical resistivity* at 20 C (68 F). 0.00186 per °C
Electrical resistivity versus temperature. See "Some Properties of Copper-Zinc Alloys".

8 *Electrical resistivity versus plastic deformation.*[6] See "Some Properties of Copper-Zinc Alloys".

F 1 *Reflectivity.* See "Properties of Copper-Zinc Alloys".

G 2 *Magnetic susceptibility.*[7] minus 0.086 $> \chi >$ minus 1.00×10^{-6} cgs

H 1 *Velocity of sound.* 12,200 ft per sec at 20 C (68 F).

J 1 *Crystal structure.* Face-centered cubic alpha; lattice parameter 3.63 kX

5 *Minimum interatomic distance.* 2.57 kX

K *Mechanical properties.* See Fig. 1 and Table I.
Modulus of elasticity (tension). 17,000,000 psi
Endurance strength. (Spring temper, flat product, 0.040 in. thick) 21,000 psi, 15,000,000 cycles. (Hard wire, 0.080-in. diam) 23,000 psi, 100,000,000 cycles.

4 *Machinability index* (free-cutting brass = 100). 20

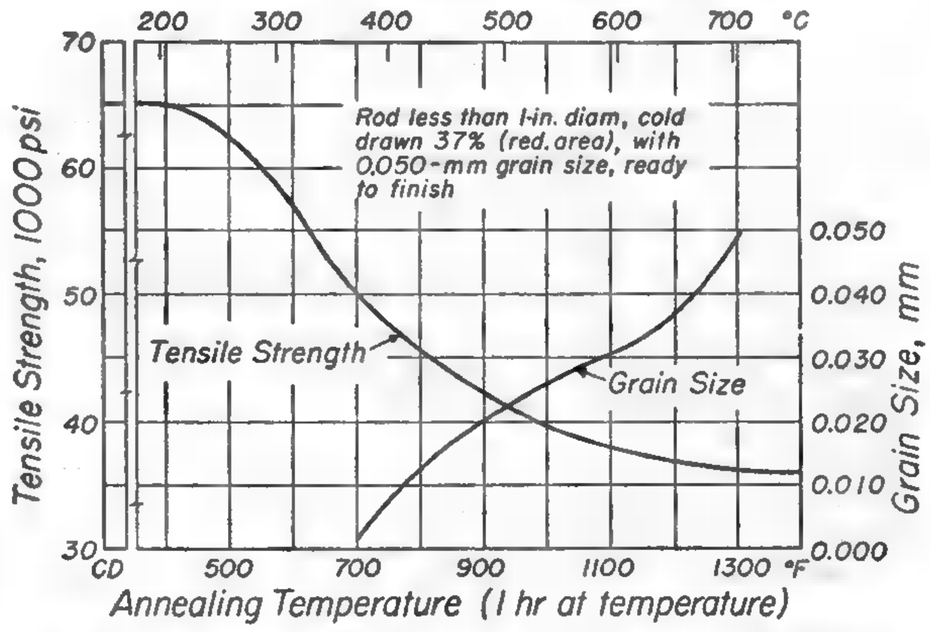

Fig. 1 Recrystallization diagram for commercial bronze (Wilkins and Bunn[4])

⅛ hard	45,000	.....	25	B 42	..	33,000

(a) 0.5% extension under load

M *Composition limits.*

Form	ASTM Designation	Components: Cu min	Cu max	Zn min	Zn max	Impurities: Pb max	Fe max	Others (total) max[a]
Sheet	B 36, No. 2	89.0	91.0	remainder		0.05	0.05	...
Strip	B 130	89.0	91.0	remainder		0.05	0.05	0.13
Bullet jacket cups	B 131	89.0	91.0	remainder		0.05	0.05	0.13
Wire	B 134, No. 2	89.0	91.0	remainder		0.05	0.05	...

(a) Other than copper and zinc

2 Consequences of exceeding impurity limits. See general statement for brasses under 70 Cu – 30 Zn.

N *1 Melting and chill casting temperature ranges.* 1225 to 1250 C (2237 to 2282 F)

3 Alloying. Zinc is added to scrap and copper melt just before pouring.

5 Type of flux. Melt under charcoal.

6 Precautions in melting. See 95 Cu – 5 Zn.

7 Hot working temperature range. 750 to 875 C (1400 to 1600 F)

9 Annealing temperature. 425 to 800 C (800 to 1450 F)

10 Maximum reduction between anneals. 90%

11 Suited to forming by blanking, coining, drawing, forming and bending, heading and upsetting, hot forging and pressing, piercing and punching, roll threading and knurling, shearing, spinning, squeezing and swaging, stamping. Excellent cold working properties, good hot working properties.

17 Joining.

Soft solder with all grades solder, commercial solder fluxes or rosin.

Silver solder with all grades solder, proprietary flux, all types of flame.

Braze with P-Cu or Cu-Zn alloy, commercial brazing flux, all types of flame.

Oxyacetylene welding with bronze welding rods, commercial brazing flux, all types of flame.

Carbon-arc welding is fair.

Resistance welding is unsatisfactory except for butt welding of rod and wire.

6 Precautions in melting. See 95 Cu – 5 Zn.
7 Hot working temperature range. 825 to 900 C (1500 to 1650 F)
9 Annealing temperature. 425 to 700 C (800 to 1300 F)
10 Maximum reduction between anneals. 75%
11 Suited to forming by blanking, drawing, forming and bending, heading and upsetting, piercing and punching, roll threading and knurling, shearing, spinning, squeezing and swaging, stamping. Excellent cold working properties, fair hot working properties.
17 Joining.
Soft solder with all grades solder, commercial solder fluxes or rosin.
Silver solder with all grades solder, proprietary flux, all types of flame.
Braze with P-Cu or Cu-Zn alloy, commercial brazing flux, all types of flame.
Oxyacetylene welding with bronze welding rod, commercial brazing flux, oxyacetylene flame.
Carbon-arc welding is fair.
Resistance welding is unsatisfactory except for butt welding of rod and wire.

C *1 Density* at 20 C. 8.53 g per cu cm (0.308 lb per cu in.)
D *1 Liquidus temperature.* 955 C (1750 F)
2 Solidus temperature. 915 C (1680 F)
4 Boiling point at 760 mm Hg. About 1150 C (2100 F)
6 Thermal expansion 25 to 300 C (77 to 572 F).[1] 0.0000199 per °C (0.0000111 per °F), cold rolled
Equation for 20 to 300 C (68 to 572 F):

$$L_t = L_0\ [1 + (17.75t + 0.00653t^2) \times 10^{-6}]$$

11 Specific heat at 20 C (68 F). 0.09 cal per g per °C
12 Specific heat versus temperature. See "Some Properties of Copper-Zinc Alloys".
16 Thermal conductivity 20 C (68 F). 0.29 cal/sq cm/cm/°C/sec (70 Btu/sq ft/ft/hr/°F)
17 Thermal conductivity versus temperature. See "Some Properties of Copper-Zinc Alloys".

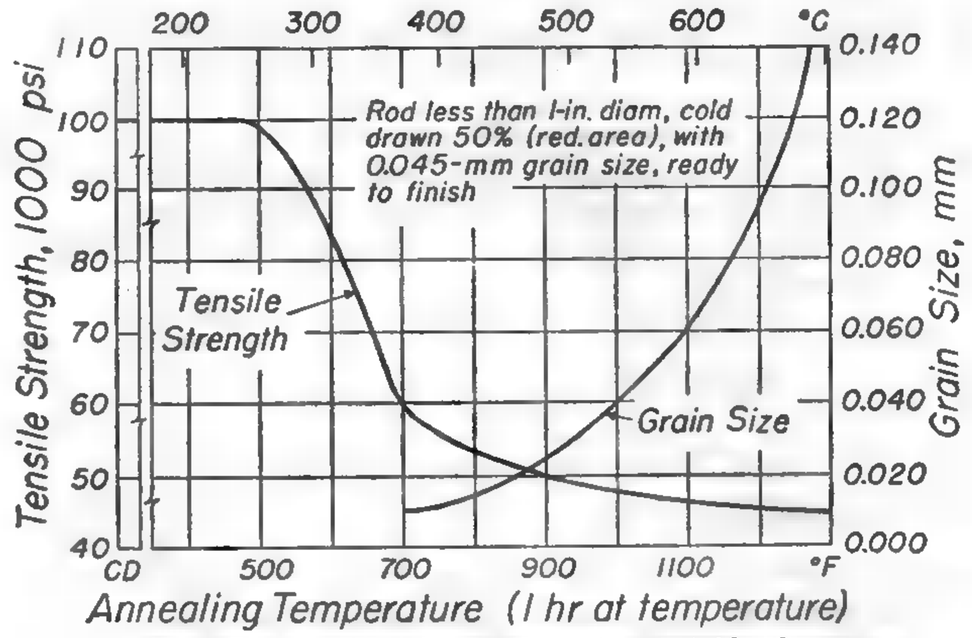

Fig. 1 Recrystallization diagram for cartridge brass (Wilkins and Bunn[2])

19 Recrystallization temperature.[2] About 350 C (660 F) for 50% reduction and 0.045-mm initial grain size. *See* Fig. 1.
E *1 Volume conductivity* referred to standard copper. 28% at 20 C (68 F), annealed
2 Electrical resistivity at 20 C (68 F). 6.2 microhm-cm (37 ohms per mil-ft), annealed
4 Electrical resistivity (liquid) at 1000 C (1832 F).[3] 39 microhm-cm (by extrapolation)
5 Temperature coefficient of electrical resistivity at 20 C (68 F).[4] 0.001484 per °C
Electrical resistivity versus temperature. See "Some Properties of Copper-Zinc Alloys".
7 Pressure coefficient of electrical resistivity.[5] This value for 74 Cu – 26 Zn is negative with increase in temperature.
8 Electrical resistivity versus plastic deformation. See "Some Properties of Copper-Zinc Alloys".
15 Hall effect.[6] minus 0.250×10^{-12} volt-cm per amp-gauss
G *1 Influence of treatments on magnetic properties.*[8] Iron in excess of 0.03% can be precipitated from cartridge brass by suitable low-temperature anneals. Precipitation is slow and occurs chiefly in the nonmagnetic form, which is converted to the ferromagnetic structure on cold working.

(a) 0.5% extension under load

2 *Magnetic susceptibility.*[9] minus 1 > χ > minus ■ × 10^{-6} cgs. Susceptibility in alpha brasses decreases with increasing zinc content.

H 1 *Velocity of sound.* 12,000 ft per sec at 20 C (68 F).

J 1 *Crystal structure.* Face-centered cubic alpha; lattice parameter 3.677 kX

5 *Minimum interatomic distance.* 2.600 kX

K *Mechanical properties.* See Table I and Fig. 1, ■ and 3.

Modulus of elasticity (tension). 16,000,000 psi

Mechanical properties at low temperature. See Fig. 2.

Impact tests.

Condition	Izod, ft-lb	Charpy, ft-lb
Wrought, annealed[12]	66, notched round specimen, no fractures	....
Cast, annealed[13]	44, no data on breaking	....
Cast[14]	35, no data on breaking	....
Hot rolled[15]	.....	14, V notch
Hot rolled, annealed.....	.....	44, no data on breaking

2 *Directional properties.* Directionality in brass is more readily developed, the higher the zinc content. Earing usually occurs at 45 deg to the direction of rolling, aggravated by heavy final reductions, low ready-to-finish and high finish anneals.[10]

Material with ready-to-finish anneal at 400 C, cold rolled 70%, and annealed for one hour at 575 C

Property	Parallel to rolling	45-deg angle to rolling	90-deg angle to rolling
Tensile strength, psi.....	48,000	44,000	47,000
Elongation in 2 in., percentage	59	66	61

NOTE: Approximate values, taken from graph in reference 10.

4 *Machinability index* (free-cutting brass = 100). 30.

6 *Minimum creep rate.* See Fig. 3.

9 *Specific damping capacity.* See references 17 to 24 and "Some Properties of Copper-Zinc Alloys", also, general statement under Electrolytic Tough Pitch Copper.

M *Composition limits.*

(a) Other than copper and zinc

2 Consequences of exceeding impurity limits.[25, 26, 27]

Tolerance for bismuth under commercial processing is virtually nil. The worst effect is in hot working. Small additions of phosphorus make brass workable with bismuth present up to 0.05%. Bismuth up to 0.97% has little effect on tensile properties of cartridge brass that has been processed by cold working and careful annealing.

Lead should be kept under 0.01% (possibly under 0.015%) for hot rolling, although additions of lead up to 4% are made to improve machinability in material processed by extrusion and cold working. Lead lowers ductility in brass.

As little as 0.017% Sb impairs the hot working qualities of cartridge brass. The presence of lead aggravates this condition.

Aluminum as high as 2% has no adverse effect on hot or cold working. However, annealing and grain size are affected.

Arsenic does not affect hot or cold working, but tends to "fine" the grain and thus to lower the ductility. Cadmium is doubtful. Some claim as much as 0.10% has little effect, others would keep it under 0.05%. Chromium affects temperature of anneal and grain size. This condition is aggravated when iron is present. Iron chiefly affects annealing. (*See also* Magnetic Properties.) Nickel restrains grain growth. Phosphorus has no adverse effect up to 0.04% but grain growth is restrained; tensile strength is increased; ductility is lowered somewhat.

N 1 *Melting and chill casting temperature range.* 1125 to 1150 C (2057 to 2102 F)

5 *Type of flux.* Melt under charcoal.

6 *Precautions in melting.* See 95 Cu–5 Zn.

7 *Hot working temperature.* 725 to 850 C (1350 to 1550 F)

9 *Annealing temperature.* 425 to 750 C (800 to 1400 F)

10 *Maximum cold reduction between anneals.* 75%

11 *Suited to forming* by blanking, drawing, forming and bending, heading and upsetting, piercing and punching, shearing, spinning, squeezing and swaging, stamp-

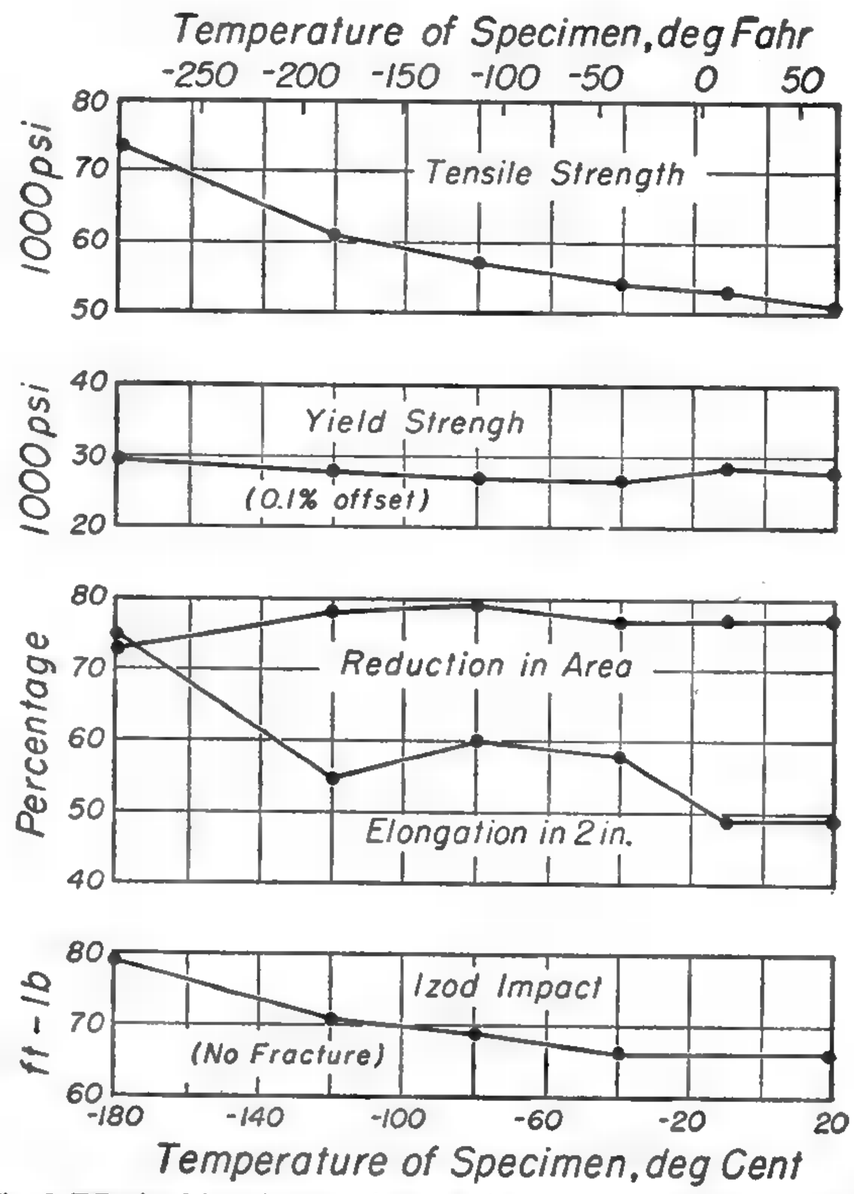

Fig. 2 Effect of low temperature on the mechanical properties of a cartridge brass (69.56% Cu, 30.50% Zn), annealed (Colbeck and MacGillivray[30])

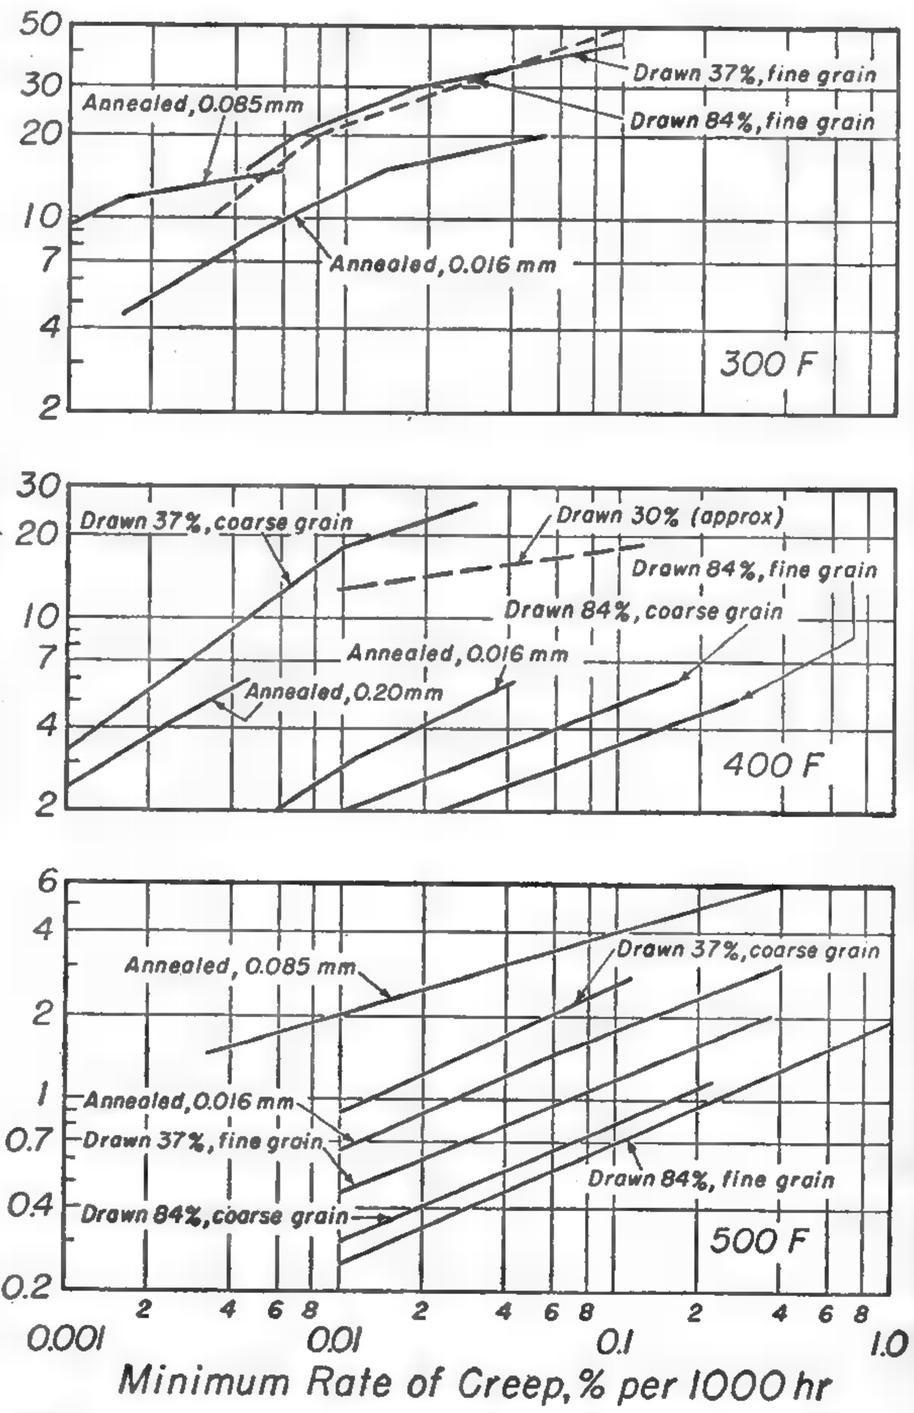

Fig. 3 Minimum rate of creep versus stress for cartridge brass (Burghoff, Blank and Maddigan[16])

ing. Excellent cold working properties, fair hot working properties.

17 Joining.
Soft solder with all grades solder, commercial solder fluxes or rosin.
Silver solder with all grades solder, proprietary flux, all types of flame.
Braze with P-Cu or Cu-Zn alloy, commercial brazing flux, all types of flame.
Oxyacetylene welding with bronze welding rods, commercial brazing flux, oxyacetylene flame.
Carbon-arc welding is fair.
Resistance welding is fair.

K *Mechanical properties.* See Table I.
Modulus of elasticity. 15,000,000 psi
4 Machinability index (free-cutting brass = 100). 70%

M *Composition limits.* Rod and bar, ASTM B 21, Grade C, *components*: 59 to 62% Cu; 0.5 to 1.0% Sn; 1.25 to 2.25% Pb; remainder zinc; *impurities*: 0.10% max Fe; others 0.10% max.

N *7 Hot working temperature range.* 650 to 750 C (1200 to 1400 F)
9 Annealing temperatures. 425 to 600 C (800 to 1100 F)
11 Suited to forming by hot extrusion, hot forging, pressing and machining.

Table I. Mechanical Properties of Leaded Naval Brass

Temper	Tensile Strength, psi	Yield Strength,(a) psi	Elongation in 2 in., percentage	Rockwell Hardness	Shear Strength, psi
		Rod (1.0 in. in diam)			
Soft anneal...	57,000	25,000	40	B 55	36,000
¼ hard (8%).	69,000	46,000	20	B 78	39,000
½ hard (20%)	75,000	53,000	15	B 82	40,000

(a) 0.5% extension under load

58.5 Cu – 39 Zn – 1.4 Fe – 1 Sn – 0.1 Mn*

A *1 Common name.* **Manganese Bronze**
2 Trade name. Manganese Bronze, Type A
3 ASTM number. B 138, Type A (rod and bar); B 124, Alloy No. 4 (forging rod)
4 Government number. Federal QQ-B-721a, Class A (bars, forging, plates, rods and shapes); Navy 46B15e, Grade A (bars, forgings, plates, rods, sheet and strip).

B *1 Typical uses.* Clutch disks, pump rods, shafting rod, valve stems, welding rod

C *1 Density* at 20 C (68 F). 8.53 g per cu cm (0.308 lb per cu in.)

D *1 Liquidus temperature.* 890 C (1630 F)
2 Solidus temperature. 865 C (1590 F)
6 Thermal expansion 20 to 300 C (68 to 572 F). 0.0000212 per °C (0.0000118 per °F)
11 Specific heat at 20 C (68 F). 0.09 cal per g per °C
16 Thermal conductivity at 20 C (68 F). 0.26 cal/sq cm/cm/°C/sec (61 Btu/sq ft/ft/°F/hr)

E *1 Volume conductivity* referred to standard copper, 20 C (68 F). 24%, annealed
2 Electrical resistivity at 20 C (68 F). 43 ohms per cir mil-ft, annealed

K *Mechanical properties.* See Table I.
Modulus of elasticity. 15,000,000 psi
4 Machinability index (free-cutting brass = 100). 30%

M *Composition limits* (ASTM spec). *See* Table II.

N *7 Hot working temperature range.* 625 to 750 C (1150 to 1450 F)
9 Annealing temperatures. 425 to 600 C (800 to 1100 F)
11 Suited to forming by hot forging, pressing, hot heading, upsetting.

Table I. Mechanical Properties of Manganese Bronze

Temper	Tensile Strength, psi	Yield Strength,(a) psi	Elongation in 2 in., percentage	Rockwell Hardness	Shear Strength, psi
		Rod (1.0 in. in diam)			
Soft anneal...	65,000	30,000	33	B 65	42,000
¼ hard (10%)	77,000	45,000	23	B 83	47,000
½ hard (20%)	84,000	60,000	19	B 90	48,000
		Rod (2.0 in. in diam)			
¼ hard (10%)	72,000	42,000	27	B 77	44,000

(a) 0.5% extension under load

76 Cu – 22 Zn – 2 Al*

A *1 Common name.* **Aluminum Brass**
3 ASTM number. B 111 (condenser tubes)
B *1 Typical uses.* Condenser, evaporator and heat-exchanger tubes; distiller tubes; ferrules
C *1 Density* at 20 C (68 F). 8.33 g per cu cm (0.301 lb per cu in.)
D *1 Liquidus temperature.* 975 C (1780 F)
2 Solidus temperature. 935 C (1710 F)
6 Thermal expansion 20 to 300 C (68 to 572 F). 0.0000185 per °C (0.0000103 per °F)
11 Specific heat at 20 C (68 F). 0.09 cal per g per °C
16 Thermal conductivity at 20 C (68 F). 0.24 cal/sq cm/cm/°C/sec (58 Btu/sq ft/ft/°F/hr)
E *1 Volume conductivity* referred to standard copper, 20 C (68 F). 23%, annealed
2 Electrical resistivity at 20 C (68 F). 45 ohms per cir mil-ft, annealed
K *Mechanical properties.* Tube (1.0-in. OD, 0.065-in. wall, 0.025-mm grain size): tensile strength 60,000 psi; yield strength (0.5% extension under load) 27,000 psi; elongation in 2 in. 55%; Rockwell hardness F 77; apparent elastic limit 16,000 psi.
4 Machinability index. (free-cutting brass = 100). 30
M *Composition limits.* Tube (ASTM B 111), *components*: 76.00% min Cu; 1.75 to 2.50% Al; remainder zinc; *impurities*: 0.075% max Pb; 0.06% max Fe; and others 0.10% max. Arsenic, phosphorus or antimony are the other additions, made for the purpose of preventing dezincification.
N *7 Hot working temperature range.* 750 to 875 C (1400 to 1600 F)
9 Annealing temperatures. 425 to 600 C (800 to 1100 F)
11 Suited to forming by hot extrusion, cold drawing, cold rolling.

95 Cu – 5 Sn*

A *1 Common name.* **Phosphor Bronze, 5%—Grade A**
3 ASTM number. B103-A; B139-A; B159-A
B *1 Typical uses.* Beater bars, bridge bearing-plates, bellows, Bourdon tubing, clutch disks, cotter pins, diaphragms, fuse clips, fasteners, lock washers, sleeve bushings, springs, switch parts, truss wire, wire brushes, chemical hardware, perforated sheets, textile machinery, welding rods.
C *1 Density* at 20 C (68 F). 8.86 g per cu cm (0.320 lb per cu in.)
D *1 Liquidus temperature.* 1050 C (1920 F)
2 Solidus temperature. 950 C (1750 F)
6 Thermal expansion 20 to 300 C (68 to 572 F). 0.0000178 per °C
11 Specific heat at 20 C (68 F). 0.09 cal per g
16 Thermal conductivity at 20 C (68 F). 0.19 cal/sq cm/cm/°C/sec
E *1 Volume conductivity* referred to standard copper. 18%
2 Electrical resistivity at 20 C (68 F). 9.6 microhm-cm
K *Mechanical properties.* See Table I.
4 Machinability index (free-cutting brass=100). 20
M *Composition limits.* See Table II.
N *1 Melting temperature range.* 950 to 1050 C (1750 to 1920 F)
9 Annealing temperature. 475 to 675 (900 to 1250 F)

11 *Suited to forming* by blanking, drawing, etching, forming, bending, heading, upsetting, roll threading, knurling, shearing, spinning, squeezing, and swaging.
17 *Joining.* This alloy can be soft soldered, silver soldered, brazed, oxyacetylene welded, carbon-arc welded, and resistance welded.

* Compiled by the Copper & Brass Research Association and the Chase Brass & Copper Co.

Table II. Composition Limits of 65 Cu–18 Ni–17 Zn

Form	ASTM Specification	Components: Cu min	Cu max	Ni min	Ni max	Zn min	Zn max	Impurities: Pb max	Fe max	Mn max
Sheet	B 122, No. 2	63.0	66.5	17.0	19.5	remainder		0.10	0.25	0.50
Wire, rod, bar	B 151-A	63.0	66.5	17.0	19.5	remainder		0.05	0.25	0.50
Wire	B 206-A	63.0	66.5	16.5	19.5	remainder		0.10	0.25	0.50

55 Cu – 27 Zn – 18 Ni*

A *1 Common name.* **Nickel Silver, 18%—Alloy B**
3 ASTM number. B 122, No. 4; B 151-B; B 206-B
B *1 Typical uses.* Optical goods, springs, resistance wire.
C *1 Density* at 20 C (68 F). 8.70 g per cu cm (0.314 lb per cu in.)
D *1 Liquidus temperature.* 1055 C (1930 F)
6 Thermal expansion 20 to 300 C (68 to 572 F). 0.0000167 per °C
11 Specific heat at 20 C (68 F). 0.09 cal per g
16 Thermal conductivity at 20 C (68 F). 0.07 cal/sq cm/cm/°C/sec
E *1 Volume conductivity* referred to standard copper. 5.5%
2 Electrical resistivity at 20 C (68 F). 31 microhm-cm
F *4 Color.* White
K *Mechanical properties.* See Table I.
4 Machinability index (free-cutting brass=100). 30
M *Composition limits.* See Table II.

* Compiled by the Copper & Brass Research Association and the Chase Brass & Copper Co.

Table I. Mechanical Properties of 55 Cu–27 Zn–18 Ni

Condition	Section, in.	Tensile Strength, psi	Yield Strength, psi	Elongation, percentage	Rockwell Hardness
		Flat Products			
Annealed[a]	0.040	60,000	27,000	40	B 55

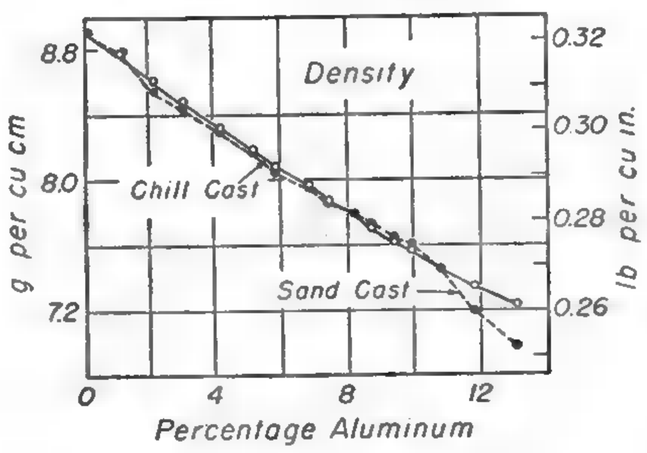
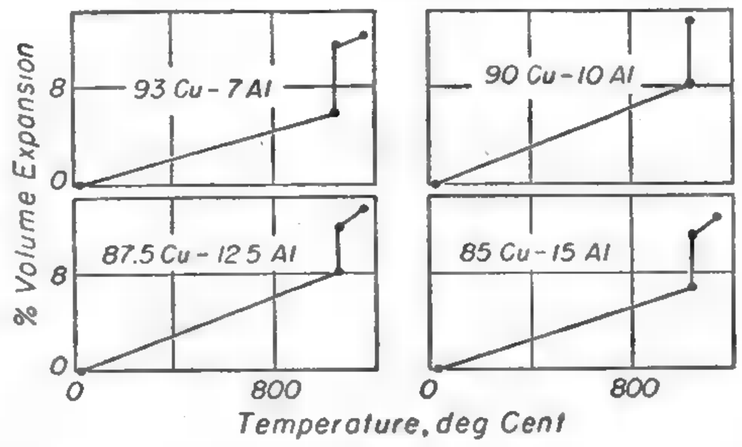
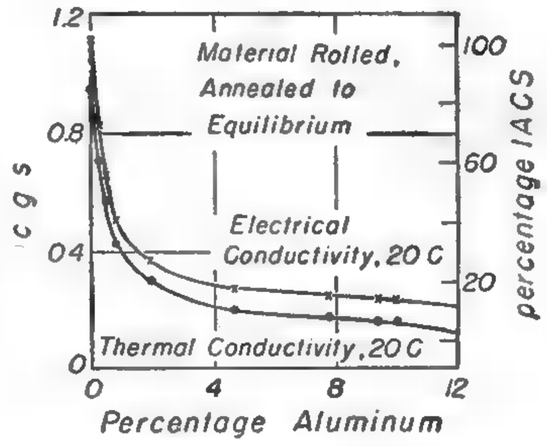
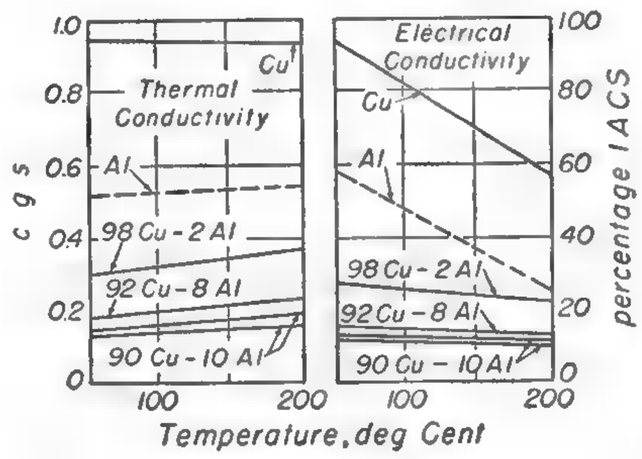
Some Properties of Aluminum Bronzes*

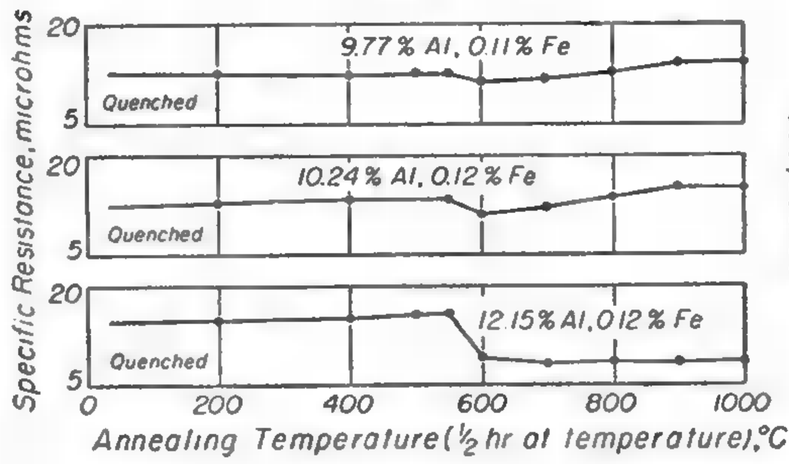
THIS COMPILATION summarizes graphically the effect of composition on some of the physical and mechanical properties of aluminum bronzes. Additional information concerning the properties of both cast and wrought alloys may be found in the data sheets for particular commercial aluminum bronzes, pages 929 to 933 and 941, 942.

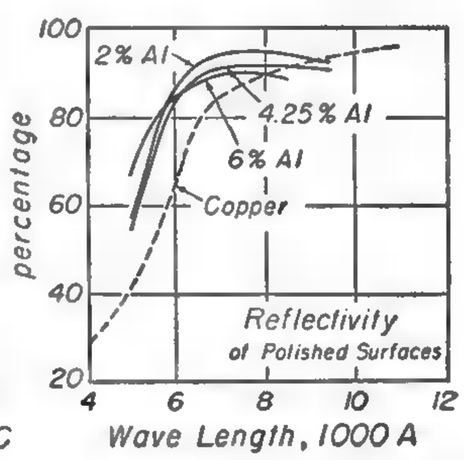


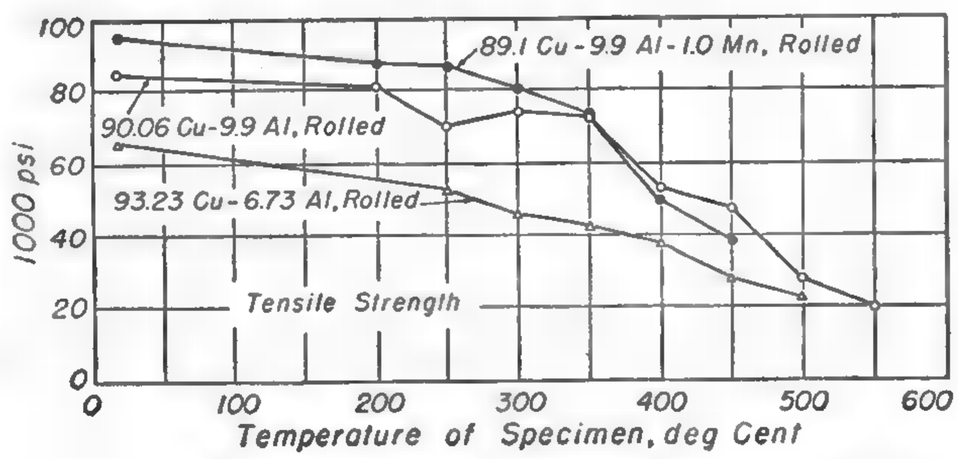


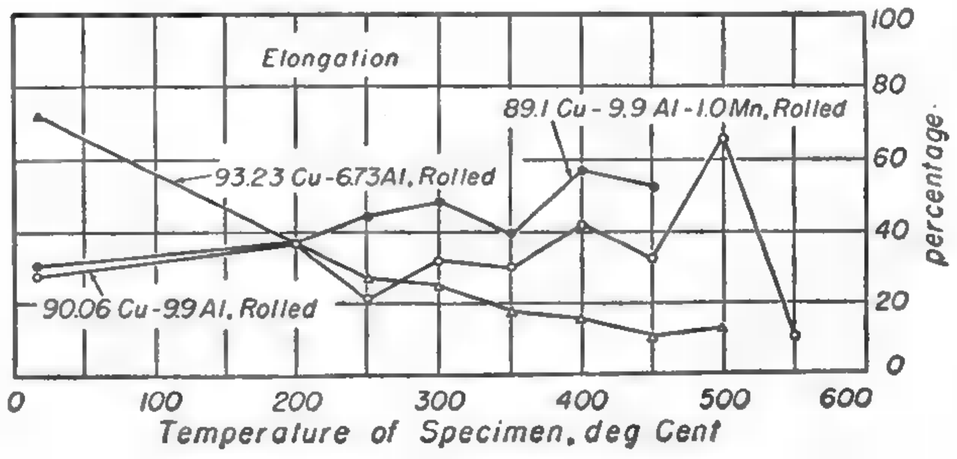












95 Cu – 5 Al*

A *2 Trade name.* **5% Aluminum Bronze**
3 ASTM numbers, government and other designations.

Form	ASTM	SAE	Federal	Army	Navy
Sheet, strip, plates.....	B 169 Alloy A	.....	QQ-B-666, Grade A	Federal	46B17c, Grade A
Rods, bars, shapes.....	.....	701A	.....	.....	.....
Rods for forging.....	B 124 Alloy 10	.....	.....	.....	.....
Tubes for condensers...	B 111	.....	.....	.....	.....

B *1 Typical uses. See* Cu – 10 Al. The low-alloy alpha-type aluminum bronzes, while suitable for both hot and cold working, are especially adapted to such cold worked forms as sheet, strip, wire, and tubing. Aluminum bronzes for "gold" decoration are usually of the 95% Cu, 5% Al type.

C *1 Density* at 20 C (68 F). 8.17 g per cu cm (0.295 lb per cu in.)

D *1 Liquidus temperature.* 1060 C (1940 F)
2 Solidus temperature. 1050 C (1920 F)
16 Thermal conductivity at 20 C (68 F).[6] 0.198 cgs
17 Thermal conductivity versus temperature. See "Some Properties of Aluminum Bronzes", top of this page.
19 Recrystallization temperature. Approx 350 C (660 F) at 44% reduction and 0.075-mm initial grain size.

E *1 Volume conductivity* referred to standard copper. 17.5%, annealed
2 Electrical resistivity at 20 C. 9.8 microhm-cm
4 Electrical resistivity (liquid) at 1100 C (2012 F).[38] 43.18 microhm-cm
5 Temperature coefficient of electrical resistivity 20 to 200 C. 0.00160 per °C. *See also* graphs at top of page.
8 Electrical resistivity versus plastic deformation at 20 C (68 F).[1] An increase from 15.6 to 17.5% IACS on annealing a sheet previously reduced 44%.
11 Slightly electropositive to copper.[39]

F *1 Reflectivity. See* graphs at the top of this page.

G *1 Influence of treatments on magnetic properties. See* Cu – 10 Al.

K *Mechanical properties. See* Table I and Fig. 1.
Fatigue tests on rod (reversed stress). Composition: 94.85% Cu, 5.62% Al, 0.07% Fe, rolled; tensile strength 72,000 psi; elongation 43%; endurance strength 19,000 psi for 10^8 cycles
4 Machinability index (free-cutting brass = 100). 20.

M *Composition limits* (ASTM spec). See Table II.
2 Consequences of exceeding impurity limits. See Cu – 10 Al.

N *Working Data. See* Cu – 10 Al.
7 Hot working temperature. 815 to 870 C (1500 to 1600 F)
9 Annealing temperatures. 425 to 750 C (800 to 1400 F)
11 Suited to forming by both hot and cold working; not

* Compiled by The American Brass Company

B *1 Typical uses.* Corrosion-resistant parts: marine pumps, shafts, propellers, trim, valves, nuts, and the like; pickling crates, chains, hooks, impeller blades in the chemical industry; beater bars and blades in the paper-making industry; also corrosion-resistant tubing of the alpha alloys. Heat-resistant parts: applications requiring strength and resistance to corrosion at high temperatures, as parts for internal-combustion engines; jaws and clamps for electric-welding equipment; gas-stove grill plates; and searchlight components. Usage where toughness, wearability, low coefficient of friction, and damping capacity are important: spindle bearings, bushings, gear wheels, pinions, worm wheels, roller-bearing cages; bearing material; wear and aligning plates for machines and for bridges; cam rollers, locking nuts, cam supports, damping bushings in airplanes. Applications where hardness and low friction (high aluminum) are desirable, as in dies for the forming and drawing of stainless steel and other metal strip and sheet, for instance, zinc and aluminum. Decorative usage (resistant to tarnish), as in coins, medallions, plaques, statues, grills, fireplace fittings, vanity sets, imitation jewelry; and as a "gold" pigment in paints.

C *1 Density* at 20 C (68 F). 7.58 g per cu cm (0.274 lb per cu in.)
5 Solidification shrinkage. 3.8 to 4.1% at the solidus. *See also* page 928.

* Compiled by The American Brass Company

† Iron, nickel and tin are usually present in amounts less than 1%. A typical composition for this alloy is: 89.25% Cu, 9.25% Al, 0.60% Fe, 0.50% Ni, 0.40% Sn.

G *1 Influence of treatment.* Commercial aluminum bronzes (without large additives) are virtually nonmagnetic. Appreciable additions of iron or nickel may make the alloys slightly magnetic. Certain alloys in the Cu-Al-Mn series, containing more than 5% Mn, are definitely magnetic (Heusler alloys).[3,8,33]

J *6 Microstructure. See* Reference 11.

K *Mechanical properties. See* Tables II, III and IV, Fig. 1.

Modulus of elasticity

12,000,000 to 18,000,000 psi for cast aluminum bronze of duplex type[12]

17,500,000 to 19,000,000 for "commercial aluminum bronzes"[3]

12,000,000 to 19,000,000 psi for aluminum bronzes in general[33]

Properties at elevated temperature. See page 928.

4 Machinability index. The aluminum bronzes are difficult to machine, but with high speed steel tools that have lower rake angles than for steel, they are machined in production without serious difficulty.

M *Composition limits* (ASTM). *See* Table V.

2 Consequences of exceeding impurity limits.

Iron greatly increases the strength and hardness of the alloy and refines the grain; in large quantities helps prevent "self annealing" (formation of coarse, brittle, cast structure).[1,3,5,11,33,25]

Nickel increases hardness and tensile strength but to a less extent than iron; increases resistance to corrosion in sea water and alkaline solutions, but not in fresh water or acids.[1,3,33]

Manganese affects the hardness and strength similarly to nickel; grain refiner; helps to incorporate lead into molten bronze (leaded aluminum bronze); in small amounts used for deoxidizing copper.[1,3,4,33]

Silicon, when carefully balanced, imparts great strength to certain aluminum bronzes; likely to have an embrittling effect in alpha-beta compositions; improves fluidity for certain casting alloys.[3,4,33,31]

Zinc and *iron* together are said to help prevent "self annealing"; zinc has a hardening effect on alpha alloys, but elongation decreases.[33]

Tin is said to be effective in preventing "self annealing"; not harmful up to 0.50%, but produces brittleness in amounts of 1.00% or more.[33]

Phosphorus addition of 0.05% is said to diminish hydrogen solubility; residual phosphorus should not exceed 0.05% because of the embrittling effect and the danger of hot shortness.[3]

Magnesium, like phosphorus, may have an embrittling effect.[33]

Cobalt increases hardness with little effect on grain size.[4]

Lead is used in bearing and machining alloys; as in brasses, however, it prevents hot rolling.[3,33]

Bismuth has a bad effect on hot working properties, as for brasses.

Antimony and *arsenic* are said to have bad effects.[33]

Table V. Composition Limits for 10% Aluminum Bronze

Form	ASTM Designation	Cu min	Cu max	Al min	Al max	Fe max	Ni[a] max	Si[a] max	Mn max	Sn max	Zn max	Te max	Others max
Rods, bars, shapes.....	B 150, type I	80	93	6.50	11	4	1	2.25	1.50	0.60	1	0.65	0.50[b]
Rods, forgings	B 124	78	93	6.50	11	4	5.50	2.25	2	0.60	..	...	...

(a) When Ni and Si are present together, only one shall be in excess of 0.25%. (b) See note under 82.5 Cu – 10 Al – 5 Ni – 2.5 Fe.

N *1 Melting practice.* General precautions are:

1 Use of high-purity metal and scrap.
2 Melting and pouring without too great turbulence (to avoid excessive formation and entrapment of oxide and gas).
3 Melting and pouring at temperatures not too high above the liquidus, in order to prevent excessive oxidation and gas absorption. Temperatures from 50 to 100 °C above the liquidus have been used successfully.

Aluminum is usually added in the form of a high-aluminum Cu-Al alloy. Fluxes may or may not be used. The charge is sometimes remelted in order to avoid "woody" structure. Strauss[33] reports that furnace atmospheres should not be reducing. Melting under carbon is advised by some, but commercial castings can be made without a cover. To minimize turbulence, Genders and Bailey[34] favor the Durville process. Bottom casting is sometimes employed. Vertical casting is used successfully for large castings.

The rate of pouring is important. Volume shrinkage is great, but it is stated that shrinkage difficulties may be caused primarily by the short solidification range.[3] A fairly rapid rate of cooling is essential to avoid "self-annealed" structure. Special precautions in regard to sand, precision and centrifugal casting are considered in reference 3. Aluminum bronzes are not generally suitable for die-casting.

7 Hot working temperature range. Varies with alloy and condition. 800 to 925 C (1470 to 1695 F) is a suitable range, with forging and extrusion temperatures near the upper limit.

11 Forming. Alpha-beta alloys are suitable for most hot working processes. They will stand a little cold work such as light drawing and rolling.

15 Heat treatment. Most references to hardening by heat treatment are concerned with alpha alloys, usually those with a high nickel content. The properties of alpha-beta alloys, however, can be varied by heat treatment. For optimum properties of a 10% aluminum bronze, Grard recommends quenching from 900 C (1652 F) and re-annealing at 675 to 700 C (1247 to 1292 F). For most commercial purposes, the alloy can be annealed at 650 C (1202 F), and then quenched. In general it is advisable to avoid annealing below 570 C (1058 F) and cooling too slowly from the annealing temperature. Forgings should be quenched. For precipitation hardening of alpha-type alloys, *see* references 9, 14, 17, 23, 19, 21.

17 Joining of aluminum bronzes in general. *Soft soldering* is not applicable. *Silver soldering* with all grades of solder; special flux; all types of flame. *Brazing* is not applicable. *Oxyacetylene welding and carbon-arc welding* are difficult, but possible with special fluxes and rods.[3] *Resistance welding* is possible with reasonably clean materials. *Metal-arc welding* is used with flux-coated electrodes.

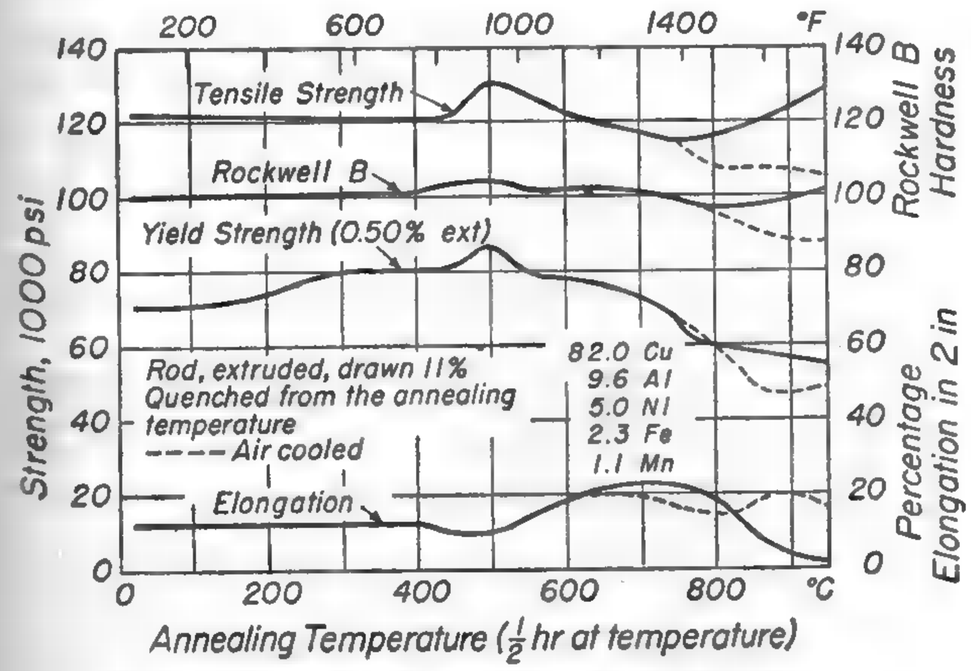

Fig. 1 Effect of annealing temperature on the mechanical properties of 82 Cu – 9.6 Al – 5 Ni – 2.3 Fe

115,800 psi; elongation in 4 $\sqrt{\text{area}}$ 10.8%; endurance strength for 56,800,000 cycles, 50,400 psi

Impact values for various aluminum bronzes are listed in the data sheet for Cu – 10 Al. (*1*) *Composition:* 82% Cu, 10.7% Al, 4% Fe, 4% Ni; forged and heat treated; Charpy 25 to 30 ft-lb. (*2*) *Composition:* 80% Cu, 10% Al, 5% Fe, 5% Ni; forged; Izod 10 ft-lb.

4 Machinability index. See Cu – 10 Al.

M *Composition limits* (ASTM spec). *See* Table II.

N *1 Melting practice. See* Cu – 10 Al.

7 Hot working temperature. 800 to 950 C (1470 to 1740 F)

11 Suited to forming primarily by hot working, but will stand slight cold reductions.

15 Heat treatment. See also Cu – 10 Al.
Grard[8] advises annealing at 900 C (1650 F) for similar compositions. Alloys of this type can be treated in several ways. Table III shows the variation in properties with heat treatment for hot rolled material.

17 Joining. See Cu – 10 Al.

References. The superscript numbers refer to the list of publications at the end of the data sheet for Cu – 10 Al.

Table II. Composition Limits for 10% Aluminum Bronzes Containing Nickel and Iron as Components

Form	ASTM Designation	Components								Impurities			
		Cu min	Cu max	Al min	Al max	Fe min	Fe max	Ni min	Ni max	Si max	Mn max	Sn max	Others max
Condenser-tube plates	B 171	remainder		8.0	11.0	1.5	3.5	4.0	7.0	...	0.5 to 2.0	...	0.50
Rods, bars, shapes	B 150, Type II	78	85	9	11	2	4	4	5.50	0.25	1.50	0.20	0.50[b]
Forging rods, bars, shapes	B 124	78	93	6.5	11	..	4	..	5.50[a]	2.25[a]	2.0	0.60	0.50

(a) B 124 and B 150. When nickel is present, silicon shall not exceed 0.25; conversely when silicon is present, nickel shall not exceed 0.25.
(b) B 150. Analysis made only for elements specified. If other elements are suspected or indicated, further analysis shall be made to determine that the total of these other elements is not in excess of 0.50%.

Table III. Effects of Heat Treatment on the Mechanical Properties of 82.5 Cu – 10 Al – 5 Ni – 2.5 Fe

Heat treatment No.	deg Cent	Tensile Strength, psi	Yield Strength (0.50% extension), psi	Elongation in 2 in., percentage	Rockwell Hardness, C scale	General Results
1	Quenched from 850, reheated to 600	109,000	63,000	25	76	High yield point with good ductility
2	Air cooled from 850	107,000	57,000	21	76	Fair qualities
3	Furnace cooled from 850 to 550, held 2 hr, then quenched	101,000	48,000	30	67	High ductility
4	Quenched from 950, reheated to 450	132,000	80,000	1.5	98	Maximum hardness and strength without cold work
5	Quenched from 850, cold drawn 23%, reheated to 450	151,000	94,100	0.5	100	Maximum hardness and strength

NOTE. Apparently there is a size factor for aluminum bronzes that limits the effectiveness of heat treatment. See page 257 of Reference 33.

55 Cu – 45 Ni

(Constantan)

See PROPERTIES OF NICKEL ALLOYS, page 1062.

Cu – 2 Be – 0.25 Co (or 0.35 Ni)

COMPILED BY PAUL A. BECK*

A *1 Common name.* **Beryllium Copper**
3 ASTM number. B 194–46aT (strip); B 195–46T (strip, special grade); B 196-46aT (rod and bar); B 197-46aT (wire)
4 Government number. Navy, Bureau of Aeronautics M 328; Navy 46C10 (INT); Army Air Forces 11070A

B *1 Typical uses.* Parts in which it is important to have a combination of excellent formability in the soft condition with high proportional limit, high fatigue strength, and great creep resistance in the hardened condition (for example, a great variety of springs); parts in which it is necessary to have corrosion resistance and relatively high electrical conductivity, or nonmagnetic behavior, coupled with high strength (springs, diaphragms, contact bridges, surgical instruments, bolts and screws); hard parts that will wear well against hardened steel (firing pins, dies, aircraft-engine counterweight bushings, small tools).

C *1 Density* at room temperature. 8.23 ± 0.02 g per cu cm (0.297 ± 0.01 lb per cu in.)
5 Solidification shrinkage. ⅛ in. per ft
6 (a) Dilation during aging (linear). minus 0.2%
(b) Increase in density during aging. 0.6%

D *1 Liquidus temperature.* 955 C (1750 F)
2 Solidus temperature. 864 C (1587 F)
6 Thermal expansion
20 to 100 C (68 to 212 F). 0.0000166 per °C
100 to 200 C (212 to 392 F). 0.0000172 per °C
200 to 300 C (392 to 572 F). 0.000019 per °C
11 Specific heat 30 to 100 C. 0.1 cal per ■
16 Thermal conductivity at 20 C (68 F).
0.20 cal/sq cm/cm/°C/sec, condition A;*
0.25 cal/sq cm/cm/°C/sec, condition AT;*
0.18, condition H;* 0.20, condition HT.*
19 Recrystallization temperature (minimum temperature for complete recrystallization in 1 hr). For 50% reduction, 480 C (900 F); 75% reduction, 430 C (810 F); 90% reduction, 370 C (700 F).
20 Grain size versus solution treatment temperature. *See* Fig. 1.

E *1 Volume conductivity* referred to standard copper. 17%, condition A;* 21%, condition AT.*
2 Electrical resistivity at 20 C (68 F). 10 microhm-cm, condition A;* 6.8 to 9.8 microhm-cm, condition AT.*

* Associate Professor of Metallurgy, University of Notre Dame, Notre Dame, Ind.

* See footnotes to table of Mechanical Properties.

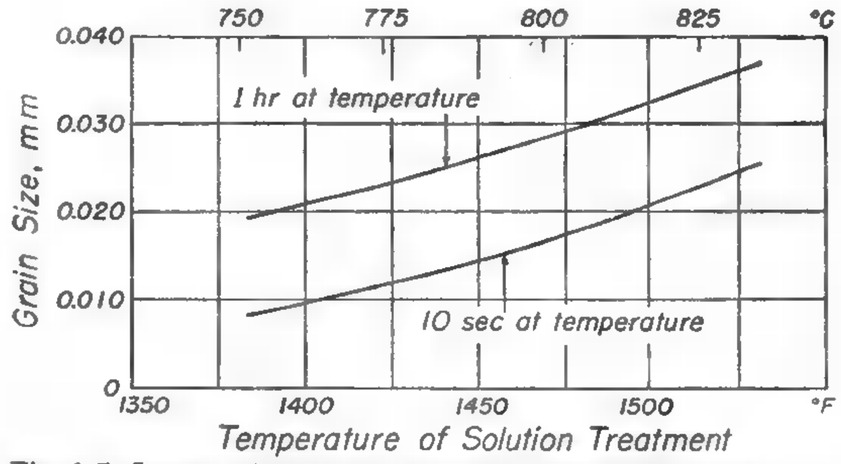

Fig. 1 Influence of solution treatment temperature and time on the grain size of beryllium copper

G *2 Magnetic susceptibility.* minus 0.45 × 10^{-6} cgs, conditions A or H; minus 0.62 × 10^{-6} cgs, conditions AT and HT.

I *1 General resistance to corrosion.* Similar to that of pure copper. It may be markedly reduced in some instances by the presence of oxidizing agents.
2 Specific resistance to corrosive agents.

Atmospheres: Excellent in industrial, marine and rural atmospheres
Natural fresh waters: Good resistance to all types
Sea water: Somewhat more resistant to sea water than is copper
Acids: Beryllium copper has good resistance to most organic acids, and may be used in contact with hot or cold dilute sulfuric acid, cold concentrated sulfuric, and cold dilute hydrochloric acid.
Alkalies: Good resistance to cold concentrated alkalies and to hot or cold dilute alkalies
Salts: Good resistance to most sulfates and chlorides. The chlorides are more corrosive than sulfates, and the salts of the heavy metals are more corrosive than the salts of the light metals.
Sulfides: Like pure copper, this alloy does not have good resistance to corrosion by sulfides, especially at high temperatures.
Organic chemicals: Excellent resistance to organic chemicals, such as alcohols, aldehydes, ketones, esters, and hydrocarbons.

CAUTION: Beryllium copper is not suitable for handling mercury or solutions of mercury compounds, ammonium hydroxide, nitric acid, ferric chloride, ferric sulfate, or acid chromates. It should not be exposed to halogen gases (fluorine, chlorine, bromine, and iodine) at elevated temperatures.

J *1 Crystal structure* of alpha. Face-centered cubic; $a = 3.565$ kX, solution treated, 2.1% Be in solid solution; and $a = 3.604$ kX, after precipitation at 300 C.

K *Mechanical Properties.* See Table I and Fig. 2.
Temperature coefficient of modulus of elasticity at 0 C (32 F). minus 35.0 × 10^{-5} per °C

Table I. Mechanical Properties of Beryllium Copper

Form	Condition*	Section, in.	Tensile Strength, 1000 psi	Yield Strength (0.01% offset), 1000 psi	Proportional Limit, 1000 psi	Elongation, percentage	Brinell Hardness Number	Rockwell Hardness Number	Modulus of Elasticity, 10^6 psi	Fatigue Strength for 10^8 cycles, 1000 psi
Strip	A	0.032	72	25	17	50	...	B 60	17	32.5(d)
Strip	½ H	0.032	95	62	50	12	...	B 93	17	35.6(d)
Strip	H	0.032	107	70	58	6	...	B 97.5	17	36.8(d)
Strip	AT	0.032	175	80	75(a)	5	...	C 41	19.5	35.2(d)
Strip	½ HT	0.032	188	105	90(a)	4	...	C 42	20	39.1(d)
Strip	HT	0.032	195	110	88(a)	3	...	C 42.5	20	40.7(d)
Strip	½ HT(f)	0.020	188.1	126	107(a)	2.5	...	30T 90.8	18.3	....
Strip	(78% red) T(f)	0.020	196.5	139	113.7(a)	1.4	...	30T 91.3	18.4	....
Rod	AT	0.75	190	140(e)	55(b)	3.7	380	....	18.4	....
Rod	HT	0.75	200	171(e)	100(b)	2.8	400	....	18.4	47 to 61.5(c)

* *Designation of tempers:*
A solution treated, quenched
AT solution treated, quenched and precipitation hardened
½ H solution treated, quenched, cold rolled 20.7% (if strip) or cold drawn 37.1% (if wire)
½ HT same as ½ H and precipitation hardened
■ solution treated, quenched, cold rolled 37.1% (if strip) or cold drawn 60.5% (if wire)
HT same as H and precipitation hardened

(a) Not corrected for true stress and strain. The traditional method for determining the proportional limit may lead to considerable error when applied to heat treated beryllium-copper alloys.
(b) Corrected for true stress and strain according to reference 4
(c) Polished specimens tested in the rotating-beam machine
(d) Cross-milled specimens tested in flexure-type machine
(e) True stress for 0.1% offset
(f) The data in these two lines were obtained under identical conditions (including identical heat treatment for minimum drift) except for the difference in the amount of cold work before heat treatment.

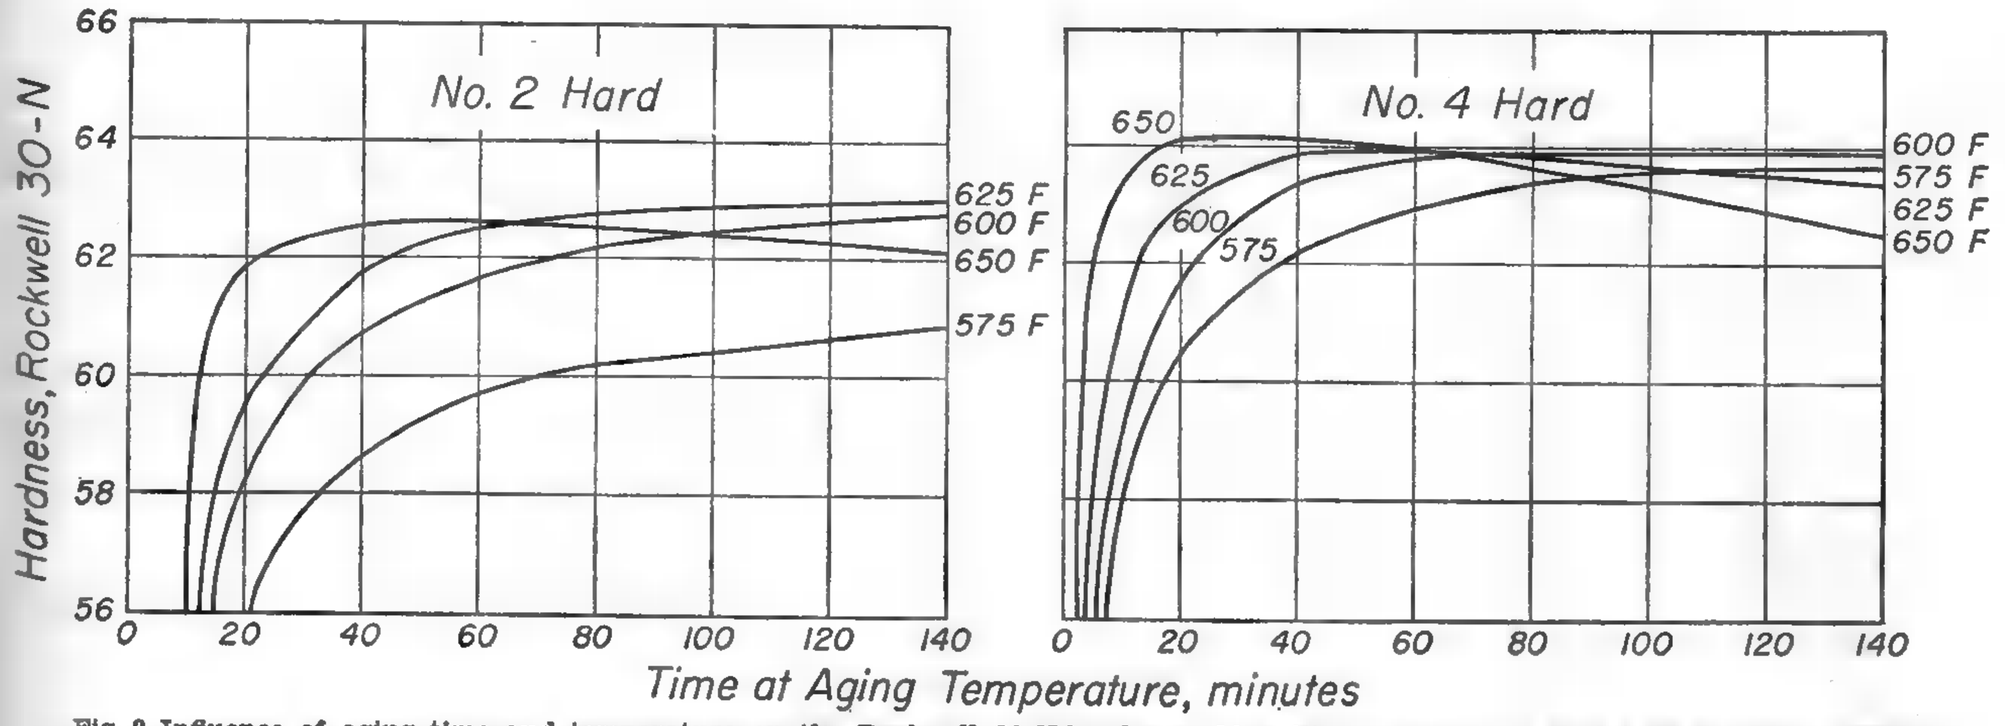

Fig. 2 Influence of aging time and temperature on the Rockwell 30-N hardness of beryllium copper alloy strip 0.028 in. thick. "Number 2 Hard" means "rolled 2 B&S numbers after solution treatment", before reheating for precipitation

M *Composition Limits* (ASTM specification for strip and wire). *Components*: 1.90 to 2.15% Be; 0.15% min Ni, Co plus Fe to 0.50% max Ni, Co plus Fe; *total impurities*, 0.50% max.

N *15 Heat Treatment. Solution treatment* at 756 to 788 C (1392 to 1450 F). In determining the total furnace time, allowance should be made for the time to reach the solution treatment temperature. This time will depend on such factors as furnace load and the thickness of the stock. The time for the stock at the actual temperature of solution treatment does not need to be longer than a few seconds. However, periods of several hours duration are often required if re-solution of the beta segregation is intended.

Precipitation hardening (aging) treatment.

From A temper, total furnace time 3 hr at 316 ± 3 C (600 ± 5 F)

From ½ H temper, total furnace time, 2 hr at 316 ± 3 C (600 ± 5 F)

From H temper, total furnace time, 2 hr at 316 ± 3 C (600 ± 5 F), up to a thickness of 0.75 in. For thicker stock, allow an additional hour for ½ H and H tempers. For accurate springs, higher aging temperatures are often used with correspondingly shorter aging time, in order to obtain minimum drift.

CASTING ALLOYS

COMPILED BY G. P. HALLIWELL*

88 Cu – 6 Sn – 1.5 Pb – 4.5 Zn

A *1 Common name.* **Leaded Tin Bronze**
2 Trade name. Navy M, Steam or Valve Bronze
3 ASTM number. B 30-45T, No. 2A (ingot)
4 Government number. QQ-B-691b, No. 1 (castings); Navy 46B8i, (castings)
5 Other designations. NFIMI-2A

B *1 Typical uses.* Steam or valve bronze bodies; high-grade steam or valve metal for use at temperatures as high as 550 F; valve bodies subject to medium pressure; oil pumps; gears; bushings; high-duty bearings; backing for babbitt-lined bearings.

* H. Kramer & Co., Chicago

Many of the data on mechanical properties have been obtained from ⅞-in. Webbert bars (*see* Fig. 3 in G. H. Clamer's 1946 AFA Foundation Lecture). For cast manganese bronzes, data are from a paper by G. P. Halliwell, Trans AFA, 51, 839 (1943)

C *1 Density* at 20 C (68 F). 8.7 ■ per cu cm (0.315 lb per cu in.)
7 Patternmaker's shrinkage. 3/16 to 7/32 in. per ft

D *2 Solidus temperature.* 982 to 999 C (1800 to 1830 F)
6 Thermal expansion 21 to 260 C (70 to 500 F). 0.0000185 per °C (0.0000103 per °F)

E *1 Volume conductivity* referred to standard copper. 14%

K *Mechanical properties.* Sand cast (0.505 in. section): tensile strength 38,000 psi; yield strength (0.5% elongation under load) 16,000 psi; elongation 35%; reduction of area 35%; Brinell hardness number (500 kg load) 66; Izod 14 ft-lb; compressive strength (0.001 in. set) 13,000 psi, (0.1 in. set) 34,000 psi; modulus of elasticity 13,000,000 psi.

M *Composition limits.* See Table I.

N *Melting.* See data sheet for 80 Cu – 10 Sn – 10 Pb.

Table I. Composition Limits of 88 Cu – 6 Sn – 1.5 Pb – 4.5 Zn

Form	Components								Impurities					
	Cu min	Cu max	Sn min	Sn max	Pb min	Pb max	Zn min	Zn max	Ni max	Fe max	Sb max	S max	Si max	P max

Ingot	69.0	73.0	4.50	5.75	22.00	24.50	0.5	0.5	0.10	0.75	0.08	0.03

(a) Copper (min) may be calculated as copper plus nickel.

85 Cu – 5 Sn – 5 Pb – 5 Zn

A *1 Common name.* 85-5-5-5
2 Trade name. Ounce Metal or Composition Metal
3 ASTM number. B 30-45T, No. 4A; B 145-46T, No. 4A
4 Government number. QQ-B-701a, No. 2; QQ-B-691b, No. 2
5 Other designations. SAE 40

B *1 Typical uses.* General castings requiring fair strength, soundness and good machining properties. Low-pressure valves, pipe fittings, gasoline-line and oil-line fittings, small gears, fire equipment fittings, small pump castings, ornamental fixtures.

C *1 Density* at 20 C (68 F). 8.80 ■ per cu cm (0.318 lb per cu in.)

D *2 Solidus temperature.* 988 to 1004 C (1810 to 1840 F)

6 Thermal expansion 21 to 204 C (70 to 400 F). 0.0000191 per °C (0.0000109 per °F)

E *1 Volume conductivity* referred to standard copper. 15%

F *4 Color.* Reddish bronze

K *Mechanical properties.* Sand cast: tensile strength 34,000 psi; yield strength (0.5% elongation under load) 17,000 psi; elongation 25%; reduction of area 25%; Brinell hardness number 60; modulus of elasticity 13,-500,000 psi; Izod 9 ft-lb; compressive strength (0.001 in. set) 11,000 psi; (0.1 in. set) 31,000 psi.

M *Composition limits.* See table below.

N *4 Preferred deoxidizers.* 15% P-Cu
5 Type of flux. None
6 Precautions in melting. Oxidizing atmosphere

Form	Components: Cu[a] min	Cu max	Sn min	Sn max	Pb min	Pb max	Zn min	Zn max	Impurities: Ni[a] max	Fe max	Sb max	■ max	Si max	P max

(a) Copper (min) may be calculated as copper plus nickel.

71 Cu – 1 Sn – 3 Pb – 25 Zn

A *1 Common name.* **Leaded Yellow Brass**
2 Trade name. High-Copper Yellow Brass
3 ASTM number. B 30-45T, No. 6A; B 146-46T, No. 6A
B *1 Typical uses.* Yellow brass alloy plumbing fixtures, fittings and trimmings; valves; chandeliers; andirons; general hardware; ornamental work.
C *1 Density* at 20 C (68 F). 8.50 g per cu cm (0.307 lb per cu in.)
D *2 Solidus temperature.* 927 C (1700 F)
6 Thermal expansion 21 to 93 C (70 to 200 F). 0.0000207 per °C (0.0000115 per °F)
E *1 Volume conductivity* referred to standard copper. 25%
F *4 Color.* Yellow
K *Mechanical properties.* Sand cast (0.505 in. section: tensile strength 35,000 psi; yield strength (0.5% elongation under load) 12,000 psi; elongation 35%; reduction of area 30%; Brinell hardness number (500 kg load) 48; modulus of elasticity 13,000,000 psi; compressive strength (0.001 in. set) 9,000 psi (0.1 in. set) 30,000 psi.
M *Composition limits.* See table at the top of page 939.
N *4 Preferred deoxidizer.* None
5 Type of flux. None
6 Precautions in melting. Oxidizing atmosphere

Form	Components								Impurities					
	Cu min	Cu max	Sn min	Sn max	Pb min	Pb max	Zn min	Zn max	Ni max	Fe max	Sb max	S max	Si max	P max

60 Cu – 1 Sn – 1 Pb – 38 Zn

A *1 Common name.* **Leaded Yellow Brass**
2 Trade name. Die-Cast Brass
3 ASTM number. B 30-45T, No. 6C; B 146-46T, No. 6C
4 Government number. QQ-B-621a, "A"; Navy 46B10h
B *1 Typical uses.* Spring bushing alloy; hardware fittings; ornamental castings; ship trimmings.
C *1 Density.* 8.40 g per cu cm (0.304 lb per cu in.)
D *2 Solidus temperature.* 913 to 940 C (1675 to 1725 F)
6 Thermal expansion 21 to 260 C (70 to 500 F). 0.0000216 per °C (0.000012 per °F)
E *1 Volume conductivity* referred to standard copper. 20 to 26%
F *4 Color.* Yellow
K *Mechanical properties.* Sand cast: tensile strength 40,000 psi; yield strength (0.5% elongation under load) 14,000 psi; elongation 25%; reduction of area, 25%; Brinell hardness number (500 kg load) 65; modulus of elasticity 14,000,000 psi.
M *Composition limits.* See table below.
N *Melting.* See preceding data sheet.

Form	Components								Impurities			
	Cu min	Cu max	Sn min	Sn max	Pb min	Pb max	Zn min	Zn max	Ni max	Fe max	Al min	Al max
Sand cast	60.00	65.00	0.5	1.50	0.75	1.50	remainder		...	0.75	...	0.50
Ingot	59.00	63.00	0.5	1.50	0.75	1.25	remainder		0.5	0.5	0.1	0.5

62 Cu – 26 Zn – 3 Fe – 5.5 Al – 3.5 Mn

A *1 Common name.* **High-Strength Yellow Brass**
2 Trade name. High-Strength Manganese Bronze
3 ASTM number. B 30-45T, No. 8C; B 147-46T, No. 8C
4 Government number. Navy 46B29(INT)-1, A and B
B *1 Typical uses.* Extra heavy-duty, high-strength alloy for large valve stems, gears, cams; bearings (slow-speed, heavy-load type); screw-down nuts; bridge parts; hydraulic cylinder parts.
C *1 Density* at 20 C (68 F). 7.9 g per cu cm (0.285 lb per cu in.)
D *1 Liquidus temperature.* 899 C (1650 F)
6 Thermal expansion 21 to 260 C (70 to 500 F). 0.0000198 per °C (0.000011 per °F)
16 Thermal conductivity. 13% that of copper
E *1 Volume conductivity* referred to standard copper. 12%
F *4 Color.* Yellow
K *Mechanical properties.* Sand cast: tensile strength 115,000 psi; yield strength (0.5% elongation under load) 70,000 psi; elongation 15%; reduction of area 15%; Brinell hardness number (3000 kg load) 210; modulus of elasticity 15,500,000 psi; Izod 12 ft-lb; compressive strength (0.001 in. set) 60,000 psi (0.1 in. set) 100,000 psi
M *Composition limits.* See table below.
2 Consequences of exceeding impurity limits. Excessive tin causes brittleness; excessive lead decreases the elongation; and excessive nickel decreases both tensile strength and elongation.

Form	Components										Impurities		
	Cu min	Cu max	Fe min	Fe max	Al min	Al max	Mn min	Mn max	Zn min	Zn max	Pb max	Sn max	Ni max
Sand cast.....	60.00	68.00	2.00	4.00	3.00	7.50	2.50	5.00	remainder		0.2	0.5	...
Ingot	60.00	68.00	2.00	4.00	3.00	7.50	2.50	5.00	remainder		0.1	0.5	1.00

58 Cu – 39.25 Zn – 1.25 Fe – 1.25 Al – 0.25 Mn

A *1 Common name.* **High-Strength Yellow Brass**
2 Trade name. Manganese Bronze
3 ASTM number. B 30-45T, No. 8A; B 147-46T, No. 8A
4 Government number. QQ-B-731b, Class A (ingot); QQ-B-726c, Class A (castings)
5 Other designations. SAE 43
B *1 Typical uses.* Propeller hubs, blades and other parts in contact with salt water and fresh water; gears; liners; valve stems; complicated lever arms where both strength and toughness are required.
C *1 Density* at 20 C (68 F). 8.2 g per cu cm (0.296 lb per cu in.)
D *1 Liquidus temperature.* 904 C (1660 F)
6 Thermal expansion 21 to 93 C (70 to 200 F). 0.0000216 per °C (0.000012 per °F)
E *1 Volume conductivity* referred to standard copper. 18%
K *Mechanical properties.* Sand cast: tensile strength 70,000 psi; yield strength (0.5% elongation under load) 28,000 psi; elongation 30%; reduction of area 30%; Brinell hardness number (500 kg load) 125; modulus of elasticity, 15,000,000 psi. Compressive strength (0.001 in. set) 24,000 psi; (0.1 in. set) 87,000 psi.
M *Composition limits.* See table below.
N *4 Deoxidizer.* None
5 Type of flux. None
6 Precautions in melting. Slightly oxidizing atmosphere

Form	Components									Impurities		
	Cu min	Cu max	Fe min	Fe max	Al min	Al max	Mn max	Zn min	Zn max	Sn max	Pb max	Ni max
Sand cast	55.00	60.00	0.4	2.00	0.50	1.50	1.50	remainder		1.00	0.40	0.50
Ingot	55.00	60.00	0.4	2.00	0.50	1.50	1.50	remainder		1.00	0.30	0.50

59 Cu – 0.75 Sn – 0.75 Pb – 37 Zn – 1.25 Fe – 0.75 Al – 0.5 Mn

A *1 Common name.* **Leaded Manganese Bronze**
2 Trade name. Stem Manganese Bronze
3 ASTM number. B 30-45T, No. 7A; B 147-46T, No. 7A
4 Government number. QQ-B-726c, Class D
B *1 Typical uses.* Free-machining manganese bronze for valve stems, marine castings and fittings, pump bodies, gas-engine bases, lever arms, brackets, gears
C *1 Density.* 8.2 g per cu cm (0.296 lb per cu in.)
D *2 Solidus temperature.* 914 to 940 C (1675 to 1725 F)
6 Thermal expansion 21 to 204 C (70 to 400 F). 0.0000205 per °C (0.0000114 per °F)
F *4 Color.* Yellow
K *Mechanical properties.* Sand cast: tensile strength 65,000 psi; yield strength (0.5% elongation under load) 30,000 psi; elongation 18%; reduction of area 20%; Brinell hardness number (500 kg load) 85; modulus of elasticity 15,000,000 psi; compressive strength (0.001 in. set) 23,000 psi, (0.1 in. set) 87,000 psi; Izod 20 to 40 ft-lb.
M *Composition limits.* See table below.

Form	Cu min	Cu max	Sn min	Sn max	Pb min	Pb max	Fe min	Fe max	Al min	Al max	Mn min	Mn max	Ni max	Zn
Sand cast	56.00	62.00	...	1.50	0.50	1.50	...	2.00	...	1.50	...	1.5	...	remainder
Ingot	56.00	62.0	0.5	1.00	0.5	1.00	0.75	1.50	0.25	1.00	0.10	0.50	0.5	remainder

66 Cu – 5 Sn – 1.5 Pb – 2 Zn – 25 Ni

A *1 Common name.* **Nickel Silver**
2 Trade name. Leaded Nickel Bronze
3 ASTM number. B 30-45T, No. 11B; B 149-46T, No. 11B
B *1 Typical uses.* Dairy and soda fountain equipment, valves and valve seats for elevated temperatures, hardware, musical instruments, keys.
C *1 Density* at 20 C (68 F). 8.8 to 8.9 g per cu cm (0.318 to 0.322 lb per cu in.)
D *16 Thermal conductivity.* 6.5% that of copper.
E *1 Volume conductivity* referred to standard copper. 4 to 5%
F *4 Color.* Silvery white
K *Mechanical properties.* Sand cast: tensile strength 50,000 psi; yield strength (0.5% elongation under load) 24,000 psi; elongation 15%; reduction of area 15%; Brinell hardness number (500 kg load) 130.
M *Composition limits.* See table below.
N *Melting.* See the next data sheet.

Form	Components										Impurities				
	Cu min	Cu max	Sn min	Sn max	Pb min	Pb max	Zn min	Zn max	Ni min	Ni max	Fe max	Sb max	S max	Si max	P max

60 Cu – 3 Sn – 5 Pb – 16 Zn – 16 Ni

A *1 Common name.* **Leaded Nickel Brass**
2 Trade name. Nickel Silver
B *1 Typical uses.* Free-machining brass for valves, hardware, boat and railroad-car fittings, pipe fittings.
C *1 Density* at 20 C (68 F). 8.95 ■ per cu cm (0.320 lb per cu in.)
D *16 Thermal conductivity.* 7% that of copper
E *1 Volume conductivity* referred to standard copper. 5 to 6%
F *4 Color.* Nickel, silvery
K *Mechanical properties.* Sand cast: tensile strength 38,000 psi; yield strength (0.5% elongation under load) 17,000 psi; elongation 25%; reduction of area 25%; Brinell hardness number (500 kg load) 75.
M *Composition limits.* Sand cast: *components,* 58.00 to 61.00% Cu, 2.5 to 3.5% Sn, 4.50 to 5.50% Pb, 15.5 to 17.0% Ni, the remainder zinc; *impurities,* 1.00% max Fe, 0.25% max Sb, 0.05% max S, and 0.50% max Mn.
N *4 Preferred deoxidizers.* Mg–Cu and Mn–Cu
5 Type of flux. Neutral
6 Precautions in melting. Oxidizing atmosphere

89 Cu – 1 Fe – 10 Al

A *1 Common name.* **Aluminum Bronze**
2 Trade name. Aluminum Bronze or 89–1–10 Aluminum Bronze
3 ASTM number. B 148-46T, grade 9B; B 30-45T, 9B
4 Government number. AAF 11076 (castings); QQ–B–671a, grade B
5 Other designations. SAE 68B
B *1 Typical uses.* General-purpose aluminum bronze for pickling baskets, steel-mill slippers, nuts, internal gears, and marine equipment welding jaws. This alloy is subject to heat treatment
D *6 Thermal expansion* at 21 to 260 C (70 to 500 F) 0.0000171 per °C (0.0000095 per °F)
16 Thermal conductivity. 14% that of copper
E *1 Volume conductivity* referred to standard copper. 14%
F *4 Color.* Yellow
K *Mechanical properties.* See table below.
M *Composition limits.* Sand cast: *components,* 86.9% min Cu, 0.75 to 1.50% Fe, 9.0 to 11.0% Al.
N *2 Casting temperature range.* 1120 to 1200 C (2048 to 2200 F)
4 Deoxidizer. None.
5 Type of flux. None
6 Precautions in melting. Oxidizing or neutral atmosphere and minimum agitation
15 Heat treatment.
A Solution treatment at 870 to 900 C (1600 to 1650 F), quenched in water and agitated rapidly; aged at 595 to 650 C (1100 to 1150 F) for 1 hr, quenched in water.
B Solution treatment, same as *A;* aged at 540 C (1000 F) for 1 hr, quenched in water.

Condition[c]	Aluminum, percentage	Tensile Strength, psi	Yield Strength,[a] psi	Elongation, percentage	Reduction of Area, percentage	Brinell Hardness Number [b]

The Lead Industry

BY F. E. WORMSER* AND R. L. ZIEGFELD*

LEAD is one of the oldest metals known to man. Probably the earliest specimen is a figure from about 3000 BC found in the Temple of Osiris at Abydos and preserved in the British Museum. The Pharaohs, Assyrians and Babylonians had many uses for lead in ornamental objects and for structural purposes. About 2000 years BC the Chinese made their first money of lead. In ancient Greece and Rome, bronze coinage contained 3 to 30% Pb.

Perhaps the most interesting historical application of lead was its general use by the Roman people for water pipes. The pipe was made in 15 standard sizes and regular 10-ft lengths. Many of these lead pipes, in an almost perfect state of preservation, have been dug up in modern times from the ruins of Pompeii and Rome, and in England where the Romans penetrated during invasions. The old Roman baths at Bath, England, use the same lead pipe that was installed by the Romans 1900 years ago. Roman lead pipe was made by folding heavy sheets of cast lead and fusing the seams together.

Many magnificent buildings, erected in the fifteenth and sixteenth centuries, still stand under their original lead roofs. Leaden ornaments, statues, leader heads and cisterns—many of them architectural treasures—have come down to us in a perfect state of preservation.

Lead Minerals. Although at least 60 minerals containing lead are known to science, the lead of commerce is derived almost exclusively from one mineral, galena, the sulfide of lead. The oxides and other salts of lead are comparatively unimportant sources of supply. Common lead minerals include galena, PbS; cerussite, $PbCO_3$; anglesite, $PbSO_4$; crocoite, $PbCrO_4$; wulfenite, $PbMoO_4$; vanadinite, $3Pb_3(VO_4)_2 \cdot PbCl_2$; and pyromorphite, $3Pb_3(AsO_4)_2 \cdot PbCl_2$.

Lead Mining. Lead ore is mined in many countries, frequently in association with zinc ore. The United States is the most important source, followed by Australia, Canada and Mexico. Other important producing areas are Silesia, Burma, Spain, North Africa, Peru and Argentina, although production in all but the last two was badly affected by World War II.

With the development of the flotation process for the treatment of complex lead-zinc ores, many mines are now productive where formerly it was impossible, or extremely difficult, to separate the lead and zinc from each other. The flotation process has revolutionized the concentration of lead ores, both simple and complex. Lead sulfide or galena, the principal lead mineral found all over the world, is especially well suited to treatment by flotation.

Smelting and Refining. When they leave the concentrating mill, lead concentrates contain more than 40% Pb, generally 60%. The concentrates are roasted to remove the sulfur and to agglomerate the fine flotation product, which is not physically desirable in a blast furnace. The roasted sinter is charged into the top of a heated blast furnace

Lead (by difference), min, per cent	99.94	99.90	99.90	99.85	99.85	99.73	99.93

(a) "Corroding lead" is a designation that has been used for many years in the trade to describe lead refined to a high degree of purity.
(b) "Chemical lead" has been used for many years to describe the undesilverized lead produced from southeastern Missouri ores.
(c) Acid lead is made by adding copper to fully refined lead.
(d) Copper lead is made by adding copper to fully refined lead.
(e) "Common desilverized lead A and B" are designations that are used to describe fully refined desilverized lead.
(f) "Soft undesilverized lead" is used in the trade to describe the type of lead produced from ores of the Joplin, Mo., district.

along with suitable fluxes and coke; the resulting impure lead-base bullion, containing silver, gold and various impurities, is shipped to the refinery for further treatment before the metal is suitable for use in industry.

In the United States, the Parkes process is widely used for lead refining. Electrolytic refining is also practiced, as well as the Betterton process, a development of recent years that depends on chlorination.

In the Parkes process the impure lead is melted and allowed to cool below the freezing point of copper, which crystallizes and is removed by skimming. The lead then passes to a reverberatory or softening furnace. Here the temperature is raised, and a blast of air oxidizes any antimony or arsenic present, thus forming a skin, which must be removed. The lead then goes to desilverizing kettles where small amounts of zinc are added. Since gold and silver have a greater affinity for zinc than for lead, these precious metals immediately leave the lead and combine with the zinc. The zinc-rich compound, lighter than lead, rises to the surface and when the temperature is lowered, solidifies in a skin, which is readily skimmed and treated to recover the precious metals.

Refined commercial lead of a purity of 99.99% Pb is common. Pig lead is generally cast in bars weighing about 100 lb each. The ores of southeastern Missouri contain too little silver for profitable desilverizing. Some of this ore contains a minute amount of copper, from 0.04 to 0.08%, which makes the pig lead derived from it particularly desirable in the chemical industries; hence its designation "chemical lead".

Secondary Lead.* The production of lead from scrap has become increasingly important in recent years, amounting to as much as 50% of total domestic production. The principal source of lead scrap is old storage batteries; sheet, pipe, cable sheathing and other lead products are also used. Large amounts of antimonial lead and some soft lead are thus produced. Considerable tonnages of scrap solder, bearing metals and type metal are recovered and used again, generally after the addition of sufficient new metal to rectify the composition.

Grades of Lead. The commercial grades of pig lead available to the consumer under ASTM Specification B 29-43 are given in Table I.

Antimonial lead is also available, containing from 1 to 25% Sb and averaging about 6 to 7%. Its principal use is in the manufacture of storage batteries.

Lead Industries. The following are the sellers of primary pig lead in the United States: American Metal Co. Ltd., American Smelting & Refining Co., Anaconda Sales Co., Bunker Hill & Sullivan Mining & Concentrating Co., Eagle-Picher Co., National Lead Co., St. Joseph Lead Co., C. Tennants Sons Co., and United States Smelting, Refining & Mining Co., Inc.

Uses of Lead. Before 1929 lead was used principally in electrical applications, as in the manufacture of lead-sheathed power and telephone cable and in the manufacture of storage batteries, but the use of lead for the manufacture of white lead was also extremely important. During the depression, the production of white lead and other pigments became more important than the electrical uses as an outlet for newly mined pig lead; more recently the electrical uses have assumed their old importance. Table II shows a tonnage comparison of the uses of lead in 1929, 1937 and 1944.

* *See also* the article "Secondary Metals", page 741.

Table II. Uses of Lead in the United States[a]

(In Short Tons)

	1929	1937	1944
White lead	119,700	86,000	60,000
Red lead and litharge[b]	30,000	57,000	80,000
Storage batteries	210,000	192,000	307,000
Cable covering	220,000	90,000	131,000
Building[c]	96,000	45,000	70,000
Tetraethyl	(d)	21,400	85,200
Automobiles	18,000	12,000	1,000
Ammunition	41,100	39,500	63,000
Terneplate	4,200	6,400	6,000
Foil	39,800	21,700	20,000
Bearing metal	33,000	15,000	41,000
Solder	37,000	22,000	41,000
Type metal	18,000	17,000	25,000
Calking	31,500	15,000	32,000
Other uses	74,000	38,700	127,800
Total	972,300	678,700	1,090,000

(a) American Bureau of Metal Statistics. Includes primary and secondary lead. (b) Exclusive of oxides for storage batteries. (c) Includes lead used in chemical construction. (d) Among "Other uses"

The market for lead may be classified conveniently into those applications where lead is used as a chemical compound and those where it is used in the metallic form, either alone or alloyed with some other metal.

The chemical compounds most important commercially are the hydrated basic lead carbonate, commonly known as white lead, basic lead sulfate (white and blue), litharge, red lead, the lead chromates, tetraethyl lead, and lead arsenate.

In the metallic form lead finds an important application in building construction as both pipe and sheet, and in solder. Lead is used also in important alloys, such as type metal, antimonial lead for storage batteries, bearing alloys, foil and collapsible tubes, as a coating for other materials, as lead weights, calking lead, gaskets, seals, cable sheathing, bullets and shot.

Basic Lead Carbonate. Basic lead carbonate is the most widely used of the lead pigments and forms the basis of the highest grade paint.

Basic Lead Sulfate. Basic lead sulfate is made directly from pig lead by a volatilization process in which the molten lead is fed through an atomizing flame in the presence of sulfur gases and air. The resulting fumed pigment is collected in baghouses.

Litharge. Litharge is a monoxide of lead (PbO) produced in powder and flake forms and containing approximately 93% Pb and 7% O.

Red Lead. Red lead, an oxide having the formula Pb_3O_4, is made by heating powdered litharge at carefully controlled temperature, lower than for making litharge.

Tetraethyl Lead. This liquid is the antiknock ingredient in virtually all modern high-test gasoline.

Sheet Lead. This useful metallic lead product is rolled in widths up to 11¾ ft, with standard widths of 8 ft, and in any thicknesses desired. Sheet lead is widely used in equipment for the chemical industry, where its resistance to attack from sulfuric acid makes it valuable in many industrial processes. Sheet lead is used also in building construction as a roofing material, for flashing, for shower pans, for X-ray-proofing and soundproofing.

Lead Pipe. Lead pipe has had a long career in transporting water and chemicals. In the plumbing industry, lead is highly favored for pipes and traps.

Soldering Alloys. One of the commonest of the lead alloys is solder, containing 50% Pb and 50% Sn by weight —the half and half grade. Other solders, with many compositions that include between 0 and 60% Sn, are widely used industrially. Plumbers' wiping solder contains 38 to 42% Sn, 0 to 2% Sb, with the remainder lead.

Hard Lead (Lead-Antimony Alloys). Hard lead contains from 1 to 12% Sb. Manufacturers of storage batteries use great quantities of antimonial lead containing approximately 7 to 12% Sb and frequently ¼% Sn. Antimonial lead sheet (6% Sb) is used widely in the United States for building construction also. Hard lead is used in shrapnel and collapsible tubes.

Bearing Alloys. Lead-base ("white metal") bearing alloys vary widely in composition. A common composition for a lead-base bearing used in railroad cars is 86% Pb, 5% Sn and 9% Sb. Copper-lead alloys for bearings contain as much as 40% Pb. Leaded bronzes contain smaller amounts of lead and are essentially mixtures of lead, copper and tin, with a lead content of 4 to 25%. Numerous alloys of lead and alkaline earth metals such as calcium and sodium are used as bearing materials. *See also* page 745.

Type Metals. These alloys are made from lead, tin and antimony. For typical compositions, see page 957.

Fusible Lead Alloys. Many lead alloys melt at low temperatures and are used for electric fuses, automatic sprinkler systems and boiler plugs. Compositions will be found on page 744 of this Handbook.

Terneplate. Terne metal, an alloy of lead and tin, is used to coat steel sheets. Terne alloy contains from 10 to 25% Sn with the remainder lead. Lead alloy coatings that contain as little as 2 to 2.5% Sn are increasingly popular.

Lead Foil. Lead foil is generally known as composition metal foil and is usually made by rolling a sandwich of lead between two sheets of tin, producing a tight union of the metals. Thicknesses of 0.0005 in. or less are common.

Ammunition. Large quantities of lead are used in ammunition for both military and sporting purposes. The alloy used may contain up to 1% As, for shot, and up to 2% Sb, for bullet cores.

Lead Storage Batteries. The production of lead storage batteries requires large quantities of metallic lead and lead pigments. These batteries consist of a series of plates made from antimonial lead and pasted with a mixture of litharge and red lead. The electrolyte is sulfuric acid. The lead used for this purpose is generally reclaimed after the battery has finished its useful life. During the depression and since, lead reclaimed from old batteries has become an important source of the metal, at times furnishing an amount of lead almost equivalent to that recovered from mining operations.

Cable Sheathing. To provide durable protection against moisture, lead sheaths are extruded around electrical power and communications cables. Chemical lead and 1% antimonial lead are most commonly employed for this purpose. Lead alloyed with 0.03% Ca has also been used.

The Melting and Casting of Lead and Lead Alloys

By E. J. Minarcik*

LEAD and lead alloys were among the earliest metals used by man. The ease of handling lead is well known; and the casting characteristics are excellent, producing sound dense castings rapidly. The low melting points (650 F and less) result in low fuel costs, low maintenance and low losses in dross. The reclamation value of scrap from castings is almost 100% of the original alloy.

The beauty and fidelity of modern high-speed printing methods, particularly of multicolor printing, attest to the quality and precision of lead alloy castings (type metals).

Fuels and Heating. The low melting points allow the use of any type of fuel that is available or most economical. The plumber's lead-pot is heated by gasoline torch and contains only a few pounds of solder. The large plant units may be heated with oil, coal or gas and may contain 500,000 pounds of lead or alloy. Electric immersion heaters are used successfully on medium-sized installations.

Melting Pots. Cast-iron, cast steel, welded steel or spun steel melting pots are used. Cast steel pots serve the longest, although the others are entirely satisfactory. Normally no special coating is necessary to protect the pot from solution by the molten metal. However, the use of fluxes on the surface of the metal may cause attack on the pot at the flux level.

Fluxes. The use of cover slags or fluxes is generally not necessary, but may be useful for certain work. Molten mixtures of halides of alkali and alkaline earth metals may be used over lead or lead alloys without danger of metallic contamination of the lead alloy. A small quantity of granular sal ammoniac (ammonium chloride) sprinkled on the surface of the molten metal, reduces the metal content of the dross. A fume hood should be provided if sal ammoniac is to be used as fluxing agent.

Methods of Casting. Lead alloys are suited to a variety of casting methods; the simplest is hand casting with wrought iron or cast-iron hand ladles. Certain lead alloys are easily die-cast. In plants producing large castings, the metal may be pumped out or drawn through a valve in a bottom-pouring pot.

The pouring temperature for most lead alloys is not critical, and may vary from 50 to 150 F above the liquidus temperature of the alloy. In automatic casting equipment, such as the type-casting machine, the temperature is controlled thermostatically.

Molds. Almost any type of mold may be used that is suitable for the job—permanent, semipermanent, plaster, special paper, rubber, wood or sand. Permanent molds may be used for high production of intricate castings, for instance, storage-battery grids. Plaster molds may be used as semipermanent molds or as single-casting molds. Rubber molds are used most often on a centrifugal casting wheel to produce intricate castings that can be released from the mold by the plasticity of the rubber. In the production of stereotypes, a matte of papier-mâché is used as a mold to produce castings of remarkable fidelity in the form of type-face replicas from which printing is actually done. Built-up wood molds are used for casting boat keels.

Sand molds are occasionally used, with care that the mold is hard enough to withstand the erosive effects of the molten metal of high density.

* Research Laboratories, National Lead Company, Brooklyn

Storage-Battery Grid Metal. The casting qualities of lead alloys containing 6 to 12% Sb are markedly improved by the addition of ¼ to ½% Sn. These Pb-Sb-Sn alloys are gravity cast in intricate steel permanent molds, with a thin layer of carbon or other material as a dressing for the mold face. The antimonial lead grid serves as a framework to carry the active ingredients of the storage-battery cell and also to conduct the electrical current to or from the terminals.

Other Lead Alloy Castings. Monotype, Linotype and Intertype are all cast automatically in a machine operated like a typewriter. The operator brings segments of the type mold into position, and as one line is finished, type metal is pressure-cast against the type-mold face and, when solid, is ejected as a finished type-mold unit. Newspaper stereotype metal is cast in curved plates, producing a replica from a paper or composition matrix. Electroplated coatings of nickel, copper or chromium have been used to prolong the useful life of the printing face of the type metal. Telephone books and short runs of printed matter are generally printed directly from the type-metal face.

Electrotype metal is used for backing thin electrotypes (copper replicas) of type or illustrations. It is cast adherently on the reverse side of the thin electrotype, with the aid of solder foil and flux or of a paste containing powdered solder with flux incorporated.

Lead and lead alloys are cast in all types of standard pipe fittings, such as els, tees, valves and the like, for use in the chemical industry. Valves are available either made completely of lead, except for the stem and handle, or made of iron completely lined with lead.

Lead-base die castings are produced for uses where either weight or resistance to corrosion is a factor. These generally lack the strength of other die castings, but they have a definite field of use.

Lead alloys have proved useful in the metal-stamping industry. Antimonial lead punches have been used widely in conjunction with the hard zinc-base dies. Low-melting lead alloys are used to hold various components of jigs and fixtures during stamping, bending or machining.

Lead alloy cast molds are used for making rubber and plastic articles. Lead alloy cast embossing plates are used for surfacing leather or plastic objects.

Lead and lead alloy gravity castings are used to produce a wide variety of products; for example, ornaments, toys, boat keels, sash weights, sinkers, wedges, groutings and packings.

The slush casting of lead alloys is discussed on page 741.

The Production of Lead Sheet and Foil

By Ray C. Skow* and Don E. Campbell*

THIS ARTICLE describes the casting of lead slabs or billets for working and the subsequent rolling of the slabs to sheet or foil.

Sheet Lead. Sheet lead is produced in a variety of thicknesses, widths and lengths, as well as from several grades of lead and lead alloys. The thickness of sheet lead in general use ranges from 1/64 in. (1 lb per sq ft) to ½ in. (30 lb per sq ft). In the trade, sheets are generally referred to according to the number of pounds per square foot—as 2 lb, 4 lb, 6 lb, 8 lb, 16 lb, and so on—rather than in fractional inches of thickness; each pound is approximately equal to 1/64-in. thickness.

A standard roll of sheet lead is 8 ft wide and 20 ft long; however, most sheet lead is ordered cut to the size that will be used ultimately by the consumer. Labor and scrap involved in cutting are thus kept at a minimum at the job site. Widths are available up to 11¾ ft and lengths are limited to about 75 ft, depending on the thickness.

The grades of lead and lead alloys used in the fabrication of sheet lead are usually specified by the consumer. The selection is based on the physical or chemical properties required in the material for its intended use.

Machinery and Equipment. The machinery and equipment in general use for the rolling of sheet lead consist essentially of the kettle, the slab-casting pan, the rolling mill and roller tables, and the cutting table. Extensive equipment for handling is necessary, in the form of an overhead crane and auxiliary devices.

The kettle may be either a gas-heated or an oil-heated cast-iron or steel vessel supported by a steel-jacketed brick-lined pit. The kettle is usually elevated sufficiently for gravity discharge of the molten lead through a controlled opening at the bottom. The capacity may be three to four times the weight of lead used for the casting of an individual slab. In larger installations, kettles are used that will hold 25 to 40 tons, and large pumps of special design are used for moving the molten lead to the pans.

The slab-casting pan is a heavy, open-top steel casting, well supported and anchored to the floor. The sides are tapered sufficiently to facilitate removal of the frozen slab and recesses are provided into which lifting clamps are inserted before the slab is cast. Larger installations cast slabs that weigh approximately eight tons each.

The measurements of the slab pan are determined by the width of the mill as well as by the size of other facilities. Generally, a mill producing sheet lead in widths of 8 ft will use a pan 8½ ft in length. Slabs are normally cast 4 to 6 in. thick. Large slabs are usually cast in a horizontal position, but slabs have been cast on end in a vertical position. Vertical slab molds are generally employed only in conjunction with small mills.

Rolling mills used for the production of sheet lead are of the reversible type and may have either a single-roll or a double-roll drive. The rolls are mounted one above the other; the lower roll has a fixed elevation, whereas the upper roll can be raised or lowered several inches to accommodate the thickness of full slabs. Larger mills for rolling lead sheets have rolls 30 in. in diam by 12 ft in effective length. These rolls have a slight crown to compensate for deflection when wide sheets are rolled.

Roller tables extend about 45 ft on either side of the main mill rolls and are at the same elevation as the top of the lower roll. The sections adjacent to the large rolls consist of closely spaced, power-driven, heavy-duty live rollers. The remainder of the roller table consists of lighter-duty idle rollers. One of the roller tables may be equipped with an elevating section in which power-driven cutters are incorporated, for cutting the broken-down slabs to length. This cutting may be done also with portable power-driven saws.

The cutting table consists of a hardwood-covered extension to one of the roller tables. The size is usually identical with that of the roller table, for it should accommodate the entire sheet and clear the roller tables for further rolling.

The drawknife used for cutting sheet lead is a sharp tool fastened to a handle so that a pull-rope can be attached. The knife is guided manually along the marked sheet. Power is applied to the pull-rope by the use of an elongated winch located at the end of the cutting table. Movable sheaves that can be placed quickly in position provide directional pull for the knife.

Operation. First, the kettle is charged with pig lead, selected according to grade or specification required. The charge is melted and alloying elements are added, if required. After a chemical analysis of the melt, the dross is removed. Slabs are then cast rapidly to prevent premature freezing while the pan is being filled, and are skimmed to remove any oxides before cooling. During the freezing, care is taken to prevent the formation of internal voids or cavities because such imperfections often carry through to the finished sheet.

Slabs are broken down while still hot (300 to 350 F)

* General Superintendent, Lead Products Division, American Smelting and Refining Company, Barber, N. J.
* Vice President, Standard Rolling Mills, Inc., Brooklyn

by being rolled across the width until the metal is about 1 in. thick. The breakdown of a hot slab requires less power and the operation is less likely to injure the equipment than when a cold slab is used. After the breakdown, it is important that the thickness of the metal remain constant since a definite relationship exists between the lengths of subsequent sections and the thickness of the finished sheets of uniform size. About 3 in. must be allowed for final trimming of the finished sheets. Accordingly, the rolled slab, still 8½ ft wide, is cut into sections of suitable length. These are subsequently rolled individually to sheets about 41 ft long. Sections are rolled at room temperature and no annealing is required between passes. Although some heat is generated in the metal during the rolling operation, it is not a factor that requires control in the production of either soft lead or antimonial lead sheet. Lead, unlike most other metals, will recrystallize at room temperature. Micrometer readings indicate when the desired thickness has been reached, although experienced workmen need to use the micrometer only as a check after the sheet is finished.

Occasionally sheets 10 ft wide are required. It is then necessary to alter the above procedure by cutting sections 8½ by 10½ ft, turning them 90 deg and rolling them to the desired thickness.

After the rolling has been completed, the long sheet is pulled over the cutting table by means of a winch. It is marked, squared, trimmed and cut to the sizes required. Finally individual sheets are rolled tightly, weighed and packed for shipment.

Lead Foil. In casting the lead billet or slab to be rolled into foil the technique is important. The relation between the temperature of the molten metal and that of the molds, as well as the rate of flow of the metal must be maintained to assure solid casts, free from excessive shrinkage spots and cold shuts. Ordinarily, a metal temperature of 775 F to 800 F and a mold temperature of 200 F are satisfactory. The rate of flow can be determined best by experience and will depend on conditions in the individual foundry. Obviously it is desirable to cast the slab as thin and as long as possible (the width is limited by the width of the rolling equipment) in order to save labor, time in the breakdown mill, and power. Probably the thinnest slab cast in actual production is ½ in. thick by 40 in. long. Continuous casting of lead ⅛ in. thick has been attempted, but the properties of the product were not suitable for the purposes of foil.

The cold rolling and heavy reductions on the breakdown mills soon reveal any defects that may be present in the cast slab. An excessive number of shrinkage spots result in the splitting of the slab down the pouring line; cold shuts cause the slab to crack at the edges. The higher the antimony content, the lighter the reduction that can be taken. Hot rolling is recommended for lead slabs that contain from 2 to 4% Sb. The product generally referred to as "lead foil" contains tin, most of which is a surface coating or "casing". This casing is a prepared sheet—100% Sn on the surface, with a tin-lead alloy backing—which is placed on either side of the slab, with the tin surface outward. Frictional heat and the pressure of the rolls are sufficient to weld the sheets and slab into a unit. The tin surface of the lead foil maintains a brighter more durable luster and prevents the ready oxidation of the lead when subjected to weather conditions. Producers of lead foil usually coil the metal at the end of the breakdown line, at ■ gage between 0.016 and 0.035 in.

One pass on the finishing mill is sufficient to reduce the coil to the gage for the finished foil. The procedure in most plants is to maintain the same gage of coil from the breakdown, regardless of the gage required for the finished foil. Different thicknesses of foil are obtained by suitable crowning of the finishing mill rolls. Foil gages may be changed slightly by modifying the lubricant used in rolling, which may be either a soap-and-water solution or an emulsified oil. However, in any rolling operation for lead foil, the success depends on the experience and technique of the finishing mill operator. The operator's attention is constantly required when rolling lead to 0.00035 or 0.0006 in., because the thin sheet of lead will be affected by the slightest change of temperature in the rolls. Such a change may cause a "belly" in the foil, making it wrinkle when coiled, or may cause a "tight spot", which can result in the breaking of the sheet. The operator must constantly adjust the application of the lubricant on the rolls. The lubricant serves as a cooling medium at the same time. Also, as the heat varies within the rolls, the gage of the foil changes; cooler rolls produce heavier foil and hotter rolls, lighter foil. On 0.00035-in. foil, the permissible tolerance is plus or minus 10%; therefore the operator must be constantly alert in order to make the necessary adjustments for keeping within the tolerance of thirty-five one-millionths of an inch. This care is particularly necessary in rolling lead foil because, having a low melting point, lead is much more readily affected by temperature variations than are metals such as aluminum, copper and steel.

The Extrusion of Lead and Lead Alloys

LEAD and lead alloys can be extruded in a variety of shapes and by methods that differ considerably, one from another. The following discussions concern the processes of extrusion used in the manufacture of shapes such as bar, wire and pipe; the processes used in producing cable sheath; and impact extrusion as employed in the manufacture of collapsible tubes.

Extrusion of Lead Bar, Pipe and Wire

By D. J. Doan*

THE HISTORY and technical aspects of the extrusion of lead and lead alloys have been summarized elsewhere.[1, 2] The earliest development of extrusion for any metal was that of plumbers' lead pipe in 1797; since then cored and solid wire solders, special shapes and bars, plumbers' lead traps and bends, and glaziers' or came lead have been added, as well as other forms.

Equipment. Vertical hydraulic presses of 400 to 1500 tons capacity are used extensively. Figure 1 shows a section of such a press, including the cylinder and ram setup. The die, fixed on the lower face of a stationary ram *D*, defines the outside diameter of the pipe. The cylinder *C* (avg diam, 8 in.) is mounted on a movable table supported by four columns. This table, in turn, is fixed to the hydraulic ram of the press. To produce lead pipe, an exchangeable core rod *B*, ⅜ to 12 in. in diam is mounted in the center of the cylinder. The charge of molten lead is run in and allowed to freeze before extrusion; the weight of the charge (650 lb avg) depends on the sizes of pipe and cylinder. The pipe is coiled before it is fully cooled, or is cut in lengths for the larger sizes. Precast billets, 2½ to 4 in. in diam and 8 to 16 in. long, are used for extrusion of solid shapes, such as bar lead or solder, and wire solder. The general setup of the press is the same as for lead pipe except that the core rod is removed. Multiple-opening dies are utilized that contain as many as 12 openings. Flux-cored solders are produced from ¼-in. tubing that has been filled with flux through an opening in the core rod during extrusion. The wire is then drawn down to size. Lead traps and bends or angles are produced on horizontal double-acting hydraulic presses, a section of which is shown in Fig. 2. The pipe *E* is extruded vertically through an exchangeable die mounted on the upper side of the cylinder *H*. The two rams *G* operate inwardly on either side from two hydraulic rams. The

* Research Metallurgist, The Eagle-Picher Company, Cincinnati

core rod is attached to the center portion of the cylinder and is exchangeable for producing different sizes. When the ram pressures are regulated differentially, more lead is forced into one side than into the other, forming a bend *F* of uniform wall thickness. The nose of the cylinder or die holder is designed to permit production of 180-deg bends *F*, and when the process is reversed, the familiar S-trap *E* is formed. The bend *F* forms the outward end of the S-trap *E*. Maintaining equal pressures on the two rams results in the production of straight pipe. Various sizes are made by exchanging dies and cores, and bends of any angle may be formed.

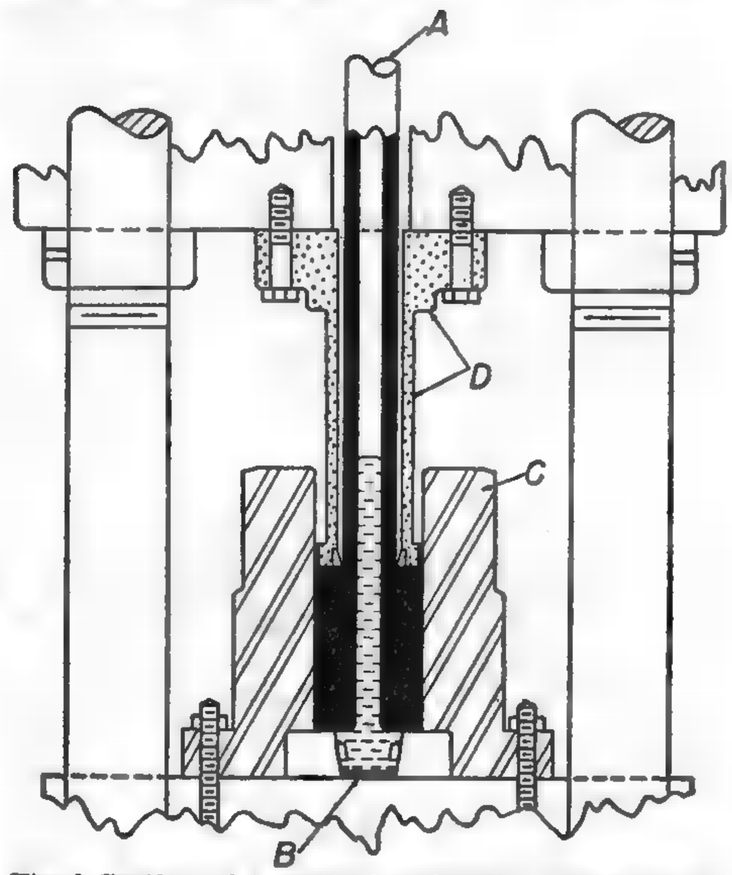

Fig. 1 Section of a vertical hydraulic press used for the extrusion of lead pipe and solder

Pressure. Lead pipe and other soft lead shapes are ordinarily extruded at 8000 to 15,000 psi on the billet area, but the pressure depends on the "extrusion ratio" (the billet area to the die aperture); and temperature, shape of die, composition of lead, and other factors are varied considerably to obtain a rate of extrusion and a product that are satisfactory. Antimonial lead (6% Sb) requires approximately twice the pressure that lead requires at the same speed and temperature. Tin-lead solders require

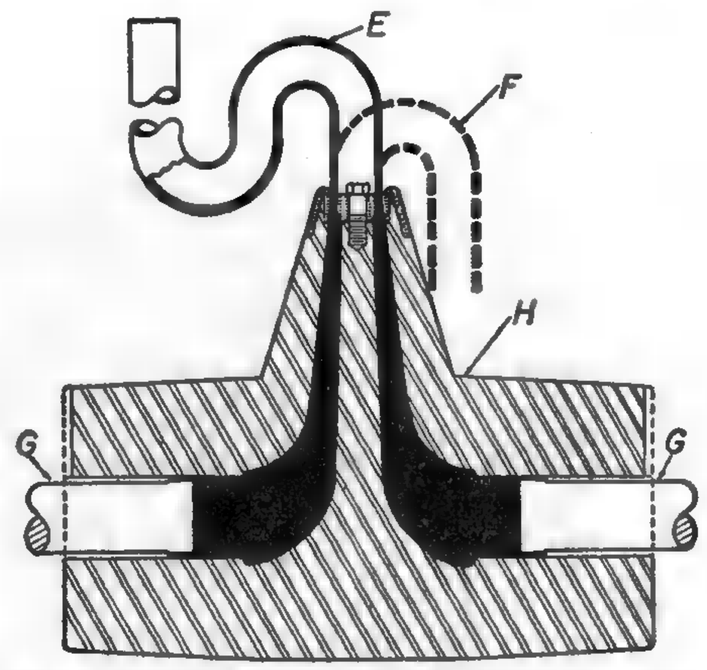

Fig. 2 Cylinder used for the extrusion of lead traps and bends or angled pipe

40,000 to 100,000 psi, depending on the same variables. Cylinders of different billet cross section are exchanged to vary the unit pressure and thus to secure the most satisfactory production.

Speed. Maximum possible speeds are always used but these are subject to wide variations that result from difficulty in handling heavy sections from the press, insufficient pump capacity at times, and susceptibility to surface cracking or "feathering" caused by incipient melting in the die. Speeds of 50 to 60 fpm for lead and about half as much for solders are not unusual.

Temperature. Lead and lead alloys may be extruded when cold, but to decrease pressures and increase speed, lead is extruded at about 400 to 500 F. Little advantage is gained by using higher temperatures.[3] Solder billets are generally preheated to approximately 200 F and the temperature of the cylinder is controlled.

Defects and Precautions. Eccentricity occurs in pipe when the core rod is not centered in relation to the die. Because of faulty casting, inclusions may be introduced in both lead and solder. In pipe, invisible longitudinal welds caused by the "spider" holding the core in a bridge die, will never knit satisfactorily.[4] Consequently these dies are seldom used. Segregation is prevented in solder wire and bar by proper casting of the billets; the molds for this purpose should be cooled by water and the temperature of the metal should be controlled. Thickness of pipe[5] and size of solder wire are measured frequently and dies are changed when worn beyond permitted tolerances.

Extrusion of Lead Cable Sheath

By G. M. Bouton* and Earle E. Schumacher*

SHEATHING of cable with lead or lead alloys consists basically in forcing solid lead, heated to a plastic condition, through the annular space between a die and the outside surface of a concentrically located tube through which the core passes.

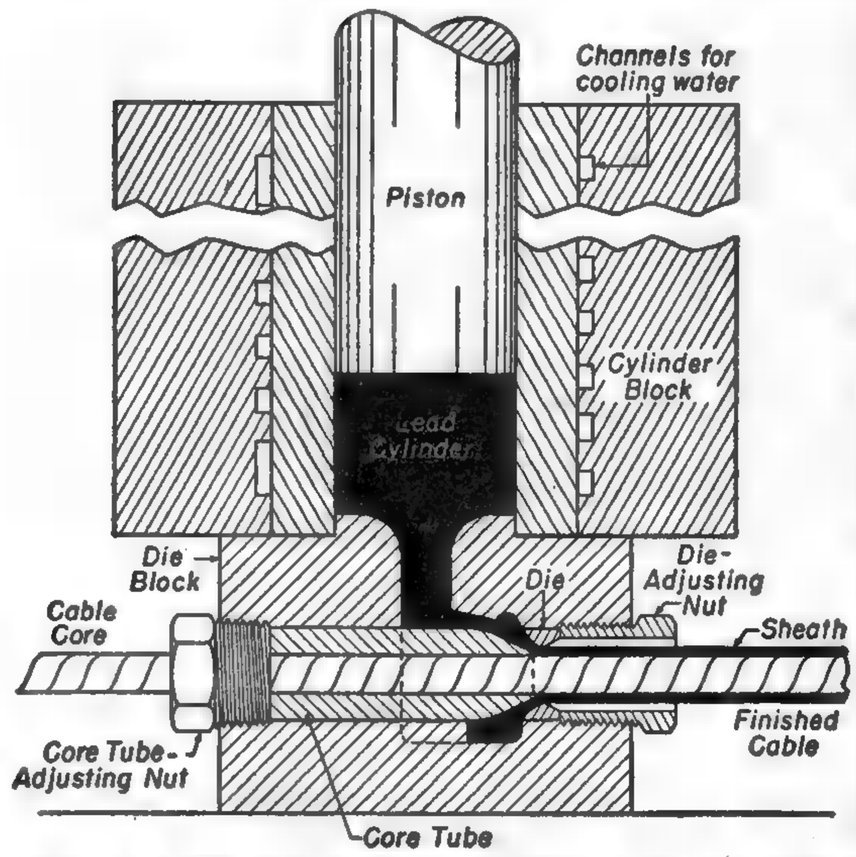

Fig. 3 Cross-sectional view of the assembly employed in the usual type of hydraulic press for the manufacture of lead cable sheath

Press. Figure 3 is a cross-sectional view of the assembly in the usual vertical type of hydraulic press used in the manufacture of cable. Commercial presses are capable of exerting forces of 1000 to 3000 tons and may extrude 600 to 2000 lb of lead in a single stroke. The die block contains a core tube through which the unsheathed cable core passes, and a sizing die to control the outside diameter of the sheath.

Operation. To begin an extrusion, molten lead or lead alloy is poured into the lead cylinder and the piston is brought to bear on the upper surface of the lead, either by raising the cylinder or by lowering the piston hydraulically. Light pressure is applied during solidification, to prevent piping and the formation of voids. Solidification is hastened by circulating water through the cooling channels in the cylinder block. After solidification, pressures of approximately 40,000 to 60,000 psi are applied to the lead, thereby forcing it through the extrusion orifice and onto the cable core. The die block is usually maintained

* Metallurgists, Bell Telephone Laboratories, Inc., New York

at temperatures from 180 to 260 C by means of gas burners or electric heaters.

Various types of die-block cavities are used in the extrusion of cable sheath, since the contour and dimensions of the cavity have considerable bearing on the extrusion pressure required and on the uniformity of sheath thickness. For example, a longitudinal supporting web is often placed below the core tube to prevent it from bending under the pressure applied during extrusion. In the large majority of presses, the lead stream divides as it passes around opposite sides of the core tube, and reunites at the lower portion of the die-block cavity, forming a seam weld (Fig. 4) that runs along the entire length of the cable. This seam weld is nearly always visible microscopically in the sheath and is sometimes a source of weakness. Certain designs of die blocks have a bridge above the core tube, which is said to produce more uniform flow of the lead. However, this construction results in seam welds at both top and bottom of the sheath.

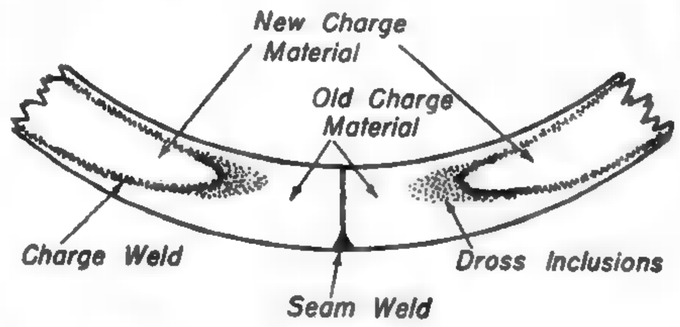

Fig. 4 Cross section of cable sheath a short distance after the start of a press cycle

Charge Weld. The intermittent filling required to sheath long cables results in another type of weld, called the "charge weld". During the introduction of the molten lead into the press, some oxide and dross are generally formed, which have a tendency to rise to the top of the charge. Subsequent extrusion of the charge pushes this layer of dross into the bottom of the lead cylinder, and when the next charge is poured into the cylinder, the layer forms a discontinuity between the old and new charges. After extrusion of the new charge, this discontinuity appears in the extruded sheath as tonguelike charge welds, which are demarcations between the material of old and new charges. The charge weld is most prominent when several feet of cable have been extruded after the charging operation, and becomes less distinct as more and more of the old charge material is expelled from the die block.

Dross. In the past few years considerable effort has been directed toward reducing the amount of dross inclusions in sheath and thus improving the strength of the welds. The following methods are among those used to reduce oxidation during pouring: (1) Pouring through a closed tube that extends nearly to the surface of the old charge at the bottom of the lead cylinder. This method minimizes splashing and also promotes better welding of the new and old charges, particularly if the bottom of the tube is moved continually around the circumference of the cylinder during pouring, or is equipped with deflectors that impart a swirling motion to the incoming lead. (2) Pouring through inert or reducing atmospheres, such as carbon dioxide or burning hydrogen or water gas. (3) Sealing the space between the cylinder and piston and pouring the lead in vacuum.

The following methods are among those used for removing dross or oxides once they are formed: (1) Skimming the top of the charge manually after pouring. (2) Slicing or cropping the dross-bearing portion of the charge by means of mechanically or hydraulically operated skimmer plates that are fitted to the top of the cylinder block. (3) Floating the dross away from the path of the piston. (4) Pushing the dross aside by special contours of the bottom of the piston as the piston is brought to bear on the surface of the molten lead. Some of these methods are used in combination.

Equipment. Other types of presses are used to a minor extent in this country. One type has a concentrically located core tube and a hollow piston that operates in a horizontal position. Molten lead is charged into the space between the wall of the lead cylinder and the core tube. This type of press eliminates the seam welds in the sheath. Another type of horizontal press operates on the "meat-grinder" principle. Molten lead is introduced at the rear of a rotating screw member through a closed tube, solidifies as it passes forward, and develops sufficient pressure to extrude between the sizing die and core tube at the front of the press. The cable core passes through a tube at the axis of the press. This type of press eliminates both charge welds and seam welds, although for the larger diameters of sheath a centering spider, frequently used for positioning the die and core tube, may introduce radial welds. Since there is little likelihood of dross being formed when this type of press is used, radial welds are not likely to be troublesome. This press has the advantage of continuous operation, thereby eliminating the physical and structural discontinuities found, between charges, in sheath made by intermittent processes. Operational difficulties have occurred more frequently with this type of press than with the intermittent type—a fact that has probably deterred manufacturers in this country from employing the continuous process more extensively.

Impact Extrusion of Lead

By John H. Fridén*

THE METHOD of producing collapsible tubes and other containers by impact extrusion has been known for approximately a century. Important industrial uses of this process, however, are less than 30 years old. Increased use of collapsible tubes for packaging in the cosmetic, food and medicine industries has required an increased production of tube, which in 1946 amounted to between 5,000,000 and 6,000,000 gross per year in the United States. This corresponds to approximately 20,000 tons annual lead consumption in this industry.

The Process. This process involves plastic deformation of soft metal, usually in the cold condition, by forcing the metal through an orifice under hydrostatic pressure. In the impact extrusion process, this pressure is exerted by a mechanical power press and the extrusion takes place in about 1/20 sec. The average speed of the press is about 60 strokes per minute. Since one finished product per stroke is the usual output, it follows that the production is 60 extrusions per minute.

A typical example of impact extrusion is an ordinary toothpaste tube. The necessary manufacturing operations follow: First a sheet is rolled and then blanked by conventional means, producing the blank shown in Fig. 5*a*. After this blank has been lubricated by tumbling, it is placed in an extrusion die, Fig. 5*b*, having an inside diameter D equal to the outside diameter of the tube to be extruded. Above the die a punch is arranged concentrically with the die, as illustrated. This punch has an outside diameter d equal to the inside diameter of the tube. Descending by action of the press, the punch first deforms the slug, as shown in Fig. 5*c*, until all the void below the punch and die has been filled and the metal is completely trapped. As the punch descends further, an annular orifice between the punch and die will be formed. The distance t in Fig. 5*c* equals the desired thickness of the wall of the tube, conventionally 0.004 to 0.005 in. The punch descends still further, displacing the metal as in an ordinary squirt gun, and since the annular opening between the punch and the die is the only place through which the metal can escape, the metal is forced to climb up the punch, as shown in Fig. 5*d*. The tube is completed when the punch has descended to the desired depth, leaving the predetermined bottom thickness, as illustrated. After the first part of the cycle has been completed, the punch withdraws, the knock-out pushes the tube out of the die, and the tube stays on the punch until removed by hand or by automatic means. The tube is thus extruded in one stroke of the press. Trimming and threading, if required, can be accomplished in one more operation.

Versatility. Caps and stoppers used in collapsible tubes

* Chief Engineer and Vice-President, Sun Tube Corporation, Hillside, N. J.

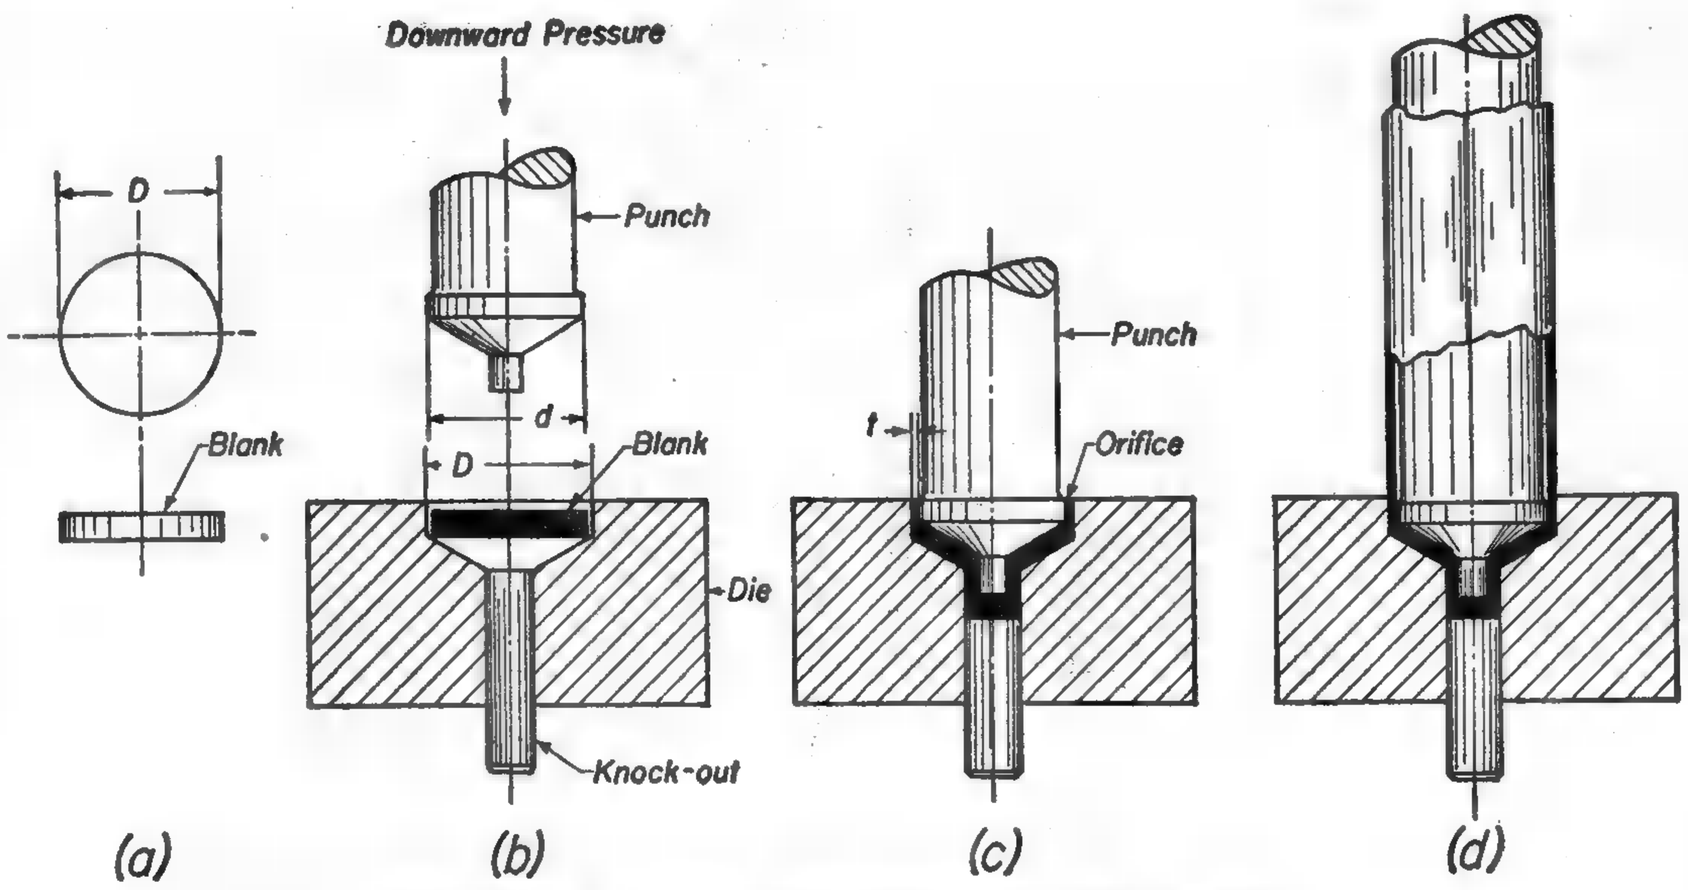

Fig. 5 Steps in producing a collapsible tube by impact extrusion

are also produced by impact extrusion. A threaded cap for collapsible tubes can be completed by impact extrusion in one operation at a speed of 80 to 90 strokes per minute. Many other articles that have lettering, protrusions, slots, depressions and such on the bottom, can be produced in one operation by impact extrusion.

Types of Presses. Ordinary straight-sided presses of the crank or eccentric type are preferred. In mass production it is necessary to equip these presses with automatic feeds, strippers, and devices for safety and removal of tubes. The size of the press is determined by the extrusion pressures involved. Between 30,000 and 50,000 psi is required, depending on the composition of the lead alloy.

Lead Alloys Used in Impact Extrusion. Although it is possible and feasible to extrude pure lead, it is frequently necessary to add some alloying element, such as antimony, copper, tellurium, tin or silver, in order to obtain the required stiffness. Alloying with elements such as tin, which improves the chemical resistivity, is often indicated. For practical purposes, a common alloy for use in the manufacture of collapsible tubes contains 97 to 98% Pb and 2 to 3% Sb. The addition of less than 1% Ag improves the appearance of the alloy.

Duplex Metal. Under some circumstances tin-coated lead tubes are desirable. In order to produce these by conventional extrusion methods, it is necessary to prepare the slug in a special manner. The method used is to wrap a previously rolled, thin sheet of tin around a lead slab and then to roll them down together in a standard rolling mill by conventional procedure. Because of the difference in the cost of tin and of lead, it is customary to use only 3 to 7% Sn. Slugs prepared in this manner extrude as readily as pure lead slugs and the tin is distributed evenly over the entire surface of the lead core.

Other metals and alloys can be extruded with lead in the same manner.

Waxing. For packaging certain materials, it is sometimes necessary to coat the inside of the tube with either wax or some synthetic material. Ordinarily a spray nozzle is used for flushing the coating through the inside of the tube, which is then drained, dried and cooled.

Joining Lead by Soldering and Welding

By Homer S. Yetman* and David M. Borcina*

SOLDERING and welding are the two methods most commonly used for joining lead. Both methods are effective with lead and, when properly performed, result in joints stronger than the metal itself. Successful joints must fit tightly and all surfaces of the lead forming the joint must be thoroughly cleaned mechanically, by shaving or by using a wire brush or scratch cloth. The outer surface of the lead should be cleaned only over the area that will become part of the joint.

Soldering. Soldered joints in lead are usually made with a soldering copper, or "iron" as it is more often called, or by "wiping", used in joining cable and in the plumbing industry. Wiping consists of pouring the just-molten solder repeatedly over the surfaces to be joined, and working the solder to shape while it is in a semimolten condition. Whether soldering is done by a soldering copper or by wiping, only mild noncorrosive fluxes are needed, affording a distinct advantage. The flux can be either salt-free mutton tallow or rosin. If a liquid flux is desired, rosin may be dissolved in alcohol. Immediately after cleaning, the flux is applied to all surfaces in contact, so that the solder will sweat between layers of lead, and to the outside as well. The lead does not have to be tinned, except in particularly difficult soldering operations.

Soldering coppers weighing about 2 lb each (4 lb per pair) are satisfactory for most work. Only the heaviest lead requires the use of heavier coppers. The soldering copper used most frequently with lead is four-sided and pyramid-tipped. The pyramid, which is the working surface, should be kept clean and well tinned with 50–50 solder. In overhead soldering operations, better control of the solder is imperative, and for this reason only the

* Lead Industries Association, New York

working side of the copper should be tinned. For all soldering operations involving the use of a soldering copper, the solder preferred has a composition of 50% Sn, 50% Pb. The solders with a high melting point, such as lead-silver solder, cannot be used successfully with lead because the melting point is too close to that of lead itself.

The most effective wiped solder joints in lead are made with solder containing from 37 to 40% Sn and the remainder lead, with or without a small percentage of antimony. Solder of this composition is preferred because of its adequate plastic range, good general working qualities, and the density of the finished joint metal, although a tin content as low as 32.5% is successful where the joints will not be under pressure. In wiping, it is the practice to apply a coating of plumbers' soil, library paste, paper or any material that will prevent the solder from adhering to the lead where it is not needed or wanted—for example, beyond the ends of the joint.

Soldered joints in lead sheet and pipe can be made by using a soldering copper or by wiping. The two joints used most commonly on sheet lead are lap joints and butt joints. Either is satisfactory with lead that weighs 6 lb or less. For heavier weights of lead, the butt joint is preferred and the edges forming the joint should be beveled. On all weights of lead pipe, the wiped lap joint is preferred wherever possible. Wiped flanged joints are sometimes used both to join and to support the pipe. Cup joints made with a soldering copper are satisfactory when the pipe is in a vertical position, and overcast or beaded joints may be made where it is possible to roll the pipe. To provide auxiliary heat, a torch is sometimes employed both in wiping and in sweating operations.

Welding. Lead welding, often referred to as "lead burning", fuses the parts of the joint together without flux or recourse to any other metal, although additional lead is frequently added to build up the joint to approximately 1½ times the thickness of the lead that is being joined. A torch with a nonoxidizing flame is used to fuse the metal; a combination of two gases is generally employed. The most popular gases are oxygen and hydrogen, although oxygen and acetylene or other hydrocarbon gases are also used. Oxygen and city gas are sometimes combined for use in shop work. Single gases, such as propane, are used satisfactorily on light weights of lead when the joint is to be welded in a horizontal position.

The flame temperature required in lead welding is low compared with that needed in other types of welding. Only the smallest tips on the torch are used. For lead weighing less than 6 lb, tip sizes 00, 0 and 1 are satisfactory; for lead weighing from 6 lb to 10 lb, tip sizes 2 and 3 are satisfactory, and above that weight, larger tip sizes can be used. These selections will vary somewhat, depending on the mechanic. On vertical and overhead work, where better control of the fused metal is necessary, torch tips as small as possible should be employed.

The preparation of the lead for welding is much the same as for soldering. The metal that will become part of the joint must be kept scrupulously clean; however, no flux is employed. Lap joints are preferred except in very heavy lead. A lead welding rod of the same composition as the lead being joined is used as a filler. The rod is usually ⅛ to ⅜ in. in diam, depending on the thickness of the lead.

The principal precaution to take in lead welding is to avoid burning through or reducing the thickness of the lead, but care should be taken to make sure that fusion occurs through the entire thickness of the joint and not merely on the surface.

When lead is joined to other metals by either soldering or welding, the other metal should first be well tinned.

The Resistance of Lead and Lead Alloys to Corrosion

By G. O. Hiers*

CENTURIES ago, sheets of lead were placed between the blocks of stone used in the construction of large stone buildings in Rome. Nearly 2000 years ago the Pantheon was built with a lead roof. Such buildings and monuments still stand with these original materials intact.

With the passage of time the property of resistance to corrosion has resulted in a growing variety of uses for lead. When sulfuric acid first became commercially significant, the manufacture of this important product was made possible on a large scale by the use of lead chemical equipment—lead chambers and pans.

About 60 years ago, extruded lead tubing was first applied as protective sheathing on electric cables used for communication and also for the transmission of power.[2]

Storage batteries, which have increased constantly in importance since they were invented, depend largely on lead. In fact, one of the major uses of lead at present is for the grids in battery plates, for the connectors, and for the active material of the plates.

Lead in the Building Industry. *Sheet Lead.* Many skyscrapers have the bases of their columns set on lead for absorption of sound and vibration. These absorption mats consist of 20-gage sheet steel at the center, with ⅜-in. thicknesses of hard asbestos sheet on both sides and, on the outside, a soft lead sheet about ⅛ in. thick. The lead casing is closed by soldering the edges, thus making a durable building element[3] that resists corrosion and effectively absorbs sound and mechanical vibration.

* Research Laboratory, National Lead Company, Brooklyn

In many buildings and homes, sheet lead is used for drain pans under shower-bath stalls. The stall flooring is usually concrete, and sheet lead, covered with tar paper or painted with asphaltum, is placed beneath. The protection is necessary for a year or so because oxygenated lime water is corrosive to lead. The free lime in "green" concrete becomes carbonated in the course of time and subsequently water that seeps through the concrete will no longer corrode the lead.[4]

Sheet lead is used extensively for roofing and otherwise weatherproofing buildings. The lead sheet used at present is about 3/64 in. thick (3 lb per sq ft). A 6% antimonial lead alloy is employed in some instances, because of its superior strength.

Recently, the ASTM[5] reported the following rates of corrosion of lead exposed outdoors for ten years:

Test Site	Corrosion Penetration (After 10-yr Exposure to the Atmosphere), 0.0001 inch[(a)]	
	Chemical Lead	1% Antimonial Lead
Altoona, Pa.	2.67	2.14
New York, N. Y.	1.67	1.13
Key West, Fla.	2.16	2.05
La Jolla, Calif.	1.62	2.36
State College, Pa.	1.88	1.29
Phoenix, Ariz.	0.94	1.09

(a) Measured from loss in weight after chemical cleaning

These values indicate that it would take 40 to 100 years

for corrosion to penetrate lead to a depth of 0.001 in. From the standpoint of durability, atmospheric corrosion of lead is fairly insignificant.

Sheet lead for roofing and gutters should be installed only by experienced workers. Changes in temperature cause changes in length of the metal and, to avoid buckling, wrinkling and cracking,[1] the resultant movements should not be restricted. Lead is used also for flashings, spandrels, drain pipes and such. Architects choose lead for its permanence, resistance to weather, and decorative value.

Lead Pipe. Modern lead pipe is made by extrusion. (*See* page 947.) For the conveyance of water, commercial lead of about 99.7% purity is frequently used. With ordinary hard water, a protective coating (probably a calcium plumbite) forms as a thin film on the wall of the pipe, and the water flows through without contamination. Distilled water or very soft water, if untreated, is not recommended for use in lead pipe because of the possibility of lead pickup or contamination. However, soft drinking water treated with lime or sodium silicate can be used safely after flowing through lead pipe.

Ordinary lead pipe having walls of substantial thickness is used underground and bare, generally without protection. During reconstruction work in various cities, lead pipes have been dug up and found in good condition, still giving good service after 50 years submersion and more. Commercial lead pipe is designed in different calibers or thickness of wall, chiefly to withstand 50, 75 or 100 psi water pressure at 70 F.

Cable Sheathing. Insulated copper wires are fed through a die in a hydraulic press and a lead sheathing is extruded over the assembled wires as a waterproof protective covering. (*See* page 948.) Chemical lead, common lead and 1% antimonial lead alloy are ordinarily used for such covering.

Lead-sheathed aerial cables last many years. Although occasional failures of the sheathing do occur, the principal cause is mechanical. As a result of dimensional changes from alternate heating and cooling, cracks develop that resemble transverse fatigue cracks. An alloy of 0.03% Ca with the remainder lead, has a higher endurance limit than lead, and is expected to give better service for aerial lead-sheathed cables. Careful supporting of the cables has minimized the cracking trouble by preventing localization of the stresses that result from movements accompanying thermal changes.

Underground lead-sheathed cables for telephone and telegraph systems are usually contained in wooden tubular covers or conduits. These in turn are usually surrounded by concrete. Similar constructions are frequently used for underground lead-sheathed electric-power cables.

Where corrosion of lead has occurred because of the presence of oxygen and the seepage of water through "green" concrete, the trouble has been corrected by diffusing gaseous carbon dioxide through the concrete conduits to kill the free lime. ($CaO + H_2O \rightarrow Ca(OH)_2$ and $Ca(OH)_2 + CO_2 \rightarrow CaCO_3 + H_2O$).

J. M. Handring[6] states: "It is estimated that in the Bell System more than 50% of all underground sheath failures due to corrosion are the result of nonstray current phenomena." R. M. Burns[2] of the same organization has conducted exhaustive studies of the underground corrosion of lead. Such studies have shown that the several varieties of lead mentioned for cable sheath have about the same resistance to corrosion in the environments to which they are subjected. Some types of soils are known to be more corrosive than others toward lead. Particle size of soil, aeration factors and the like have also been found influential. Underground corrosion tests of various metals including lead have been conducted under the auspices of the National Bureau of Standards.[7]

Storage Batteries, Pickling and Electrolytic Processes. For many years, the largest single market for lead has been the storage battery industry. Briefly, lead storage batteries function as follows: A charged battery has an anode of lead peroxide (PbO_2), a cathode of sponge lead (Pb) and an electrolyte of sulfuric acid in a concentration of about 35%. It delivers an amperage that depends on the area of the plates and the number of plates per cell. The voltage per cell varies from about 2.0 or less at the beginning of discharge to about 1.8 or less at the end of discharge. At the end of discharge the electrolyte has weakened and a coating of lead sulfate has formed on the surfaces of the plates.

In some large stationary batteries of the Planté type, the plates are usually of comparatively pure sheet lead, such as ASTM corroding lead, and have surfaces serrated to provide greater surface area. In other types of large batteries, and also in smaller batteries such as are provided in automobiles for starting, lighting and ignition, antimonial lead alloys are used for the grids, posts and connector lugs.

Repeated charging and discharging of a battery can cause prohibitive corrosion of the grids, if the alloy is of inadequate purity. Typical specifications for battery grid metal are indicated in the following:

Antimony	7 to 12%
Tin	0.10 to 0.50
Arsenic	0.05 max
Copper	0.05 max
Bismuth	0.05 max
Nickel	0.005 max
Zinc	0.005 max
Silver	0.002 max
Iron	0.01 max
Manganese	0.001 max
Lead	Remainder

Metals to be electroplated or coated by the hot dip process are frequently pickled in hot dilute sulfuric acid, in lead-lined tanks. The sheet lead thus used is frequently about ⅛ in. thick or more and is generally chemical lead or tellurium chemical lead. Lead pipes of the same composition carry the steam for heating the pickling baths.

In the production of copper and zinc by electrolytic refining, many tons of sheet made of 6% antimonial lead are used for tank linings and for insoluble anodes. For chromium plating, tank linings of antimonial lead sheet are frequently used with insoluble anodes. Lead is similarly employed for copper plating, nickel plating, zinc plating and with various other plating solutions. An insoluble anode of 99% Pb, 1% Ag is frequently employed in the electrolytic refining of zinc.

Lead Equipment in the Chemical Industry. Lead and some of its alloys are extensively employed in the construction of equipment for the production, transportation, storage and use of many corrosive chemicals. Following is a list of some more or less common chemicals in contact with which lead or its alloys have been used successfully:

Aluminum sulfate	Sodium bisulfate
Ammonia vapor	Sodium chloride solution, or sea water
Ammonium sulfate	Sodium hydrosulfite
Antimony trichloride	Sodium hyposulfite
Bleaching solutions	Sodium sulfate
Brown acid solutions	Sodium sulfide
Carbonate, soluble	Sodium sulfite
Chlorine gas	Sulfonations
Hydrofluoric acid	Sulfur chloride
Koch's acid	Sulfur dioxide
Mixed acids	Sulfuric acid
Nitration mixture of H-acid	Sulfurous acid
Paranitrophenol	Sulfuryl chloride
Phosphoric acid	Zinc chloride
Phosphorous chloride	

This is by no means a complete list of chemicals with which lead may be or has been used, nor does it signify that the behavior of lead is necessarily satisfactory with all the listed chemicals under every circumstance. More detailed information on the performance of lead in contact with various chemicals is given in the list at the end of this article. Because conditions vary so widely from plant to plant and process to process, it is wise to judge each installation on its own merits and, if possible, to make tests under actual operating conditions. The many variables determining the suitability of lead may include temperature, concentration, grade of lead or type of alloy, rate of flow, presence of oxygen, degree of abrasion and presence of impurities.

In selecting lead for equipment that must withstand corrosion, it is important to determine the correct grade or alloy for the purpose. When unalloyed lead is used, it is ordinarily the ASTM grade known as "chemical lead". This grade differs from corroding and common lead mainly in the copper content, which ranges between 0.040 and 0.080%.

There are installations where still greater strength and rigidity are needed than are supplied by chemical lead or chemical tellurium lead. In such installations an alloy may be used. The alloys may also have better corrosion resistance under some operating conditions.

One of the most common lead alloys thus employed is antimonial lead, containing as much as 12% Sb, but since this alloy loses strength rapidly at elevated temperatures, its principal use is at temperatures ranging from 210 to 250 F. For high temperatures, an alloy of lead with 0.035 to 0.050% Te has been employed quite extensively in the last few years because of high resistance to fatigue failure. This alloy work hardens and is said to have good resistance to corrosion, particularly by hot sulfuric acid.

Joints in lead used for corrosion-resistant equipment are made by fusion welding, a method of joining that is commonly known by a somewhat misleading term, "lead burning". This method is used so that no metal other than lead will be exposed to corrosive attack. Likewise, it is necessary to see that the lead exposed to attack is homogeneous in composition, in order that all exposed metal may resist attack uniformly. Therefore, if metal has to be added through the use of a filler or so-called "burning bar", in making joints, the bar should have the same composition as the lead being joined. Thus, chemical lead should be joined by the use of a chemical lead filler bar, 6% antimonial lead by the use of a 6% antimonial lead filler bar, and so on. Oxygen and hydrogen are the gases most generally preferred for lead welding, but others, such as oxygen and acetylene, and oxygen and city gas, are also used. See "Joining Lead and Lead Alloys", the preceding article.

Forms of Equipment. Because of its low strength, lead is usually supported by some other stronger material, such as steel, wood or concrete. (Occasionally chemical equipment is made of cast lead alloy, but then the walls are unusually thick to gain the necessary strength; valves, pumps and fittings are also frequently made of cast lead alloy.) Sometimes the supporting structure may be merely a framework of steel, but more often the entire outer shell is made of strong material and lined with lead that is applied in various ways. Small tanks may simply have the sheet-lead lining hung in them by turning the lead over the upper edge.

For better support, the lining is often held by 2-in. half-round steel straps fastened at frequent intervals inside the lead and through it to the outer steel shell. These straps are covered with strips of lead welded to the lead lining on either side. Vertical strips are usually about 24 to 30 in. apart, and tanks with high walls—for example, 10 ft or more—also have horizontal supports.

For another method of support, lead rivets, welded to the back of the lead lining, extend through holes in the shell and can be riveted on the outside; or the lead rivets may extend through holes in both lining and shell, so that the rivet head on the inside can be welded all around to the lead lining.

The strap method of support is invariably used for lining the top of closed equipment. Both for support and for protection against abrasion, brick linings are often used inside lead linings, particularly where high temperatures are involved.

When the transfer of heat is important, lead linings may be bonded to the supporting shell. In equipment operating under a vacuum or requiring the greatest strength, the lining is always bonded. If temperatures are not high, tin or solder may be used to bond the lead to the steel, but some processes employ a nonmetallic flux to form a bond* that can hold its strength at temperatures nearly as high as the melting point of lead.

Pipe. Horizontal runs of pipe made of lead or lead alloy are usually supported continuously in steel or wooden troughs, or in specially constructed shells of sheet metal. Vertical runs are supported at frequent intervals, for example, every 18 in.; long runs are provided with expansion bends if they operate at high temperatures. When greatest strength is essential, lead-lined steel pipe may be used; the inside of the steel pipe is coated with a bonding agent, such as solder, and extruded lead pipe is inserted. The lead is expanded under steam pressure against the warmed steel and is thus "sweated" to the steel pipe.

Pipe made of lead or lead alloy may be joined by direct welding or by welded flanges and bolts. Lead flanges are usually backed by loose steel flanges. Flanged joints are generally used for lead-lined steel pipe.

Heating or cooling coils made of lead pipe are important items in many pieces of chemical apparatus. Usually they are helical in shape but may take other forms. For support, lead spacers are welded at intervals, ordinarily not more than 18 in. apart, around the coil between the turns. Where greater strength is needed, the coils may be made of copper tube, completely covered with lead.

Commercial Products. Below is a list of stock or standard manufactured lead items for use in industry or generally available at short notice in various parts of the United States: angles, anodes, bars, bends, electrodes, evaporators (cast lead), exhaust fans (cast regulus metal), filters, gaskets (cast, stamped or asbestos filled), grids for filters, laboratory equipment—dishes, bottles, fume ducts and the like, perforated sheets, pipe and fittings (lead, lead-lined steel, steel-reinforced) and lead-covered copper tubing, rotary and centrifugal pumps, rings, sheets, spacer blocks, spray nozzles, traps, valves (compression, gate, diaphragm check), washers, wedges and wire.

The thickness of sheet-lead linings depends largely on the extent of corrosive attack. Sheet lead lighter than 8 lb (⅛ in. thick) is rarely used in chemical equipment. Frequently, different thicknesses are used for different parts of equipment; for example, tank bottoms are often lined with heavier lead than the sides because of greater wear. Abrasion may also be a factor in determining the correct thickness.

Sheet lead is designated by its weight per square foot; 1 sq ft of sheet lead weighs 1 lb for each $\frac{1}{64}$ in. of thickness. This relationship holds true up to 16-lb sheet lead, which is ¼ in. thick. Sheet lead ½ in. thick is designated as 30-lb sheet, and 1 in. thick as 60-lb.

The thickness of lead pipe depends on several factors, including corrosive attack, abrasion, and the pressure to be withstood. For instance, if wall thickness is calculated in the usual manner to accommodate a given pressure, additional wall thickness is allowed to compensate for loss through corrosion or abrasion. Pipe 1½ in. in diam with ½-in. walls is commonly used with steam pressures as high as 45 psi. The formula commonly used to calculate wall thickness is

$$P = \frac{2ST}{D}$$

where P is constant working pressure in psi; S is allowable fiber stress taken as 200 psi for chemical lead at room temperature, and decreasing to 80 psi at 300 F; T is wall thickness in inches; and D is inside diameter in inches.

To the wall thickness thus calculated must be added allowances for corrosion and abrasion. If the pipe is not used under pressure, then corrosion or abrasion is the principal factor. The lightest weight of pipe generally selected under such conditions is the class known as "B" or "M" weight in sizes as large as 2 in. in diam and with walls as thick as ¼ in. in the larger sizes. Standard weights of lead pipe are designated by the actual inside diameter and by a letter showing the wall thicknesses or weight per foot.

Resistance of Lead to Chemical Corrosion. The following list is a general guide to the performance of lead in contact with various chemicals:

Acetic Acid. Moderately corrosive to lead, but corrosion is greatly accelerated by high concentrations and temperatures. Acetic anhydride and glacial acetic acid are handled in lead.

Acetone. Lead is used satisfactorily.

Acetylene. Little effect on lead.

Alcohol, Ethyl. Almost no effect on lead. When used in beverages, only a minute amount of lead contamination is tolerable.

Alcohol, Methyl. No effect on lead.

Aluminum Sulfate or Alum. Lead can be used satisfactorily.

Ammonia. Lead is not affected by the dry gas, and also not by the liquid unless sodium or potassium is dissolved in it.

Ammonium Azide. No effect on lead.

Ammonium Chloride. Lead may be used at ordinary temperatures with concentrations up to 10%.

Ammonium Hydroxide. Lead is satisfactory with liquid or gas at virtually all temperatures and concentrations.

* Such coverings are known to the trade as "homogeneous" lead linings or coverings.

Ammonium Phosphate. Lead can be used satisfactorily.
Ammonium Sulfate. Lead may be used freely.
Antimony Chloride. Lead is somewhat corroded, but is used with comparative economy for chlorinating the trichloride to pentachloride.
Benzyl Chloride. Lead can be used satisfactorily.
Boric Acid. Lead can be used satisfactorily.
Brine. (See *sodium chloride.*)
Bromine. Lead may be used when the bromine is cold and acid-free.
Calcium Carbonate. This compound that is found in natural waters forms a good protective coating on lead, and is added to water to reduce plumbo-solvency.
Calcium Hydroxide. This compound, present in green cement, corrodes lead in the presence of moisture and oxygen. However, added to soft water, it reduces plumbo-solvency.
Carbonates, Soluble. These act as a protection to lead by formation of lead carbonate coating.
Carbon Dioxide. This acts as a protection to lead in natural waters unless carbon dioxide is present in excess, when it increases solubility. Lead is used in acid-carbonate systems for generating CO_2.
Chlorinated Hydrocarbons. Action on lead varies from slight to severe, depending on breakdown to HCl and presence of organic acids.
Chlorination Process. Lead is slowly corroded at temperatures ordinarily used, but length of service is satisfactory compared with that of other common metals and the use of lead permits greater economy.
Chlorine. Dry chlorine does not affect lead and lead may be used with moist chlorine at about 110 C or less with slight corrosion. Amounts of chlorine used in water treatment do not affect lead.
Chromic Acid. Since chromates form a good protective coating on lead, lead may be used with fairly high concentrations of this acid. Antimonial lead is widely used in electroplating.
Cinders. Lead embedded in cinders should be protected.
Coal Tar. Lead is used in refining and recovery of many by-products.
Concrete, Cement or Mortar. When green, the free lime present attacks lead. Aging to carbonate lime or applying asphalt coating on lead is recommended to prevent such corrosion.
Copper Sulfate. Lead is used for anodes and tank linings in electroplating.
Ether. Little or no effect on lead. Lead is used in the manufacture of ether.
Ferric Sulfate. Lead is used in dissolving pots.
Ferrous Sulfate. Lead is used for tank linings and coils in production and service.
Formaldehyde (Formic Acid). Action on lead is similar to that of acetic acid.
Hydrochloric Acid. Use of lead is not generally recommended, but it has been used with some corrosion in concentrations as high as 30% at normal temperatures and 20% at 100 C. Antimonial lead shows better resistance than ordinary lead.
Hydrofluoric Acid. Lead is commonly used since it has fair resistance to the dilute acid.
Hydrogen Chloride (Anhydrous Hydrochloric Acid). Very little effect on lead.
Hydrogen Peroxide. When alone this compound is not likely to affect lead, but it accelerates corrosion when acid is present.
Koch Acid Reduction Mass. Lead may be used safely.
Magnesium Chloride. Corrosive to lead as well as to other metals.
Malachita Green Solution. No appreciable effect on lead at 80 C.
Mixed Acids. Mixtures of sulfuric and nitric acids can be used with lead at ordinary temperatures if water present is less than 30%.
Naphthalene. Lead may be used.
Nitration Mixture of H-Acid. Lead is used with rather high corrosion.
Nitric Acid. Lead is not generally recommended with this acid, but is used with little corrosion when concentrations are higher than 80% at normal temperature.
Nitrobenzol and Nitrochlorbenzol. Corrosive to lead.
Nitrocellulose. Lead is widely used as in all rayon manufacturing processes.
Nitroglycerine. Lead is used to handle spent acid.
Nitrosyl-Sulfuric Acid. Action on lead is least at specific gravity of about 1.5 to 1.6. Close control minimizes corrosion.
Organic Acids. In general, these accelerate the corrosion of lead, but their presence in solutions does not always preclude the use of lead.
Oxygen. Dry gas merely tarnishes lead. In presence of water, initial attack is usually followed by formation of protective coating by salts such as carbonates, sulfates and silicates in water. In absence of these salts, aeration may be employed to remove oxygen, because of its action on all metals.
Oxy-L Acid. Lead is corroded to some extent but is almost the only economical metal that can be used with satisfaction.
Phenol. Lead is used satisfactorily.
Phosphoric Acid. Lead may be used with concentrations as high as 80% at temperatures lower than 200 C. Impure acid has even less effect on lead and can be used in concentrations as high as 85%.
Photographic Solutions. Lead is generally satisfactory.
Potassium Permanganate. This compound attacks lead.
Pyridene. No effect on lead.
Silicates. These form protective coatings on lead and thus can be recommended for treating natural waters if necessary.
Sodium Bisulfate. When highly concentrated, this can be handled in lead.
Sodium Carbonate. Dilute solutions do not affect lead; in natural waters this forms a protective coating on lead.
Sodium Chloride. Lead is satisfactory for dilute solutions at ordinary temperatures. Sea water or brine is commonly handled in lead or antimonial lead.
Sodium Hydrosulfite. Lead can be used satisfactorily.
Sodium Hydroxide. Lead can be used with concentrations up to 25% and temperatures to 80 C.
Sodium Hyposulfite. Lead can be used satisfactorily.
Sodium Hypochlorite. This compound attacks lead.
Sodium Sulfate. Lead can be used satisfactorily with solutions as strong as 10% concentration boiling.
Sodium Sulfide. Lead can be used satisfactorily with these solutions at temperatures as high as 100 C.
Sodium Sulfite. Lead can be used with solutions as high as 20% in concentration at 25 C.
Sulfur Chloride. Little effect on lead.
Sulfur Dioxide. This has little effect on lead when dry and can be used moist at about 200 C or less.
Sulfuric Acid. Lead is the standard material for handling this acid. Lead can be used with concentrations as high as 96% at room temperature and 85% at temperatures as high as 220 C. Lead is sometimes used satisfactorily even at temperatures as high as 250 C.
Sulfurous Acid. Lead is satisfactory at about 220 C or less.
Tannic Acid. Somewhat similar to acetic acid.
Tartaric Acid. Somewhat similar to acetic acid.
Thionyl Chloride. Lead is used satisfactorily as high as 220 C and sometimes higher.
Titanium Sulfate. These solutions can be handled satisfactorily in lead.
Victoria Green Solution. Lead may be used satisfactorily as high as 80 C.
Water, Distilled. Lead is dissolved very slowly in proportion to amount of dissolved oxygen.
Water, Natural. Usually no effect on lead because of the protective coating formed from dissolved salts. Very soft waters or those of peaty origin may dissolve lead slightly, as they do other metals. In some localities, such action is prevented by treatment of the waters with lime or sodium silicate. The generally suggested tolerance limit for lead in drinking water is 0.10 parts per million.
Wood. Most wood has little or no corrosive effect on lead. A few instances of corrosion by wood that contains organic acids, such as green oak, have been reported. Wood to be lined with lead should be inspected for the presence of borers.
Zinc Chloride. Lead can be used satisfactorily.

The section of the foregoing article dealing with Lead Equipment in the Chemical Industry is adapted from a paper by F. E. Wormser, which appeared under the title "Lead Equipment Used in Industry" in Metal Progress, February 1943.

The Metallography of Lead and Lead Alloys

By J. R. Vilella*

Because of the softness of lead and lead alloys, the preparation of specimens for microscopic examination has always been difficult. Two hindrances are encountered: (1) The finished surface is usually scratched too heavily. (2) The surface metal flows, forming a layer of cold worked metal that masks the true structure.

The usual way of overcoming these difficulties has been to etch deeply so as to get below the surface imperfections. However, a deep chemical attack roughens, blackens and obliterates the fine details of the structure. It is therefore desirable to finish the samples with a minimum of scratches and flowed metal so as to permit light etching.

Two basic methods have been described,[1,2] as well as several modifications thereof, intended to overcome these surface difficulties. One method is based on the use of a strong, rigid microtome, equipped with a specially sharpened knife capable of producing a smooth cut surface suitable for etching and microscopic examination without further polishing. The other method, requiring no special equipment, is based on the fact that scratches and flowed metal can be eliminated by a series of alternate light polishings and etchings.

Microtome Method. The success of this method depends on three factors.

1 *A Microtome Sufficiently Rigid for the Service.* Lucas, who originated the method, employs a Jung microtome, type K, originally designed for wood sectioning;* but he states that given a solid, substantial instrument, good results are largely a matter of personal skill in sharpening the knife and manipulating the apparatus. Schumacher and Bouton[3] have successfully employed an inexpensive biological microtome. They have also obtained fair results by means of a wood chisel and a special clamp.

2 *A Knife Properly Sharpened.* A knife that has been properly sharpened, honed and stropped is indispensable for the success of this method. A dull or serrated edge will yield surfaces covered with scratches and cold worked metal. A razorlike edge is also unsatisfactory because it chips and turns over easily. Best results are obtained when the knife is sharpened to a fine chisel edge and is free from all but the finest imperfections. If used judiciously, a good edge will cut 50 or more lead specimens between stroppings. Sharpening the knife is a laborious operation that requires considerable skill. Detailed instructions are usually supplied by the manufacturers.

3 *An Instrument That Cuts Very Thin Slices.* Lucas has found that unless the instrument cuts sections as thin as 2 microns, the cut surface is not suitable for etching. The shavings themselves are not used for metallographic study, but if they are thicker than 2 microns, the cut surface of the specimen will contain cold worked metal and scratches. This is an indication that the knife has not been honed or stropped properly. It should be noted that even specimens that have been well cut and then etched, present to the unaided eye the appearance of slight furrows or undulations on the prepared surface. These are not troublesome under the microscope.

Wood Chisel Method. This method gives satisfactory results when used properly. The specimen is mounted in a hardened tool steel clamp and excessive material is removed with a coarse hacksaw. A rough chisel cut is made, and then a fine one, using the surface of the clamp as a guide.

Polishing With Standard Equipment. This method is rapid and can be carried out successfully with ordinary polishing equipment or by hand. When properly performed, such polishing leads to the formation of ideal surfaces for examination at low and high magnifications.

Procedure. 1 To minimize distortion of the surface metal, the sample should be cut with a sharp hacksaw. Care is necessary to avoid dragging and pushing. It is well to rub a few drops of oil on the saw blade.

2 The specimen should then be ground, with gentle pressure, on a coarse abrasive paper that has been spread previously with a concentrated solution of paraffin in kerosene. This treatment prevents the particles of lead from adhering to the paper and forming a glaze that would drag and distort the surface metal. At least $\frac{1}{64}$ in. of metal should be ground away during this step. The speed of the revolving disks should not exceed 500 rpm at any stage during the entire operation.

3 The specimen is then ground successively on 2, 1, 0, 00 and 000 abrasive papers, all previously spread with the solution of paraffin in kerosene. Grinding on successive papers should be continued for at least one minute after all the scratches left by the preceding paper have disappeared. Care should be taken to exert the minimum pressure needed to secure good cutting action. The scratches left by 000 paper are frequently too deep to be removed easily during the next step (wet polishing). For this reason the specimen should be ground, when necessary, on an old 000 paper that has been well worn by previous use. This last paper, as a rule, yields very fine, even scratches that disappear easily during wet polishing. The specimen should now be freed from paraffin and grit.

4 Wet polishing requires clean broadcloth spread abundantly with soap. The abrasive is a water suspension of the finest levigated alumina obtainable. If, at this stage of the operation, a black smudge appears on the surface of the specimen, polishing should proceed very gently, and care should be taken to keep the cloth thoroughly wet with alumina and soap until all traces of smudge have disappeared and the surface appears bright.

5 The scratches left after polishing on broadcloth are often rather deep and remain visible after etching. For

* United States Steel Corporation Research Laboratory, Kearny, N. J.

* With the Jung microtome, specimens of lead, tin, platinum, gold and silver have been sectioned successfully. Harder metals, such as aluminum, aluminum alloys, copper, zinc, and the brasses and bronzes, may be prepared roughly by sectioning, and may then be given a final polish on magnesium oxide, thus expediting considerably the usual procedure of preparation.

Table I. Etching Reagents for Lead and Lead Alloys

No.	Authority	Composition	Remarks
1	Rutherford[4]	3 parts glacial acetic acid 1 part 9% hydrogen peroxide	Etch for 10 to 30 min, depending on depth of flowed metal on the surface. Dry with alcohol and clean with concentrated nitric acid. The nitric acid is removed by sudden immersion in a large volume of water.
1a	Lucas[1,3]	3 parts glacial acetic acid 1 part 30% hydrogen peroxide	Etching time varies from 6 to 15 min. Used for lead, lead-tin, lead-antimony, and lead-calcium alloys.
2	Vilella[2]	1 part glacial acetic acid 1 part nitric acid 4 parts glycerol	Etching from 10 to 15 sec. Affords best results when used in conjunction with method of alternate polishing and etching. For lead, lead-antimony, lead-calcium, and low-tin alloys. Use freshly prepared solution and discard after using.
2a	Bassett and Snyder[5]	3 parts glacial acetic acid 4 parts nitric acid 16 parts water	Use at a temperature of 40 to 42 C. Recommended for pure lead and lead-tin alloys up to 3% tin. Etching time depends on depth of distorted metal on prepared surface.
3	Johnston[6]	Concentrated nitric acid	Plunge specimen in concentrated acid. Wash in a rapid stream of water. Repeat operation as often as necessary. If acid becomes diluted by water carried by specimen it must be rejected and fresh acid used.
4	Bassett and Snyder[5]	60% solution of perchloric acid	For electrolytic etching. No. 6 dry cell used to supply energy. Also recommended by Dean, Zickrick and Nix.[7]

removing these scratches, the specimen may be polished by hand on a clean pad of silk velvet, well soaked with soap and alumina. The sample should then be washed carefully to remove all traces of soap.

Etching. According to those who advocate the sectioning methods of preparing lead specimens, the sample may be etched as it comes from the microtome. One etching is sufficient to disclose the true structure of the metal. Occasionally a cotton swab, well soaked in the etching reagent, is used for eliminating the heavier knife marks usually present in specimens prepared by the microtome or the chisel method.

The etching of specimens prepared by conventional polishing methods is not considered a process completely independent of polishing. Even well-prepared surfaces are seldom entirely free from a film of cold worked metal that must be eliminated in order to show the true structure of the specimen. This film cannot always be removed satisfactorily by the etching reagent alone, no matter how long the specimen is exposed to the action of the reagent. A prolonged etching attack usually results in pitting and roughening the surface and obliterating the fine details of the structure. It is advantageous to employ a method of alternate polishing and etching, during which the reagent gradually removes the film of distorted metal while frequent light polishings prevent the evils of a long continued chemical attack. The procedure is as follows:

The polished specimen is etched in a suitable reagent and its structure is noted under the microscope. The specimen is then repolished gently on the velvet pad until bright, when the surface is etched again and examined. A considerable improvement in the appearance of the structure will be noted. The surface of the metal should be polished and etched repeatedly, as long as the appearance of the structure improves. Ordinarily three repolishings suffice, but occasionally more may be required.

The etching reagents for lead and lead alloys are listed in Table I.

Factors That Determine the Applications of Lead

By R. L. Ziegfeld*

LEAD probably has more varied fields of application than any other metal. Many of these applications depend on the chemical properties of such lead compounds as white lead, red lead, litharge, lead arsenate, lead chromate, tetraethyl lead, lead azide and lead silicate, to mention only some of the most important. Since these are chemical rather than metallurgical products, they will not be discussed further here.

However, a still larger tonnage of lead is used in metallic form, either alone or as lead alloys. In most of these applications, the physical properties of the metal determine whether it should be used, or the manner in which it should be employed.

The outstanding characteristics of lead include heavy weight, high density, softness, malleability, flexibility, low melting point, low strength, low elastic limit, ability to alloy with certain other metals, lubricating properties, low electrical conductivity, high coefficient of expansion, and high resistance to corrosion under a wide variety of conditions. Lead is ordinarily selected for use because of one or more of these properties. However, the product or installation should be designed with consideration for the other properties.

Weight and Density. Because of the high specific gravity, lead must usually be excluded where light weight is required, unless some other desired characteristic can be obtained from lead only. As an example, lead is not generally desired in aircraft on account of weight, yet lead storage batteries are used in aircraft because they alone have the desired electrochemical characteristics.

Several instances can be cited where some other characteristic of lead makes it possible actually to reduce the weight of the equipment in which lead is used, despite the high specific gravity of lead. On certain aircraft equipment, lead coatings have sometimes reduced total weight, since they can be thinner than coatings of some lighter materials and still give equal protection. Lead counterbalances on aircraft often reduce weight, because the weight can be concentrated at the point where it has the greatest effect.

Although lead is often out of the question where light weight is important, lead is always considered for weights and counterbalances. In such uses, the higher cost of lead is balanced against its greater ability to save space, as compared with materials of lower specific gravity. Other desirable features are the low melting point and easy casting of lead, making it possible to fit lead weights into irregular and out-of-the-way spaces. When lead is selected for such work, softness and low strength must sometimes be considered if the weight is subjected to mechanical abuse. In such instances, the lead weight is often enclosed in a cast-iron or steel shell.

High density makes lead suitable for a number of purposes. Notable among these is X-ray protection, since the ability of a substance to stop beta rays and gamma rays is proportional to density. Thus for X-ray machines, radium and other radioactive materials and isotopes, lead is usually employed as the protective medium. However, with high-powered machines, the thicknesses of lead required are expensive, so that if space and weight are not too important, concrete is generally employed, often in combination with lead. X-ray experts now recommend using lead in combination with concrete whenever concrete is employed, because lead reduces scattered radiation.

Softness and Malleability. The softness of lead accounts for its use in some instances or makes it necessary to take precautions in others. For example, the softness of lead is largely responsible for its value as a calking material, making it possible to fill the calked joint completely. Softness accounts, at least in part, for the use of lead in bearing metals, gaskets, washers, and lead-headed nails.

On the other hand, softness often makes it necessary to take certain precautions in the use of lead. In pipe lines, for example, high velocities may result in erosion. This disadvantage is sometimes eliminated by increasing the size of lines to reduce velocity, or by increasing the wall thickness to compensate for losses caused by erosion.

The malleability of lead finds its widest commercial application in the manufacture of lead foil, where it is rolled as thin as 0.0005 in. or even less.

Flexibility. Although this is not strictly a property, it is the best word to describe an important characteristic of lead, resulting from its properties. Flexibility is at least a contributing factor in many commercial applications of lead. One of the best examples is cable sheathing; others include piping, molds for rubber hose, and collapsible tubes.

* Secretary, Lead Industries Association, New York

Low Melting Point. This property of lead, and particularly of lead alloys, results in the use of lead for many purposes, such as solder and fusible alloys. The low melting point makes lead castings and type metal easy to manufacture, but is often a disadvantage—in chemical equipment, for instance, where lead must be confined to use at relatively low temperatures. However, this disadvantage may be lessened to some extent by supporting lead properly with other materials or by actually bonding it to steel for support.

Strength. The fact that lead has both low tensile strength and low creep strength must almost always be considered in applying lead commercially. Strength is important more often than not. Even when strength is essential, however, the low strength of lead does not necessarily preclude its use. Lead products can be designed so that lead will reinforce itself, or inserts or supports of other materials can be provided. Alloying with certain other metals, notably antimony, is a common method of strengthening lead. But in most uses for lead, adequate support should always be provided. Thus horizontal lead pipes are usually supported continuously and vertical pipes are supported at frequent intervals. Sheet-lead linings in deep tanks are supported by lead-covered steel straps.

Lubricating Properties. The fact that lead has good self-lubricating properties results in a number of commercial applications. As a coating on wire and on sheet metal, lead acts as a drawing lubricant. Used in powder or wire form, lead imparts proper lubricating properties to friction materials like brake linings. As a powder, lead is employed in heavy-duty lubricating greases and in pipe-joint compounds.

Expansion. The relatively high coefficient of thermal expansion of lead is another property that must be considered in many uses of lead. For instance, in pipe lines subject to wide variations of temperature, provision must be made for free expansion. In lead roofing and flashing, where expansion is always a factor, it is provided for by using small sheets to minimize expansion in any one sheet, and by loose-locking each sheet to the next, in order to prevent cumulative expansion.

Alloying. Lead alloyed with other metals is used commercially in large tonnages. Antimony and tin are the alloying metals most commonly employed. Antimony is generally used to give greater hardness and strength, as in storage-battery plates, sheet, pipe and castings. Tin also increases hardness and strength, but the lead-tin alloys are most commonly used for their melting characteristics, as in solder. In solder, terne metal and other lead alloy coatings, tin imparts the ability to bond with metals like steel and copper. High-purity lead has very slight bonding ability. Both tin and antimony improve the casting qualities of lead. Bismuth and tin are often alloyed with lead to obtain the extremely low-melting alloys. Although lead does not alloy readily with copper, it is combined in rather high percentages with copper in certain bearing alloys, and is frequently used in smaller percentages in bronzes and free-machining brasses. Likewise, though lead is difficult to alloy with steel, fractional percentages of lead are used in the production of free-machining steel. Calcium, magnesium, and sodium in fractional percentages are sometimes alloyed with lead in special bearing alloys and cable sheathing. Cadmium additions prove helpful in coating copper wires with lead.

Resistance to Corrosion. This property of lead determines its use more often than any other. Lead is highly resistant to corrosion by the atmosphere, water and a long list of corrosive chemicals in everyday use, most common of which is sulfuric acid. The selection and use of lead under corrosive conditions is discussed in detail in the article on page 951. Where long life and resistance to corrosion are factors, applications of lead are subject to the limitations of its other properties, such as low strength and high expansivity. As pointed out elsewhere, there are usually ways to surmount these limitations, but they should be kept in mind while designing to get best results with lead.

No attempt has been made here to discuss in detail all the properties of lead determining its fields of application, or all the fields of application of lead. Rather, some salient points and examples have been mentioned as a guide in judging the suitability of lead for a particular purpose.

Type Metals

By Bruce W. Gonser* and J. Homer Winkler*

TYPE METALS, a class of metals used in the printing industry, are generally alloys of lead, antimony and tin, with small amounts of copper in the hardest alloys. Various other alloying elements, such as cadmium and tellurium, have been added to type metals, but any advantage from these elements has been insufficient to warrant such additions, except for special purposes. Tin-base alloys might be suitable for type metals, but are considered too expensive. Zinc-base alloys—for example, a 94% Zn, 6% Al alloy—offer too much difficulty in handling. A modified 95% Al, 5% Si alloy has been used to a very limited extent in making aluminotype printing plates, but the advantages in lightness and resistance to corrosion by colored inks have usually been more than offset by the need for casting in plaster of Paris molds. For present commercial usage, therefore, the term "type metals" refers to lead-base alloys of compositions listed in Table I.

The lead base provides low cost, low melting point and ease in casting—properties desired in all type metals. Additions of antimony not only harden the alloy and make it more resistant to compressive impact and wear, but also lower the casting temperature and minimize contraction during freezing. Tin adds fluidity and greater ease in casting, reduces brittleness, and imparts a finer structure—a property helpful in reproducing fine detail.

Constitution.[2, 4, 6] The constitution of the Pb-Sn-Sb alloys is described elsewhere.* A ternary eutectic exists at 462 F (239 C) with the composition of the linotype metal, 84% Pb, 4% Sn and 12% Sb. At 476 F (246.5 C), with the composition 80% Pb, 10% Sn and 10% Sb, there is the eutectic of a pseudobinary system of the compound SbSn and lead.

Compositions for Specific Uses.[1, 3] Electrotype metal contains the lowest percentages of tin and antimony, since it is used as a backing metal only, and is not required to resist wear. In making an electrotype, a thin copper (or nickel plus copper) sheet is electroformed over a wax, lead, or thermoplastic impression to give a wear-resistant replica of the surface to be printed. This "shell" is removed, flux and solder-foil are applied to the nonprinting side, and molten electrotype metal is poured into the shell to give an adherent backing of requisite thickness. Since such a printing plate is frequently curved for attachment to rotary presses, it is necessary that the plate of electrotype metal (0.065 to 0.250 in. thick) be ductile. Fluidity of the molten metal is also essential to avoid local cavities or soft spots in the printing surface. Thus, the ratio of tin to antimony is high, as compared with other type metals. Electrotypes are used where long printing runs are required and where the highest quality of printing is needed.

Stereotype metal is also cast in fairly large printing plates of relatively thin cross section. The metal is cast against a fiber composition impression of the surface to be printed, usually in curved vertical steel molds, and frequently with the porous fiber mat held in place by vacuum. Good castability is needed to reproduce the printing surface accurately. Unlike electrotype metal, however, stereotypes are ordinarily used directly for printing; hence

* Battelle Memorial Institute, Columbus, Ohio

* *See* Constitution of Alloys Section, page 1267.

a harder, wear-resistant metal is needed. This necessitates the use of higher contents of tin and antimony. Sometimes, for greater resistance to wear, stereotypes are lightly electroplated with chromium or nickel. Newspapers with a large circulation are usually printed from stereotypes, so that a number of presses can be operated simultaneously on the same work.

Linotype or slug-casting metal is die-cast by such machines as the Linotype, Intertype, and Ludlow casters. These produce an entire line of type characters in each casting. The Linotype and Intertype machines are used in newspaper type composition because of the speed of production that can be obtained. For this purpose, a low melting point and short temperature range during solidification are of greatest importance, and the ternary eutectic alloy or compositions near this are favored.

(d) 1.5% Cu
(e) 2.0% Cu

Monotype metal is also die-cast by machine. In this method, since only one type character is cast at a time, a rapid cooling rate is possible, permitting the use of harder alloys of higher melting range. Monotype metal must have excellent casting characteristics, resistance to wear, resistance to the pressures of printing, and of molding for electrotype or stereotype production. The pressure may amount to 2500 psi. Rules, spacing material, metal mounting units, and bearers used in assembling the type composition in chases for printing or molding, are cast on Lanston monotype or Elrod machines.

Foundry type metal is used exclusively to cast type for hand composition. The cast type is used over and over again instead of being melted before reuse, as other type metals are. If not used to print directly, this type is subjected to heavy pressure in forming molds for electrotypes, stereotypes and other duplicate plates. Such service requires the hardest, most wear-resistant alloy that is practical to use. Small additions of copper as a hardener are feasible for foundry type since the metal is remelted infrequently, and then not in printing establishments, but at the plant of a type founder, where dross losses and composition can be carefully controlled.

In making all the machine-cast type, including foundry type, the molten metal is forced into metal dies under only moderate pressure, so there is a tendency for the casting to be porous within, although the printing surface is sound because it is chilled first. There is a tendency for the alloys with high tin and antimony contents—for instance, with more than 12% Sb—to segregate during slow cooling, but these alloys make homogeneous chill castings. To avoid the necessity for handling several alloys of not widely different composition, there has been some tendency to use a compromise composition for monotype, linotype and stereotype metal. The U. S. Government Printing Office has used an 82% Pb, 6% Sn, 12% Sb "universal" alloy for this purpose.

Contraction During Solidification.[7, 8, 9] A common fallacy in accounting for the sharpness of definition of printing characters is to ascribe this excellent reproduction to a slight expansion of the type metal during solidification, rather than to fluidity of the molten metal. In reality, as shown in Table II, all type metals contract slightly.

Table II
Contraction of Type Metals During Solidification[7]

Metal	Composition, percentage Lead	Tin	Antimony	Contraction During Solidification, %
Electrotype	92	4	4	2.6
Stereotype[a]	83.7	4	11.3	2.0
Linotype	79	5	16	2.0
Monotype	76	8	16	2.0
Lead	100	...	...	3.4
Tin	...	100	...	2.8
Antimony	...	...	100	1.4[b]

(a) Specimen contained 0.5% Cu
(b) H. Endo, reference 10

Bismuth additions to type metals will overcome contraction, although the cost of the metal is greatly increased and the mechanical properties are generally inferior.[5] Tests with electrotype metal indicate that an addition of about 25% Bi is necessary in order to obtain an alloy that does not shrink during casting and cooling to room temperature.*

Age Hardening of Type Metals.[11, 12, 13] The solid solubility of antimony in lead decreases with decreasing temperature below the eutectic temperature, making age hardening possible by rapid cooling of the alloy. Type metals, or lead containing both antimony and tin, likewise

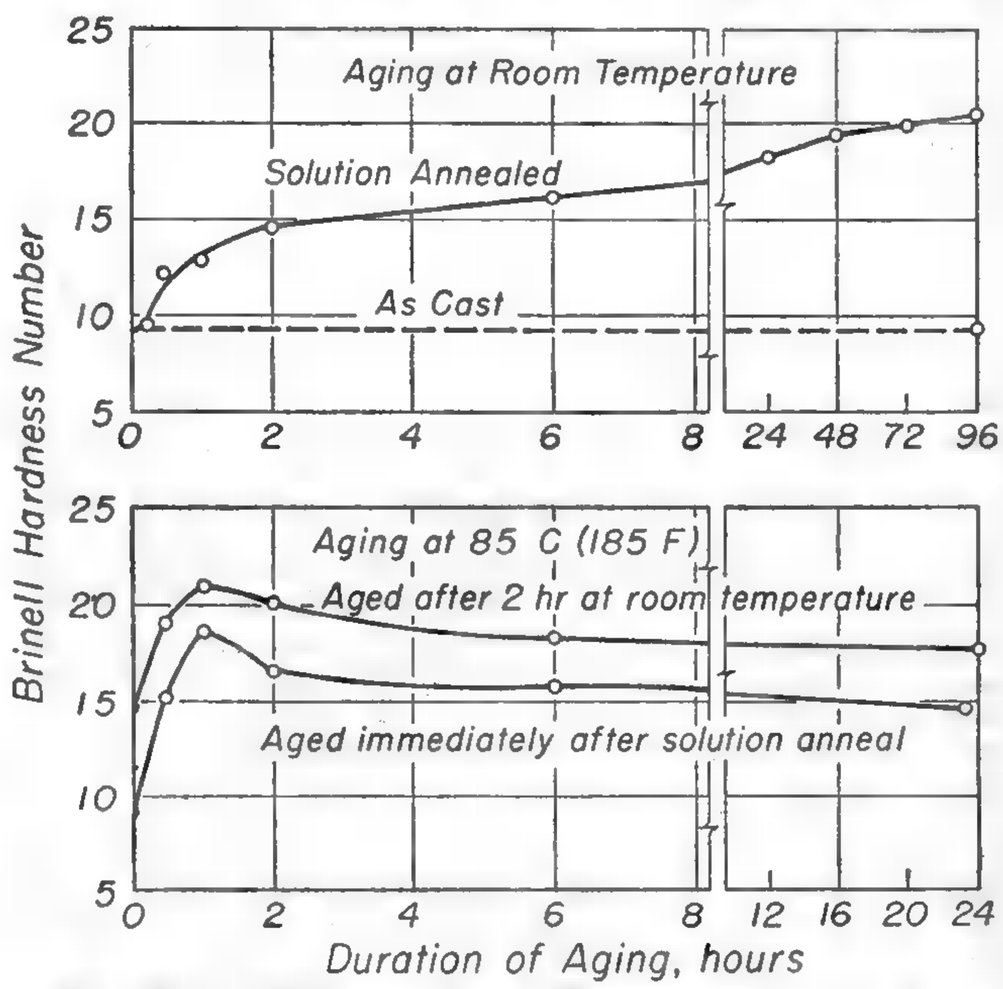

Fig. 1 Age hardening of a type metal containing 97% Pb, 1% Sn, 2% Sb. Alloy solution annealed for 30 min at 455 F (235 C) before being cooled to room temperature.

age harden after proper quenching. In electrotype metals that contain only a small amount of tin and antimony, this effect is much more pronounced than in the harder stereotype and machine-cast type metals.

Frequently, in practice, a slow increase in hardness is noted in electrotype backing metal as cast, and in chill-cast type metal of higher tin and antimony contents. If the metal is quenched from ■ temperature just below the eutectic, age hardening proceeds slowly as shown in Table

* B. W. Gonser and R. M. Schaffert, unpublished data

III. This hardening time can be greatly shortened by aging the metal at slightly elevated temperatures, as for one minute at 212 F (100 C) or for an hour at 185 F (85 C). Increased hardness can be attained also by initiating the aging treatment at room temperature, or by pausing for an hour or two at room temperature before heating to an elevated temperature. Figure 1 illustrates the effect of these factors. When the metal is aged at an elevated temperature after being held for 24 hours at room temperature, a slightly higher hardness is attained, which decreases very little even after six months of storage. Age hardening has been used to a limited extent in practical plant operation, to harden electrotypes.[14]

Table III

Effect of Aging on the Hardness of Type Metals[11]

Composition, %			Brinell Hardness Number[a]					
			As	Duration of Aging at Room Temperature[b]

(b) Water-quenched after solution annealing for 30 min at 455 F

Effect of Impurities.[3,16] Since type metals, other than foundry type, are remelted and recast repeatedly, there is always danger of contamination by unwanted metals, as well as by oxide and dross formed during melting and handling of molten metal. Also, since new type metal usually comes from secondary metal refineries, it is seldom as pure as the virgin constituent metals. Copper, zinc, nickel, aluminum, and arsenic are the principal metallic impurities that may cause trouble in type metals.[1,4] Iron is present in very small amounts, principally because of the action of tin on the iron equipment used in melting and casting; but iron is not usually considered a harmful impurity, except that it increases the amount of dross.

Copper forms needles of high-melting intermetallic compound with both tin and antimony. Aside from its general effect in hardening the metal, when present in amounts of 1 or 2%, smaller amounts of copper may cause unwanted hard spots. Moreover, the crystals tend to catch at the nozzle in machines used for casting, and to interfere with the flow of metal. The presence of more than 0.1% Cu is considered definitely harmful. Nickel has much the same effect as copper since, in a similar manner, it forms a high-melting, hard, intermetallic compound with tin. Prolonged heating will remove this compound as a dross, but an increase in the amount of dross is not desirable.

Zinc increases the surface tension of lead alloys and seriously impairs castability, particularly when present in amounts greater than 0.1%. Aluminum has a similar effect. These metallic impurities all contribute to loss of metal by the formation of dross. Since cadmium has properties similar to those of zinc, it might be expected to be harmful also, but actually small amounts of cadmium are helpful. An addition of 0.5% Cd has been suggested in order to lower the melting point slightly and to improve castability.

Some users of type metal consider that arsenic decreases the fluidity of the metal; others have found that normal amounts, up to 0.15%, cause no trouble; and as much as 0.75% As has been added purposely to increase hardness and castability. With increase in hardness there is loss of ductility, however. Addition of 0.1% As to electrotype metal increases the hardness about one Brinell number. Such an addition has no appreciable effect on age hardening characteristics.* Arsenic has been held at least partially responsible for corrosion of the nozzles of type-casting machines.

General Handling Characteristics. The type metals melt and cast easily, without being particularly sensitive to temperature, segregation or oxidation. In machine casting, of course, where speed of solidification is important, the temperature of the molten metal should be controlled carefully to obtain solidification in the time before ejection. With monotype metal for casting into chill molds, the temperature of the molten metal is kept about 150 to 200 F above the liquidus; with stereotype metal, where the casting box is kept comparatively hot, the temperature of the metal needs to be only about 70 F above the liquidus.

Since the alloys that contain more antimony than the eutectic composition are chill-cast, segregation is no problem in the cast alloys. It is likely to occur, though, in pots of molten metal, unless the metal is stirred. Metal is lost by formation of dross chiefly in the remelting pots, rather than in the casting machines. Tin and antimony are oxidized selectively, as in the fire refining of lead; hence the composition gradually becomes lower in these metals. A nearly constant composition is maintained, however, by the addition of an alloy abnormally high in tin and antimony.

Oxide skim and dross form on the surface of molten type metal, particularly when the metal is overheated or is being cleaned by treatment with steam or compressed air. Fortunately this coating is readily removed. It is seldom forced into the mold to cause casting defects, but it may cause considerable mechanical trouble by clogging lines and die openings. The dross contains a high percentage of unoxidized metal that has become entrained in the oxide and high-melting crystals. Part of this metal is recovered by treatment with charcoal-oil mixtures, which are reducing as well as combustible, or with tallow, palm oil, or rosin.

Grain Refinement.* Grain size of type metal depends on the rate of cooling during solidification. A fine grain size is favored and may be obtained by lowering the temperature of the molten metal or by reducing the temperature of the mold, or both. Small amounts of added elements also affect the grain size drastically. Addition of only 0.1% As or about 0.15% Te is sufficient to give electrotype metal a desirable fine grain, without appreciably affecting the hardness or ductility. Small amounts of calcium, lithium, or magnesium increase markedly the grain size of electrotype metal, probably because of deoxidation.

PROPERTIES OF LEAD AND LEAD ALLOYS

Lead (99.90+ Pb)

COMPILED BY C. R. INCE* AND G. O. HIERS*

A *1 Common name.* **Chemical Lead**†
3 ASTM number. B 29–43 (pig lead)
B *1 Typical uses.* Principally as a material of construction in the chemical industry; also for most of the things for which other grades of lead are used.
C *1 Density* at 20 to 25 C (68 to 77 F). 11.340 g per cu cm (0.4097 lb per cu in.)
D *1 Melting point.* 325.6 C (618 F)
19 Recrystallization temperature. Below 0 C (32 F) for 99.999% Pb
I *2 Resistance to specific agents.*

Corrosive Agent	Resistance	Remarks
Acetone	Resistant	
Acetylene	Resistant	
Acid acetic	Moderate general attack	Used to handle acetic anhydride and glacial acetic acid
Acid chromic	Resistant	
Acid citric	Moderate general attack	
Acid hydrochloric	Moderate general attack	Use not recommended generally
Acid hydrofluoric	Resistant	
Acids mixed	Resistant	At ordinary temperatures with 30% H_2O
Acid nitric	Severe general attack	Used at normal temperatures above 80% conc
Acid phosphoric	Resistant	Up to 80% conc at 200 C
Acid sulfuric	Resistant	Up to 96% conc at room temperature or 85% conc at 220 C
Acid sulfurous	Resistant	
Acid tartaric	Moderate general attack	
Air	Resistant	
Alcohol ethyl	Resistant	
Alcohol methyl	Resistant	
Aluminum sulfate	Resistant	
Ammonia	Resistant	Unless Na or K is dissolved in it
Ammonium chloride	Resistant	Up to 10% conc at ordinary temperature
Ammonium hydroxide	Resistant	
Ammonium phosphate	Resistant	
Ammonium azide	Resistant	
Benzol	Resistant	
Bromine	Resistant	When cold and free from acid
Carbon dioxide	Resistant	
Carbon tetrachloride	Resistant	At ordinary temperatures
Chlorine	Resistant	Moist to 110 C, or dry
Dyestuffs	Generally resistant	
Formaldehyde	Moderate general attack	
Magnesium chloride	Severe general attack	
Magnesium sulfate	Resistant	
Motor fuel	Resistant	
Nickel sulfate	Resistant	
Oxygen	Resistant	
Phenols	Resistant	
Photographic solutions	Generally resistant	
Sodium carbonate	Resistant	
Sodium chloride	Resistant	Dilute solutions at ordinary temperatures
Sodium hydroxide	Resistant	Up to 25% conc and 80 C
Sodium sulfate	Resistant	Up to 10% conc boiling
Sulfur dioxide	Resistant	Moist up to 200 C, or dry
Water chlorinated	Resistant	
Water sea	Resistant	

K *Mechanical Properties.* See Table I and Fig. 1 and 2.
8 Surface tension (in natural gas atmosphere).

Temperature, deg Cent	350	410	480	525	550
Temperature, deg Fahr	662	770	896	977	1022
Surface Tension, dynes per cm	440	437	431	424	423

* St. Joseph Lead Company, New York
* National Lead Company, Brooklyn
† Only Chemical Lead is discussed here, but there are other commercial grades of lead more than 99.90% pure.

L *4 Preferred tension-test specimen.* Flat, ½ in. by ⅛ in. with 2-in. gage length
Preferred fatigue-test specimen. See Fig. 3.
Preferred hardness tests. Rockwell, using ½-in. ball, 30-kg load, 30-sec duration (special scale); Brinell, using 10-mm ball, 100-kg load, 30-sec duration

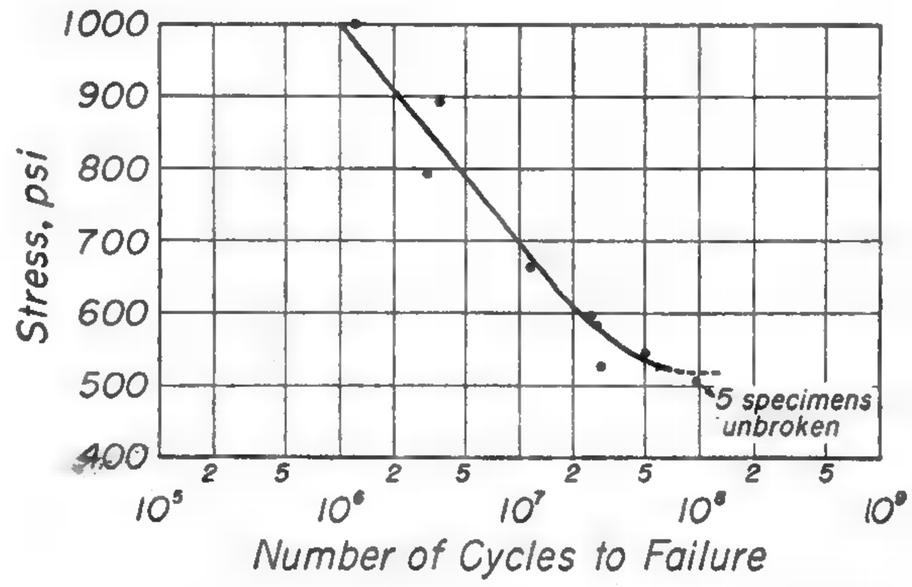

Fig. 1 Fatigue characteristics of chemical lead. Commercial rolled sheet, ⅛ in. thick. Length of specimen parallel to the direction of rolling. Stressed by flexure, 860 cycles per min.

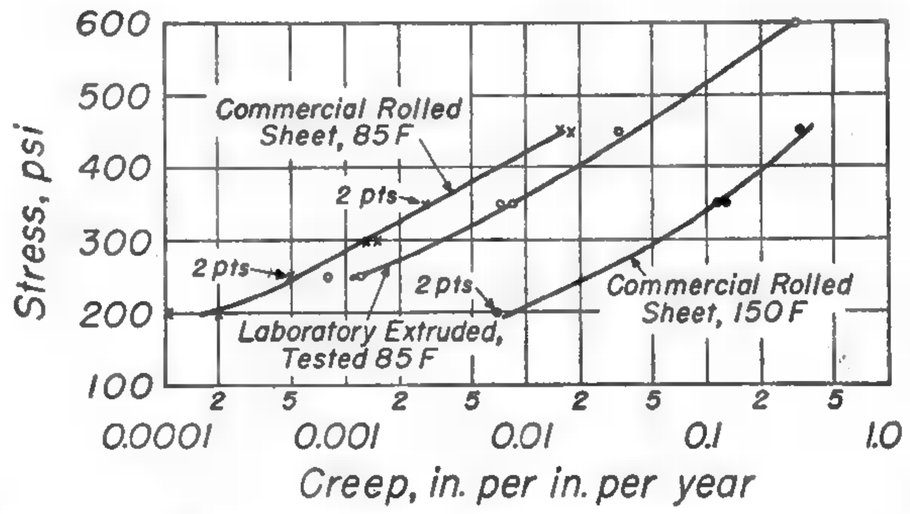

Fig. 2 Creep of chemical lead. Specimens, ¾ in. by ⅛ in. with 10-in. gage length. Length of specimen parallel to the direction of rolling or extrusion.

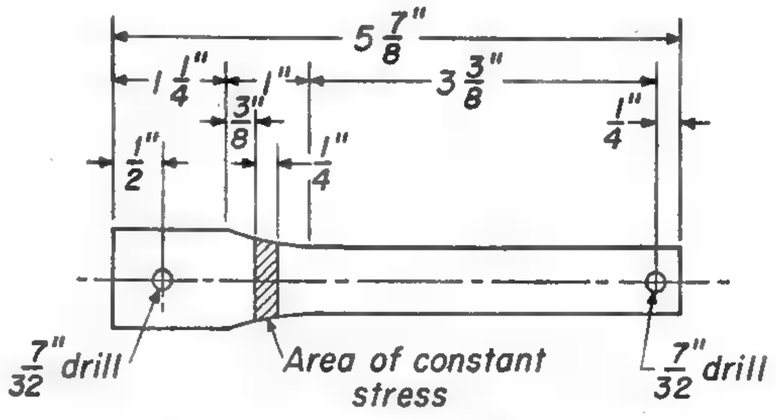

Fig. 3 Fatigue-test specimen for sheet lead

N *1 Melting temperature range.* 400 to 450 C (750 to 850 F)
2 Casting temperature range (ingot). 420 to 445 C (790 to 830 F)
11 Suited to forming by casting, cold rolling and extrusion

See also data sheet for 99.73+ Pb.

Table I. Mechanical Properties of Chemical Lead

Lot	Tensile Strength, psi	Yield Strength (0.5% offset), psi	Percentage Elongation	Rockwell Hardness (special scale)	Micro-character K	Conditions of Material
A	2961	....	42.2	84	....	Laboratory rolled. 2-in. gage length. Less than 30 days after rolling
A	....	....	....	80.9	6.14	Cross section of pig
B	2750	....	35.0	75	....	Laboratory rolled. 2-in. gage length. 3 years after rolling
C	2580	1380	22.0	75	....	Laboratory rolled. 8-in. gage length. 3 years after rolling
C	2800	....	44.0	80	....	Laboratory rolled. 2-in. gage length. 30 days after rolling
C	2150	....	48.0	70	....	Laboratory extruded tape. 2-in. gage length. 30 days after extrusion
D	2630	....	52.0	75	....	Commercial rolled sheet. 2-in. gage length. Cut parallel to direction of rolling. Age unknown
D	2510	1320	27.0	75	....	As above, except 8-in. gage length
E	2575	....	57.0	78	....	Commercial extruded sheet. 2-in. gage length, cut as above. Age unknown
F	2385	1180	29.0	71	5.58	Commercial rolled sheet. 8-in. gage length, cut as above. Age unknown
G	....	....	....	....	5.77	Commercial, steel-backed lead plate

Lead (99.73+ Pb)

COMPILED BY G. O. HIERS*

A *1 Common names.* **Corroding Lead, Common Desilverized Lead, Soft Undesilverized Lead**
3 ASTM number. B 29-43
4 Government number. QQ-L-171

B *1 Typical uses.* Storage batteries, sheath for electric cable, paint, ammunition, anti-knock fluid, sheet, calking, insecticides, type metal, solder, bearing metals, foil, ceramics, liquid medium for heat treating, collapsible tubes, coatings, seals, powder.
2 Precautions in use. Avoid inhalation of lead dust and fumes. Do not use lead to conduct very soft water for drinking, or in contact with food products.

C *1 Density* at 20 C (68 F).
(cast) 11.34 g per cu cm (0.4092 lb per cu in.)
(rolled) 11.36 g per cu cm (0.41 lb per cu in.)
2 Density versus temperature.

Temperature, deg Cent	20	318	(l) 327	400	600	800
Density, g per cu cm	11.34	11.00	10.686	10.597	10.359	10.139

D *1 Melting point.* 327.4 C (621.0 F)
4 Boiling point. 1725 C (3137 F)
6 Thermal expansion (linear)
17 to 100 C (63 to 212 F) 0.0000293 per °C
−190 to 19 C (−310 to 66 F) 0.0000265 per °C
11 Specific heat at 0 C (32 F). 0.0309 cal per g
12 Specific heat versus temperature.

Temperature, deg Cent	−180 to 20	0 to 100	150	200	
Specific heat, cal per g	0.0300	0.03046	0.03176	0.03243	
Temperature, deg Cent	250	300	365	378	459
Specific heat, cal per g	0.03312	0.03380	0.0335	0.0338	0.0335

Heat content (above 25 C) versus temperature

Temperature, deg Cent	100	200	300	400	500	600	800	1000
Heat content, cal per g	2.3	5.5	8.8	18.0	21.3	24.6	31.2	37.7

13 Latent heat of fusion. 6.26 cal per g
15 Latent heat of vaporization. 223 cal per g
16 Thermal conductivity at 0 C (32 F). 0.083 cal/sq cm/cm/°C/sec
17 Thermal conductivity versus temperature.

Temperature, deg Cent	100	200	400	500	600	700
Ther cond, cal/cm/°C/sec	0.081	0.077	0.038	0.037	0.036	0.036

E *1 Volume conductivity* referred to standard copper. 8.3%
2 Electrical resistivity at 20 C (68 F). 20.648 microhm-cm
4 Electrical resistivity (liquid) at 340 C (644 F). 97.867 microhm-cm
5 Temperature coefficient of electrical resistivity 20 to 40 C (68 to 104 F). 0.00336 microhm-cm per °C
Electrical resistivity versus temperature.

Temperature, deg Cent	100	200	300	400
Resistivity, microhm-cm	27.021	36.478	47.938	101.8

10 Electrochemical equivalent.
(valence 2) 1.0736 mg per coulomb
(valence 4) 0.5368 mg per coulomb
11 Electrolytic solution potential vs. hydrogen. 0.122 v
16 Supraconductive at 4 deg Kelvin

F *1 Reflectivity.* 62% for $\lambda = 5890$ A
2 Refractive index.
Solid, 2.01 in yellow light
Molten, 0.415 for $\lambda = 6020$ A
3 Absorptive index.
Solid, 3.48 in yellow light

G *2 Magnetic susceptibility.* minus 0.12×10^{-6} cgs

H *1 Velocity of sound* at 18 C (64 F). 4026 ft per sec

I *1 General resistance to corrosion.* Similar to that of chemical lead (99.90+ Pb)

J *1 Crystal structure.* Face-centered cubic; $a_0 = 4.9389$ kX
5 Minimum interatomic distance. 3.492 kX

K *Mechanical Properties.*

Form	Tensile Strength, psi	Yield Strength, psi	Percentage Elongation	Percentage Reduction of Area	Brinell Hardness Number
Sand cast	1700 to 1900	800	30	100	3.2 to 4.5
Chill cast	2000	...	47	100	4.2

Form	Modulus of Elasticity, psi	Impact Value (Charpy), ft-lb	Shear Strength, psi	Endurance Limit for 10^6 cycles, psi	Poisson's Ratio
Sand cast	2,000,000	....	1825	470	....
Chill cast	.....	10.4	1825	...	0.40 to 0.45

7 Viscosity at 376 C (709 F). 0.0167 cgs units
8 Surface tension at 400 C (752 F). 438 dynes per cm

N *17 Joining.*
Soft solder with 50-50 or 40-60; rosin or stearic acid flux.
Oxyhydrogen welding. No flux; slightly reducing flame. Thin lead requires small torches; thick lead, larger torches.

* Research Laboratories, National Lead Company, Brooklyn

Pb – 0.028 Ca

COMPILED BY E. E. SCHUMACHER*

B *1 Typical uses.* Cable sheath and creep-resistant pipe or sheet
2 Precautions in use. Same as for lead
C *1 Density* at 20 C (68 F). 11.34 g per cu cm (0.409 lb per cu in.)
D *1 Liquidus temperature.* 327.5 C (621.5 F)
2 Solidus temperature. 327.4 C (621.3 F)
E *1 Volume conductivity* referred to standard copper. 8.2%
2 Electrical resistivity at 20 C (68 F). 21.1 microhm-cm
I *1 General resistance to corrosion.* Similar to lead.
K *Mechanical Properties.* See Table I.
6 Minimum creep rate at 26.7 C (80 F). 360 psi, 0.1% per year
M *Composition Limits.* Extrusions, *components:* 0.023 to 0.033% Ca; 0.02 to 0.1% Cu; 0.002 to 0.02% Ag; *impurities:* 0.005% max Bi; 0.005% max Sn.
N *3 Alloying.* Add calcium as 1 to 2% Ca-Pb at 380 to 400 C (715 to 750 F).
Precautions in melting. Do not break the surface of the melt more than necessary.
16 Joining. Solder with most soft solders; stearin flux.

* Bell Telephone Laboratories, Inc., New York City

Table I. Mechanical Properties of Pb – 0.028 Ca

Condition	Tensile Strength, psi	Percentage Elongation	Endurance Limit, 700 cycles per min, psi
Extruded	3000	40	....
Extruded and aged 1 yr at room temperature	4500	25	1700

94 Pb – 6 Sb

COMPILED BY H. E. HOWE*

A *1 Common name.* **Hard Lead**
B *1 Typical uses.* Rolled sheet, extruded pipe for industrial purposes where similar corrosion resistance but higher strength is necessary than in soft lead
C *1 Density* at 18 C (64 F). 10.88 g per cu cm (0.393 lb per cu in.)
5 Solidification shrinkage. 3.11%
D *1 Liquidus temperature.* 285 C (545 F)
2 Solidus temperature. 252 C (486 F)
6 Thermal expansion 20 to 100 C (68 to 212 F). 0.0000272 per °C
11 Specific heat 20 to 100 C (68 to 212 F). 0.0322 cal per ■
16 Thermal conductivity 20 to 100 C (68 to 212 F). 0.069 cal/sq cm/cm/°C/sec
E *1 Volume conductivity* referred to standard copper. 7.6% (held at 225 C, quenched, and aged 150 days)
2 Electrical resistivity at 20 C (68 F). 25.3 microhm-cm
I *2 Resistance to specific agents.* See Table I.
K *Mechanical Properties.*

Table I. Resistance of 94 Pb – 6 Sb to Corrosion

Corrosive Agent	Resistance	Corrosive Agent	Resistance
Acetone	Good	Ammonia	Resistant
Acid acetic	General attack	Ammonium sulfate	Resistant
Acid carbonic	Severe general attack	Bromine	General attack
Acid citric	Severe general attack	Calcium chloride	General attack
Acids fatty	Satisfactory in absence of O_2	Carbon dioxide	Moderate attack in H_2O solution
Acid formic	Severe general attack	Carbon tetrachloride	Resistant in anhydrous
Acid hydrochloric	General attack	Copper sulfate	Resistant
Acid hydrofluoric	General attack	Ferric chloride	Severe attack
Acid nitric	Severe general attack	Hydrogen sulfide	General attack
Acid oxalic	Severe general attack	Iodine	General attack
Acid phosphoric	Resistant	Magnesium sulfate	Resistant
Acid sulfuric	Resistant	Potassium nitrate	General attack
Acid tartaric	Moderate attack	Refrigerants	Resistant in anhydrous
Air	Resistant	Sodium sulfate	Resistant
Alcohol ethyl	Resistant	Water distilled	Considerable attack
Alcohol methyl	Resistant	Water sea	Resistant
Alcohols higher	Resistant		
Aluminum sulfate	Resistant		

Condition	Tensile Strength, psi	Elongation in 2 in., percentage	Brinell Hardness Number	Endurance Limit (20,000,000 cycles), psi
Chill cast	6840	24	13.0	2500
Commercially cold rolled 95%	4100	47	...	1500
Extruded	3300	65	10.7	1200

Strength and Hardness at Elevated Temperatures.

COMPILED BY G. O. HIERS*

A *1 Common name.* **Silver Lead Solder**
3 ASTM number. B 32-46T, Alloy grade 02
B *1 Typical uses.* For coating and joining
2 Precautions in use. Generally applied by hot dipping or with a torch.
D *1 Melting point.* 310 C (589 F)
I *2 Resistance to specific agents.* The tin is required in order to make this alloy resistant to humid air.
K *Brinell hardness number.* 13.0
M *Composition Limits* (ASTM B 32-46T, Alloy grade 02). *Components:* 97.5% Pb nominal; 0.75 to 1.25% Sn; 1.3 to 1.7% Ag; *impurities:* 0.40% max Sb; 0.25% max Bi; 0.08% max Cu; 0.02% max Fe; 0.005% max Al; 0.005% max Zn; others (total) 0.08% max.

95 Pb – 5 Sn

COMPILED BY G. O. HIERS*

A *1 Common name.* **5-95 Soft Solder**
3 ASTM number. B 32-46T, Alloy grade 5B
B *1 Typical uses.* For coating and joining metals
2 Precautions in use. Usually applied by hot dipping or by torch
C *1 Density* at 20 C (68 F). 11 g per cu cm (0.397 lb per cu in.)
5 Solidification shrinkage. 3.6%
D *1 Liquidus temperature.* 312 C (594 F)
2 Solidus temperature. 270 C (518 F)
6 Thermal expansion 15 to 110 C (59 to 230 F). 0.0000287 per °C
16 Thermal conductivity at 54 C (129 F). 0.085 cal/sq cm/cm/°C/sec
E *1 Volume conductivity* referred to standard copper. 8.8%
2 Electrical resistivity. 19.5 microhm-cm
G *2 Magnetic susceptibility.* minus 0.01×10^{-6} cgs
I *2 Resistance to specific agents.* This alloy is resistant to acetone, milk, mineral oils, motor fuel and petroleum products, and sea water. It is resistant to air, but does tarnish. It is subject to moderate general attack by ammonium sulfate, photographic solutions, potassium chloride, sodium chloride, sodium sulfate.
K *Mechanical Properties.* Tensile strength 3400 psi; yield strength 1500 psi; elongation 50%; reduction in area 80%; Brinell hardness number 8.
M *Composition Limits* (ASTM B 32-46T, Alloy grade 5B). *Components:* 95% Pb nominal; 4.5 to 5.5% Sn; *impurities:* 0.50% max Sb; 0.25% max Bi; 0.08% max Cu; 0.02% max Fe; 0.005% max Al; 0.005% max Zn; others (total) 0.08% max.

80 Pb – 20 Sn

COMPILED BY G. O. HIERS*

A *1 Common name.* **20-80 Soft Solder**
3 ASTM number. B 32–46T, Alloy grade 20B
B *1 Typical uses.* For coating and joining metals; for filling dents or seams in automobile bodies (body solder).
C *1 Density* at 20 C (68 F). 10.20 g per cu cm (0.368 lb per cu in.)
5 Solidification shrinkage. 3.0%
D *1 Liquidus temperature.* 277 C (531 F)
2 Solidus temperature. 183 C (361 F)
6 Thermal expansion 15 to 110 C (59 to 230 F). 0.0000265 per °C
16 Thermal conductivity at 54 C (129 F). 0.089 cal/sq cm/cm/°C/sec
E *1 Volume conductivity* referred to standard copper. 9.8%
2 Electrical resistivity. 17.5 microhm-cm
G *2 Magnetic susceptibility.* minus 0.08×10^{-6} cgs
I *2 Resistance to specific agents.* This alloy is resistant to milk, mineral oils, motor fuel and petroleum. It is fairly resistant to air, but does tarnish on exposure.
K *Mechanical Properties.* Tensile strength 5800 psi; yield strength 3650 psi; elongation 16%; reduction in area 50%; Brinell hardness number 11.3; impact value, Charpy 12.2 ft-lb; shear strength 4740 psi.
M *Composition Limits* (ASTM B 32-46T, Alloy grade 20 B). *Components:* 80% Pb (nominal); 20% Sn; *impurities:* 0.50% max Sb; 0.25% max Bi; 0.08% max Cu; 0.02% max Fe; 0.005% max Zn; 0.005% max Al; others (total) 0.08% max.

50 Pb – 50 Sn

COMPILED BY G. O. HIERS*

A *1 Common name.* **50-50, Half and Half, Soft Solder**
3 ASTM number. B 32-46T, Alloy grade 50A, 50B
B *1 Typical uses.* For general purposes, the most popular of all lead-tin solders
C *1 Density* at 20 C (68 F). 8.89 g per cu cm (0.321 lb per cu in.)
5 Solidification shrinkage. 2.3%

The Magnesium Industry

BY W. G. HARVEY*

MAGNESIUM was isolated as a metallic element and some of its properties determined as early as 1830. Commercial production was not attempted, however, until the beginning of the twentieth century. With density approximately 1.74, or about two-thirds that of aluminum, magnesium is the lightest of the structural metals. The gradual increase in its production and use in the years before World War II can be attributed to the lightness of magnesium alloys, which answered the demand for weight saving in aircraft and in portable equipment and moving parts of many types.

Occurrence. The principal ores of magnesium are dolomite, magnesite and carnallite. In addition, magnesium occurs as magnesium chloride in certain natural salt brines. These brines were the chief source of the magnesium produced in this country in the years before World War II. Another important and virtually inexhaustible source of magnesium is sea water, which contains approximately 0.5% magnesium chloride. This fact would indicate that a cubic mile of sea water contains about nine billion pounds of metal. During World War II, sea water furnished the raw material for the greater portion of magnesium production.

Production Methods. Before 1928, magnesium was made in the United States either by the electrolysis of magnesium chloride or by the electrolysis of magnesium oxide dissolved in molten fluorides. The electrolysis of magnesium oxide was discontinued in 1928, and from then until 1939 the electrolysis of magnesium chloride, derived from underground natural brines, was the only source of the magnesium produced in America.

The war years were characterized by a sharp increase in the production of magnesium. A number of new processes were developed and modifications were made in existing ones. The diversification of methods was largely justified by the necessities of war, such as the movement to safer plant locations, the shortage of certain materials and the need for

* American Magnesium Corporation, Cleveland

Prepared for the Magnesium Committee

economizing in the use of direct-current electricity. At the peak of production in 1943, the following processes were in operation:

Type of Process	Reducing Agent	Source of Magnesium	Derived from
Electrolytic reduction	Electricity (direct current)	Magnesium chloride	Natural brines, potash waste liquors, sea water, dolomite, magnesite
Thermal reduction	Carbon	Magnesium oxide	Sea water
	Ferrosilicon	Magnesium oxide	Dolomite

In the electrolytic process, the cell feed in all instances is molten and substantially anhydrous magnesium chloride. The source of this magnesium chloride varies with the particular installation, and may be underground brines, sea water, waste liquors from the potash industry, dolomite or magnesite. The content of magnesium chloride in brines, waste potash liquors and sea water is low, but its extraction, while not simple, constitutes a well-developed chemical process. Large volumes of raw material must be handled. It is important that the water from the magnesium chloride be eliminated carefully, especially in the final stages, to avoid decomposition. Complete dehydration is not considered essential. Ocean water is treated with lime, which precipitates the magnesium content as hydroxide. This hydroxide is then converted into a concentrated magnesium chloride solution by means of hydrochloric acid made from the chlorine produced by the electrolysis.

One of the electrolytic processes obtains the magnesium chloride by direct action of the byproduct chlorine on dolomite (or magnesite), thus producing an anhydrous cell feed without the need for dehydration. The electrolytic processes, regardless of the source of raw material, are based on the decomposition of substantially anhydrous magnesium chloride into metallic magnesium and chlorine gas. Differences between the density of the molten electrolyte and that of the produced metal cause the metal to rise to the bath surface, where it is ladled out into molds. The chlorine gas is removed through suitable ducts by gentle suction and is used to produce more cell feed by a cyclic process. When the cell feed is not completely anhydrous, some hydrochloric acid gas is produced.

The thermal reduction processes owed their value to the fact that they could be built and put into operation quickly and did not depend on direct-current electricity as a source of power. These processes were of two types, one using carbon and the other using silicon, in the form of ferrosilicon, for the reduction of the oxide. In the carbon reduction, the magnesium oxide (mixed with some suitable form of carbon) is heated to more than 2000 C in a closed electric-arc furnace. Magnesium is liberated as a vapor together with carbon monoxide gas. Since this reaction is reversible at lower temperatures, it requires some form of shock cooling, using natural gas or hydrogen. Oil has also been used for cooling. This rapid reduction in temperature condenses the magnesium vapor to a fine dust which, after being formed into briquettes, is distilled to produce ingot metal. This method is known as the Hansgirg process.

Table I

Production of Primary Magnesium in the United States

Year	1000 Pounds	Year	1000 Pounds	Year	1000 Pounds
1915	88	1926	323	1937	5,782
1916	75	1927	366	1938	6,433

1925	245	1936	4805	1947	18,000 (a)

(a) Estimated

Reduction of calcined magnesite or dolomite by the use of ferrosilicon is known as the Pidgeon process. Finely ground ferrosilicon is briquetted with calcined dolomite in the correct proportions and is placed in highly evacuated cylindrical retorts, generally installed in a horizontal position. The temperature of reduction is about 1150 C. The reduced magnesium condenses in the cooler end of the retort in the form of crystalline rings of metal. This is essentially a batch process.

All these processes had their justification in the need for producing enough magnesium to meet the rising demands of military uses. At peak, the total capacity installed in the United States was approximately 586,000,000 lb annually, divided by processes into 72% electrolytic, 4% carbothermic, and 24% ferrosilicon.

The production of primary magnesium for 1915 to 1947 is shown in Table I. Table II gives the percentage produced by the three basic processes in 1942, 1943, 1944 and 1945.

Table II. Production of Magnesium—By Process

Process	Percentage of Total 1942	1943	1944	1945
Electrolytic	94	85	81	91
Carbothermic	2	4	5	0
Ferrosilicon	4	11	14	9

Principal Products. Pure magnesium is produced in the form of ingots, powder, ribbon, wire, and extruded and rolled strip. The alloys of magnesium are available in the following forms: sand castings, permanent mold and die castings; extruded round, square, rectangular and hexagonal bars, shapes and structural sections; tubing and hollow shapes; rolled plate and sheet; and hammer and press forgings.

Alloys. Pure magnesium has only moderate strength (27,000 psi in the annealed condition); consequently, where structural stresses are involved, magnesium-rich alloys are used. With the exception of iron, chromium and, to a lesser extent, manganese, magnesium will alloy with most of the common metals. However, only a few of these form useful alloys. Certain alloys containing aluminum or zinc or combinations of these are used extensively, while an alloy containing tin and aluminum has good hammer-forging properties. In Table III is a list of the most common magnesium alloys with their approximate compositions and principal uses.

Table III. Composition of Magnesium Alloys

ASTM Designation	Percentage Al	Zn	Mn	Sn	Principal Use
A10	10.0	..	0.10	..	Sand and permanent mold castings

AZ61	6.5	1.0	0.20	..	Extrusions and forgings
AZ80	8.5	0.5	0.15	..	Extrusions and forgings
TA54	3.5	..	0.50	5.0	Hammer forgings
AZ91	9.0	0.7	0.20	..	Die castings

Fabricating Methods. Magnesium alloys react with moisture at or near the melting point; consequently, sand castings cannot be made successfully in the ordinary green sand molds used for other metals. A number of inhibitors have been developed for mixing with the green sand to prevent this reaction. Among the most popular are sulfur, boric acid, diethylene glycol, ammonium fluoride, or combinations of these substances. A small amount of the inhibitor is sufficient when mixed thoroughly with the green sand. Some modification of standard casting methods is generally employed to compensate for the lighter weight of the molten magnesium metal. This is accomplished by using more gates and risers and making these higher and of greater cross section.

The mechanical properties of most magnesium alloys used for casting can be improved by heat treatment. Castings are often aged after heat treatment, when the castings are to be used in highly stressed applications.

Certain magnesium alloys, developed particularly for extrusion, can be fabricated by this process into virtually any shape for which die equipment can be constructed. The

alloys plastic from 500 to 650 F are suitable for forging.

Methods for rolling sheet involve an initial breakdown of either large cast ingots or specially made extruded slabs at an elevated temperature. This hot rolling operation reduces the ingots to approximately ¼ in. in thickness. Reduction is continued by hot slabbing until the thickness reaches ⅛ to $\frac{1}{16}$ in. Further reduction, accomplished by cold rolling, produces satisfactory mechanical properties and surface finish. It is necessary to anneal magnesium sheet frequently during cold rolling. Sheet is supplied in hard and annealed tempers and also as hot rolled. Widths as great as 60 in. and lengths as great as 144 in. can be produced with a maximum weight of 220 lb.

Uses. Pure magnesium is employed as a deoxidizer for brass, bronze, nickel, silver and monel metal. It is particularly useful in the nickel industry because of the ability to reduce nickel sulfide and to render the nickel more malleable. Magnesium serves as an important constituent with other metals. A number of high-strength aluminum alloys contain from 0.2 to 10.0% Mg. In the form of powder, magnesium is used as a pyrotechnic for marine and railroad signals and in military applications. Shavings and coarse powder are used for the synthesis of certain organic chemicals.

These applications of pure magnesium have been cited because they are particularly important; however, they constitute only a small proportion of the present uses. The majority of present and future uses are in alloy products, where high strength and lightness are obtainable. The magnesium alloys weigh approximately two-thirds as much as aluminum and one-fourth as much as brass and iron. In aircraft, magnesium castings are used for many engine parts, such as accessory drive housings, blowers and nose pieces, for landing wheels and many parts of the fuselage.

In other industries, magnesium products are used for parts of bread slicers, pneumatic tools, portable sewing machines, typewriters, textile machinery and packaging equipment. In general, in the form of sand castings, permanent mold and die castings, as extrusions and as forgings, magnesium alloy products are used in equipment which must be portable or in which it is desirable to reduce the inertia of moving parts.

Magnesium Sand Foundry Practice

By M. E. Brooks*

THE MAJOR APPLICATION for magnesium alloys is in sand castings, covering a wide variation in complexity of design. Production castings are being made varying in size from a few ounces to as much as 1000 lb. Magnesium sand castings are used in aircraft parts for engines, landing gear and control mechanisms. They are also used in lawn mowers, pneumatic tools, portable saws, X-ray units, and in many other fields where the combination of strength and light weight is advantageous.

Molding Sand. The preferred molding sand for the casting of these alloys is synthetic, made either from washed silica sand or from bank sand, and bonded with 3 to 4% bentonite. The base sand should have an AFA grain fineness of 60 to 90, which is adequate to ensure the desired high permeability.

All green molding sand must be treated with a chemical agent to inhibit the action of the water vapor on the hot metal. At present, American foundries are using various combinations of agents—usually a mixture of two or more of the following materials: sulfur, boric acid, and ammonium fluoride compounds. The concentration of the protective agent decreases slowly as the sand is used, and more agent must be added to maintain proportions.

Gating and Feeding. The proper gating of a casting is one of the most important concerns in operating a magnesium foundry. The metal should enter the mold cavity near the lowest point and flow through a number of small gates rather than a few large ones. For the common type of gating, a runner is placed completely around the casting with a number of gates entering the casting uniformly around its perimeter. To make sound castings, it is necessary to use large risers properly placed to feed heavy sections. Chills should be used to assist in making heavy sections sound. Cast iron makes the best chill material for magnesium alloys.

Cores. Cores should be made from an open sand and must be strong and hard enough to withstand handling. Care should be taken to ensure that cores are well vented, with adequate provision for the core gases to travel back through the cores to the outside of the mold. Magnesium alloys are so light that back pressure, built up in the cores or in the mold, will cause blowholes in the casting. Since magnesium alloys are subject to "hot short" cracking, they must be given freedom to shrink during solidification. If the grain of the metal has been properly refined, these alloys will tolerate harder cores than aluminum casting alloys.

The core binder used should be one that allows easy knock-out, generates a minimum of gas, does not cause the cores to pick up moisture after baking, and allows the core surface to break down under the heat of the poured casting. Although good oil binders have been used satisfactorily, the urea formaldehyde resin binders are more desirable. The use of about 1% each of sulfur and boric acid in a urea formaldehyde core mixture will give enough protection for most castings. Another protective agent that has been used to some extent with satisfactory results is potassium fluoborate. About ½% of this, in addition to the sulfur and boric acid in the core mixture, will give good protection for castings that have heavy sections. In general, cereal binders are used only as an auxiliary to other binders for giving special properties to the cores.

Melting Crucibles. Crucibles fabricated from steel plate are used for melting and casting magnesium alloys and vary in capacity from approximately 60 to 1000 lb. These crucibles are heated with either gas or oil, and under normal conditions of operation, the products of combustion have no effect on the quality of the metal.

Since boiler plate, when unprotected, scales badly under conditions of use, it has been found desirable, both for safety and for economy, to protect the crucibles by treatment with aluminum. This is accomplished by spraying aluminum on the sandblasted or grit-blasted steel surface and then heat treating to alloy the aluminum with the steel. When properly applied, this treatment decreases the scaling to such an extent that crucibles are usually discarded because of distortion resulting from load at high temperatures rather than because of scaling.

Some regular and thorough method of checking the soundness of the crucibles should be carried on at all times. The large premelting crucibles, in particular, should be checked with calipers at regular intervals and should be discarded when spots are found that are too thin for safe use. Also provision should be made in the installation of large premelting furnaces so that if the crucible should leak in service, the molten metal will not flow out onto the working floor, but all of it will be carried into a convenient steel cooling pan.

Both in the large premelting furnaces and in the smaller furnaces for heating the metal for casting, care should be taken to ensure that no appreciable amount of iron scale is allowed to build up. If iron scale is allowed to accumulate in these furnaces and the crucible leaks molten magnesium alloy into this hot iron scale, a thermit reaction may result, causing serious consequences. This can be avoided by keeping the furnaces clean and scale free.

Fluxes. The fluxes used in melting magnesium alloys are mixtures of chlorides with small amounts of other mate-

* The Dow Chemical Company, Midland, Mich.

Prepared for the Magnesium Committee

rials. Since magnesium chloride is a major constituent, the fluxes are hygroscopic. The two types used in sand foundry melting are known as open-pot flux 230 and crucible flux 310. The open-pot flux fuses to a thin fluid during melting and remains thin in normal operation. The crucible flux fuses to a thin liquid when first heated during the melting operation, but changes to a dry, scaly crust after being held at about 1400 F or higher.

If the metal is melted in a premelt crucible, a melting flux of the open-pot type should be used in the quantities required to prevent burning. Care must be taken to prevent the accumulation of large quantities of this flux, or of sludge, in the bottom of the crucible, since such accumulations will decrease the life of the crucible because of excessive scaling on the outside.

Scrap. All ordinary clean foundry scrap may be melted directly in the premelt furnace and transferred to the casting crucibles for pouring. The normal ratio of ingot to scrap is about one part of ingot to four parts of scrap, although 100% scrap can be melted with no bad effects on the quality or properties of the casting. Scrap that is damp should always be dried thoroughly before being placed in the melting crucible. If the moisture content is large, a blow may result when a damp casting is placed in the crucible, and even a small amount of moisture is undesirable because it may cause gassed metal. Hydrocarbon oils on a magnesium alloy that is being melted may also cause gassed metal.

The only impurity that is likely to be picked up in ordinary foundry operations is silicon. If castings are charged into a melting furnace with cores only partly knocked out, or with sandblast or foundry sand on the casting, the SiO_2 will be reduced by the molten magnesium alloy, with an increase in the silicon content of the metal.

Melting. After the casting crucible has been filled, either from the premelt furnace or by melting directly in the crucible, the metal must be stirred thoroughly to clean it. This can be done by means of an iron stirring rod or by treatment with chlorine gas. If the metal is to be stirred by hand, the surface of the melt should be covered with a thin layer of crucible flux, and the melt should be stirred with an iron rod in such a manner that the flux is mixed with the metal. This flux wets the nonmetallic impurities and the stirring helps to coalesce these particles, causing them to separate from the metal as sludge. Enough flux should be used to maintain a liquid film on the surface of the melt during stirring. The metal should be heated to between 1320 and 1350 F during this operation.

In all melting operations, the amount of flux used should be the minimum that is necessary to control burning and to clean the metal properly. If the premelt method is used, a normal consumption is about 2% each of the open-pot and crucible fluxes. If all metal is melted in the casting crucibles, about 3% of the crucible flux is normal consumption.

The use of chlorine gas in magnesium foundry melting practice has been developed recently and is similar to that used in aluminum melting. It not only removes gas from the metal, thus decreasing trouble from microporosity, but also stirs and cleans the metal, thus replacing the hand stirring. The gas is bubbled through the melt in the casting crucibles at about 1350 F for the length of time found necessary to remove the dissolved gas, usually between 5 and 15 minutes. The gas is bubbled through the metal at the highest rate possible without spattering metal from the crucible.

Grain Refinement. The grain size of the cast metal is refined by superheating and the mechanical properties are improved. Superheating practice varies somewhat in different foundries. In general, 5 to 15 minutes at a temperature of 1650 F, or heating to 1700 F, gives good grain refining. For best results, the crucible should be removed from the furnace at a temperature of about 1650 F and should be cooled in air to the casting temperature. Slow cooling to casting temperature in the furnace causes part of the grain refining effect to be lost.

An alternate method of grain refinement consists of treating the metal at about 1400 F with a material that contains carbon. At present (1947), this method has not been used enough in production to permit a definite recommendation. The two variations of this method that have been tried most extensively involve stirring solid fine graphite into the melt and treating the metal with chlorine gas bubbled through carbon tetrachloride.

Pouring. Just before time to pour the casting, the flux and oxide skin on the top of the metal are either completely removed from the crucible or pushed back from the pouring lip; then a protective agent is dusted on the molten metal. The crucible is tilted and the metal is poured into the pouring basin in such a way that the stream does not go directly down the sprue. The proper use of a pouring basin is absolutely necessary in producing magnesium alloy castings of good quality. Some oxidation always takes place on the stream of metal flowing into the pouring basin, and since the magnesium oxide has very nearly the same specific gravity as the magnesium alloy, it does not separate from the metal unless a properly designed pouring basin is used. The dimensions of the pouring basin will vary with the size of crucible from which the metal is poured. The pouring basin may be made of cast iron, core sand, or green sand rammed up in a box. The basin must be long enough so that the stream of metal from the crucible will not go directly into the sprue. The injection of a small amount of sulfur dioxide gas into the mold cavity, just before pouring, will help prevent oxidation on the surface of metal while castings of heavy section are being made.

The proper pouring temperature for each casting can be determined by trial and should be that at which misruns are avoided and sound castings are produced. In general, the pouring temperature of castings ranges from about 1400 to 1600 F.

Since magnesium alloys are hot short, it is essential that they should be allowed to stand in the mold undisturbed while cooling through this range. The interval of time required will vary with the size of casting. Small bench castings can be shaken out a few minutes after pouring, but large castings (poured weight, 200 to 500 lb) may have to stand for an hour.

Cleaning. The first step after shake-out and knock-out should be a sandblast operation to reveal gross surface defects. The blasting material commonly used is a flint silica sand of 35 AFA fineness.

Gates and risers of magnesium alloy castings are usually removed by means of a band saw. The band saws are coarse toothed, usually 4 or 5 teeth to the inch, and set with a large clearance angle to clean out the chips from the cut. The saws operate at from 4000 to 9000 linear ft per min. In order to provide maximum safety, care must be taken not to permit the accumulation of large quantities of chips; good housekeeping should be practiced and chips should be cleaned up at short intervals. It is also necessary to keep the saws sharp and to change them as soon as they get dull. The saw guides used should be of such a design as to minimize sparking.

The rough cleaning operations are done on a grinding wheel wherever possible, because that is the most rapid way to remove metal. Magnesium grinding dust must be collected in a recommended type of collector that contains a water-spray dust-precipitation unit. Ducts from the grinding wheel to the collector should not be more than 3 to 4 ft long and should not have abrupt turns or changes in section. The sludge must be cleaned from the collectors at a definite time, preferably daily, and the material should be disposed of safely. At no time should the sludge be allowed to dry out; it should be kept wet with an excess of water.

Magnesium sludge is best disposed of by burning. This is accomplished by spreading in a thin layer, 3 to 6 in. deep, on a porous burning area that will allow the water to drain and by covering the sludge with combustible waste. Small quantities of sludge may be disposed of by mixing with 4 to 5 parts of sand and burying or by placing in a dump area.

If the sludge is collected at a central point from the individual collectors, it should be stored in covered metal drums, kept wet, stored away from buildings or other combustibles, and disposed of daily.

The general over-all cleaning of the castings is done with rotary files. The operating conditions in this work

area are such that the possibility of the filings becoming ignited is slight, but they should be cleaned up frequently.

Finished castings also are blasted just before the final surface treatment operation, primarily to give a uniform appearance to the pickled casting. This final blasting may be done with either sand or steel grit. No hazard has been observed that is caused by the dust from sandblasting, but if steel grit is used, the dust formed is usually flammable and should be collected in a wet type of dust collector.

Pickling. All castings are given a chrome pickle treatment before shipment. This is primarily for protection against corrosion during shipment and storage in the customer's plant before machining. After machining, more effective chemical treatments form a paint base.

The chrome pickle treatment consists of dipping for about one minute in an aqueous solution containing 1.5 lb of sodium dichromate, and 1.5 pt of concentrated nitric acid per gallon. The strength of this solution is checked by a simple analytical method and the constituents are added in amounts necessary to maintain the composition.

The most suitable tank materials are type 316 stainless steel, 2 S aluminum, or synthetic rubber materials applied over a mild steel base.

Heat Treatment. The mechanical properties of most magnesium alloy castings are improved by suitable heat treatment. The type of heat treatment given depends on the service in which the casting is to be used. The solution heat treatment gives maximum toughness and shock resistance. The aging or precipitation heat treatment, after the solution treatment, gives maximum hardness and yield strength with some sacrifice of ductility. The stabilization heat treatment is a recent development and is really high-temperature aging. Its full use has not been developed, but stabilization will probably find the major use as a stress-relief treatment on cast parts where service conditions do not require maximum strength.

The commercial use of alloys A8, A10, A12, and AZ101 has been limited and the heat treating recommendation given here may need revision upon further development.

The solution heat treatment for the various alloys is given in Table I.

These alloys are slightly plastic at the solution temperature, and the castings must be placed in the furnace in such a way as to prevent warping during heat treatment. This means that some castings must be placed on supports, and heavy castings must not be piled too high.

The aging heat treatment for alloys A8, A10, A12, and AZ101, requires 16 hr at 350 F; for AZ63, 16 hr at 370 F; for AZ92, 10 hr at 425 F. No special atmosphere is required for this treatment.

The stabilization heat treatment cycle consists of 4 hr at 500 F. No special atmosphere is required.

In the solution heat treating furnaces the temperature must be uniform throughout the load within plus or minus 5 F. Control within plus or minus 10 F is satisfactory for the stabilization or aging treatments.

Table I. Schedule for Solution Heat Treatment

Alloy	Solution Temperature, deg Fahr	Duration of Heat Treatment, hours
A8 and A8X	800	10
A10	800	16
A12	800	20
AZ63 and AZ63X[a]	730	12
AZ92[a]	770	20
AZ101[a]	790	20

(a) This alloy must be heated to temperature in not less than 2 hr.
NOTE. All the above alloys should be heat treated in an atmosphere containing 1% SO_2.

Impregnation. Some castings meant to hold oil or air pressure in service, have sections that cannot be made sound because of design or limitations of foundry practice. These areas may be made pressure-tight by using any one of several impregnants. Sodium silicate solutions as well as mixtures of some synthetic resins are used. Of these resins a mixture of styrene and linseed oil has found wide acceptance as an impregnant.

Castings may be impregnated either individually or as a batch in an autoclave built to withstand vacuum and pressure. The impregnation step must follow any required solution heat treatment since temperatures above 500 F will destroy the impregnant.

Repair of Castings. Certain types of defects in magnesium alloy castings may be repaired by shielded-arc welding. The method uses a tungsten arc shielded by helium or argon gas to prevent oxidation of the metal during the welding operation. The defects that can be successfully welded are sand holes, blowholes, gouges and, in general, defects where the operator can be sure of the exact extent of the affected area.

Castings should be welded in the heat treated condition. After welding, the castings are solution heat treated again for one-half hour at temperature, and then aged if required. Castings from alloy AZ63 can be given the full solution heat treatment after welding, without harm to the weld area, but castings from the other alloys must not be held longer than one-half hour for reheating, to avoid trouble from grain growth.

Castings to be welded may be preheated to a temperature of 725 F and welded in the range from 650 to 725 F. They must then be returned to the preheating furnace long enough to equalize the temperature of the casting before cooling in air. The quality of welds is checked by both visual inspection and radiography.

The Permanent Mold Casting of Magnesium Alloys

BY EDWIN C. SANDHAM*

MAGNESIUM permanent mold castings combine the advantages of uniformity, accuracy, high ratio of strength to weight, high production rates and low cost.

Application. Castings are made ranging from a few ounces to more than 70 lb in weight, as long as 6 ft, and more than 400 sq in. in projected area. Because both light and heavy sections may be cast sound, and massive equipment is not required to close the molds, larger castings are quite practical.

Walls as thin as ⅛ in. are cast, although $\frac{5}{32}$ in. is preferable in areas more than 2 in. wide, and $\frac{3}{16}$ in. in areas more than 4 in. wide or 30 sq in. in area. Sections from ⅛ to more than ▮ in. thick may be cast pressure-tight and of full strength.

Ordinarily, a minimum of 1000 to 2000 pieces or about 2000 lb is required to justify the purchase of permanent mold equipment. Typical casting costs are appreciably less than those of sand castings when made in large quantities.

* Partner, Est Company, Grafton, Wis.
Prepared for the Magnesium Committee

Alloys and Properties. Most magnesium permanent mold castings may be made of the 9% Al, 2% Zn alloy AZ92. In the as-cast condition, the average mechanical properties of this alloy exceed those of sand castings by about 15%, but in the heat treated or heat treated and aged conditions the mechanical properties are equivalent to those of sand castings.

This applies also to the 6% Al, 3% Zn alloy AZ63. This alloy has greater toughness than alloy AZ92 but is more difficult to cast in permanent molds.

With proper design and treatment, alloys that contain 8 to 10% Al and 0.25 to 0.75% Zn have the best permanent-molding characteristics, satisfactory strength, and resistance to corrosion. The fact that permanent mold castings are uniform in properties permits high design stresses and actual loading.

Alloys containing cerium have better mechanical properties than the present alloys above 400 F.

Molding Practice. The general method of casting magnesium alloys in permanent molds is similar to that used for aluminum; that is, molten metal is hand ladled from a melting pot into a hot iron or steel die, filling the cavity by gravity. Devices operated by hand or by power are used to close the die and eject the casting, since high pressures are not applied as in pressure die casting.

Cast or wrought steel melting pots that hold 300 to 800 lb of metal are charged with flux, and ingot, scrap or melted metal, usually continuously. The welded steel ladles have bottom-pour spouts shaped to prevent flux and drosses from entering the mold. A single heating to the pouring temperature (1200 to 1350 F) produces an inherently finer grain in permanent mold castings than in sand castings. Superheating or inoculation may be employed to obtain a further grain refinement, which is quickly lost by holding at temperatures near 1300 F.

The mold comprises two or more sections into which have been cut the cavities and suitable gates and risers. In making sand castings, the sand mold is destroyed when the casting is removed, and undercuts, openings and intricate detail are possible. The permanent mold, however, is formed of rigid sections, and must be shaped to permit easy removal of the hot casting. Undercuts on the outside of the part are produced only by loose pieces or by retractable slides or metal cores, which add to the mold and casting cost, and slow the operation. Round holes or those of other shapes may be made by pulling out metal cores before opening the mold. Such methods are limited to holes larger than about ¼ in. in diam and with a depth of two to five times the diameter.

Undercuts or holes that cannot be formed with metal cores are made by using a new baked sand core for each casting. Cores made of silica sand and a dry type of mineral or cereal binder have the necessary strength, permeability and rapid rate of baking. Such cores require less than ½% each of sulfur and boric acid for protection against burning and other defects associated with casting against sand surfaces. Such "semipermanent" mold castings are more expensive than "full permanent mold" castings, but offer most of the advantages of the method.

Draft angles necessary to permit removal of the casting from the mold are: 2 deg minimum, 3 to 4 deg preferred on the outside of the casting, and 3 deg minimum, 4 to 7 deg preferred on inside dimensions and cored holes.

A considerable amount of skill and experience is required in the designing of all parts of the die in order to meet the operating requirements described below.

Proper filling of the cavity is ensured by making suitable gates through which the metal is poured. The size must be adequate, the position correct and provision must be made for the escape of air that would otherwise be trapped. Good surfaces, free from seams, pits or other defects, are secured primarily by gates shaped to avoid turbulence of the metal. Rapid and efficient operation of the equipment depends on temperatures, the devices used to move the die parts and castings, and other factors. Most important, and most dependent on proficiency in the foundry, is the production of adequate soundness of the metal in the casting. The tendency for magnesium alloys to shrink or develop porosity and reduced strength is controlled by providing gates and risers or shrink heads, which supply the necessary additional molten metal to feed each part of the casting. Changes in the shape of the gate can be made only by taking the die out of service, and then only within the limits prescribed by the shape of the part and the die.

Permanent molds for magnesium are commonly made of cast iron, and usually produce from 20,000 to more than 100,000 pieces. Because of the light weight and low heat content of magnesium, die wear is slower than the wear of dies used with aluminum, iron or copper alloys, or for pressure die castings. All surfaces of the cavity are covered with a refractory coating, applied to the hot die by spray or brush. Various coatings are used; an effective one is a suspension of one volume of kaolin and one volume of sodium silicate in ten to thirty volumes of water. By this means, thin sections are made to fill, and proper rates of cooling are employed to produce sound castings and to maintain a fast operating cycle. Gates and risers are small compared with those needed on light metal sand castings; typical ratios of metal poured to trimmed casting weight are 2 to 1 for aircraft, and 1½ to 1 for commercial castings.

Because the design and economical operation of the die depend so much on the shape and details of the part itself, the foundry should recommend the best design modifications regarding cores, undercuts, wall thickness, draft angles and fillets. The rules for magnesium casting design given on page 1005 in this Handbook are particularly applicable to permanent mold castings, because the results of their application are sharply defined and predictable. Parts otherwise difficult to make may be cast economically if the proper conditions are present.

Trimming and Other Operations. The part is separated from the gate by means of a band saw, circular saw, or a fast simple operation on a lathe or drill press. Because the part is already smooth and can be accurately fixtured for the trimming operation, subsequent grinding, filing and sandblasting are eliminated or sharply reduced.

Heat treating, when required, is done in the same manner as for sand castings.

For most parts, with good foundry practice, impregnation is not necessary to ensure leakproof permanent mold castings. When impregnation is necessary, one pressure treatment with the customary natural or synthetic oils should be sufficient.

Castings are usually finished with a chrome pickle treatment. For further information, see the article "Surface Protection and Finishing of Magnesium Alloys", page 991.

The Die Casting of Magnesium Alloys

By J. C. Fox*

THE salient properties of magnesium alloys—ultra lightness, high ratio of strength to weight, excellent machinability, dimensional accuracy, excellent surface finish, and low cost—account for the wide use of magnesium die castings.

In common with the die casting of other alloys, the chief requirements for the successful production of magnesium alloy die castings are: the use of a suitable casting machine to hold and operate a die under pressure, a properly designed die, and a suitable alloy.

In addition to these common requirements, magnesium, because of its particular physical behavior in the molten state, needs special methods of handling when molten.

The Die-Casting Machine. The die-casting machine found most suitable for the production of magnesium die castings is the so-called "high-pressure cold chamber" type. (For an illustration of such a machine, see the article on page 1078.) The molten magnesium alloy is held in a separate furnace beside the machine. The alloy is ladled into an opening of a piston-cylinder arrangement on the casting machine, and directly after pouring, the alloy is forced into the die by means of a hydraulically operated ram.

Injection plunger speeds may vary from 5 to 500 in. per sec. The slower speeds are used particularly with relatively heavy-sectioned gates, giving rise to a flowing effect of the metal as opposed to a spraying effect, usually obtained with the higher plunger speeds. The slow shot, when coordinated with properly controlled gating, venting, pressure, die and metal temperatures, produces sound castings, while the higher speeds are necessitated chiefly for thin-walled

* Chief Metallurgist, Doehler-Jarvis Corporation, New York
Prepared for the Magnesium Committee

castings having thin gate runners. With such conditions the higher speeds are required to fill out a casting properly and to produce good surface finish. The higher speeds of plunger operation, generally used with thin-sectioned gate runners, produce a "spray" effect of alloy into the die cavity.

Die-locking pressures ranging from 1,000,000 to 3,000,000 lb are necessary because of the high injection pressures regularly used. The casting machine must have a supporting frame that is rigid and massive enough to prevent deflection when the die is mounted on it, and to keep the two halves of the die closed when the pressure is exerted in making a casting.

Alloys. The die-casting alloy in most general use today is the 9% Al, 1% Zn alloy AZ91. This alloy is balanced with regard to castability, resistance to corrosion and other properties. The 10% Al, 0.5% Si alloy AS100 has been used to some extent. It has better castability but inferior properties and resistance to corrosion.

Recently a new alloy AM11 (1.25 Al, 1% Mn) has been used commercially to some extent. This alloy has greater ductility but a lower yield strength than AZ91; it can be aged to produce strengths approaching those of AZ91 and still retain good ductility. Lower injection speeds and larger gates are generally employed.

The mechanical properties and the compositions of the die-casting alloys are given in the data sheets, page 1019.

To minimize burning and to retard oxidation at elevated temperatures above the liquidus, a very small amount of beryllium, in the form of a beryllium-aluminum alloy, is added to the molten alloy. The amount of beryllium added is generally less than 0.001%.

Casting Technique. Unlike other die-casting alloys, magnesium alloys must be protected against burning and oxidation while in the molten state. This is done by means of an atmosphere containing sulfur dioxide (SO_2) gas, generated in a specially constructed, double-walled dome, mounted over the alloy melting pot. When elementary sulfur is placed between the walls of the dome, the heat from the pot causes the sulfur to melt and the sulfur vapor to issue through holes surrounding the ladle-opening in the sides of the cover. The sulfur vapor burns on contact with air, forming SO_2, which inhibits the oxidation of the alloy effectively up to operational temperatures of 1250 F.

The cast carbon steel pots for holding the magnesium alloy usually have a capacity of about 400 lb. It is essential that the temperature of the alloy be controlled automatically for the best results.

Fluxes. The die-casting flux is quite different in action from other melting fluxes. The main function of the flux is to refine the molten metal during stirring of the melt. The flux then settles to the bottom of the pot. No protection is offered the surface metal except the protection provided by the sulfur dome.

When ingot and scrap are melted in another pot and liquid metal is transferred to the die-casting pot, the melting practice is the same as given in the section on sand foundry procedure, page 969, for the open pot and crucible.

Dies.* Since magnesium-base and aluminum-base alloys have approximately the same melting points and casting temperatures, the dies for both these alloys can be used interchangeably. The nominal composition of the steel most commonly used is 0.40% C, 5% Cr, 1% Mo and 0.5% V.

This steel will give long die life when heat treated (1800 to 1825 F, air quench, temper at 1050 to 1075 F) to a Brinell hardness of 418 to 460.

Die-casting dies for magnesium are quite similar in design to those used for aluminum alloys, but particular attention must be paid to the factors of gating, venting, size of fillets, and regulation of change of section, in dies for magnesium production.

The magnesium alloy must enter the die with as little turbulence as possible. Therefore the proper gating must be provided, especially where there are cores, lugs, and other protuberances interfering with the smooth flow of the alloy into the die cavity. As in the die casting of other alloys, the maximum efficiency of castings can be achieved only by careful co-ordination of such factors as gating, venting, pressure, temperature of dies, metal temperature and controlled plunger or injection speeds.

Die Temperatures. The control of the die temperature is extremely important in the production of sound castings with good surface finish. Temperatures of the dies may range from 300 to 600 F. The best operating temperature for each die is determined only after actual experience in production. The amount of metal entering the die and the rate of production usually determine the temperature of the dies. Water cooling of the die is resorted to, especially for some heavy-sectioned parts that tend to increase the temperature of certain die sections. Relatively cold dies are likely to produce run-marks, swirls and surface porosity; extremely hot dies promote the formation of excessive oxide films on the die, resulting in rough-surfaced castings.

The Casting of Magnesium Ingots for Working

By Kurt R. Gustafson*

FURNACES for melting, alloying, refining, settling and casting magnesium alloys are generally of the pot type, heated by gas or oil, and have capacities of 100 to 4000 lb. The burners may be set tangentially to the crucible or fired into a combustion chamber immediately below it. Burners of the radiant type, using premixed air and gas, may permit longer service for the pot and faster melting rates. Pots are usually of cast or welded steel, protected with a sprayed metal coating for longer service. Though all operations may be performed in the same furnace, it is generally considered that a product of higher quality can be obtained when separate pots are used for settling and casting.

The metal may be transferred from one pot to another by pumping or pouring; however, pumping is the more popular method. Pumps are of the centrifugal type, driven by an air motor. Ample clearance is provided between the housing, impeller and impeller shaft to prevent binding when the pump becomes heated.

All equipment and tools must be of low-nickel steel (0.2% max Ni). Other tools used in the melting, alloying and preparation operations are a sludging tool, alloying tool, mechanical stirrer, skimming tool, tool for adding calcium, and flux pot.

Durville-type molds, air-cooled cast-iron molds and the direct chill method are used in producing ingots. Because the greatest quantity is produced by the direct chill method, this procedure will be discussed. A sketch of the basic parts of the casting unit is shown in Fig. 1. Since the hydraulic piston that governs the length of the ingots is usually 144 to 168 in. long, the casting operation is semicontinuous. More than one mold is generally used, and as many as six have been operated successfully.

Melting. During the melting, a cover of flux is used to prevent oxidation or burning. When a crucible is being started, the walls are wetted with flux and a small quan-

* Revere Copper and Brass Incorporated, Magnesium-Aluminum Division, Baltimore

Prepared for the Magnesium Committee

tity of flux is placed in the bottom. Pig or heavy scrap is charged first, followed by light scrap. Charging is continued until enough material has been added to ensure a full crucible when melting has been completed. Additions are made while the melting proceeds from the bottom; thus the newly charged metal is supported by solid metal and does not enter the molten bath until it is thoroughly preheated. When it is necessary to introduce solid metals into a molten bath—for example, into the heel of the previous melt—the material to be charged is thoroughly preheated on the sides of the crucible. During charging, precautions are taken to prevent bridging, which may result in a sudden dropping of the solid metal above into the molten heel beneath. It is advisable to work the charge with a poker in order to maintain a constant settling of the solid metal into the molten heel; also, melting efficiency is improved in this way.

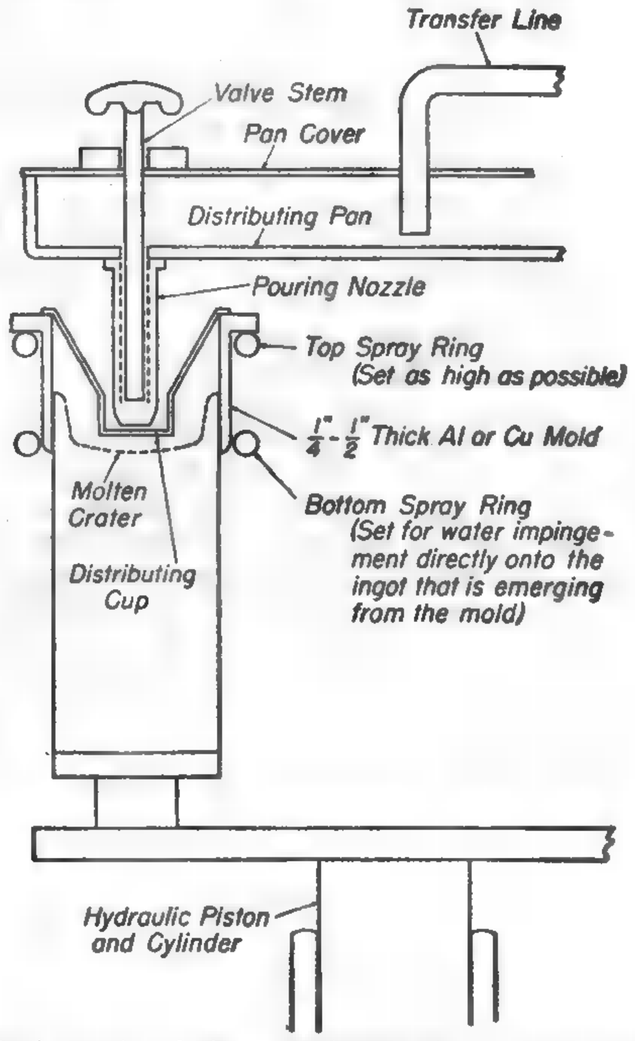

Fig. 1 Basic parts of the unit for casting magnesium ingots

Alloying. Pre-alloyed pig may be used for preparation of all wrought magnesium; however, in large-scale operations it may be advantageous to use magnesium pig and perform the alloying operation. Aluminum, zinc and manganese comprise the chief alloying components of magnesium alloys; aluminum is added to increase strength and hardness in alloys AZ31X, AZ51X, AZ61X and AZ80X,* while zinc and manganese are added to improve the resistance to corrosion. In alloy M1, manganese is added to increase both mechanical properties and corrosion resistance. Calcium in quantities of 0.1 to 0.3% is added to alloys M1 and AZ31X. Exactly how calcium functions in these two alloys is not definitely established at present; however, improvement is observed in the surface of M1 and AZ31X extrusions and M1 rolled sheet when calcium is present. Further, some fabricators maintain that additions of calcium to AZ31X and M1 improve rolling characteristics and reduce susceptibility to splitting in direct chill casting. Beryllium may be added to the aluminum-bearing alloys to reduce their reactivity with water.

High-purity aluminum and zinc are added immediately after the melting, by placing small pieces in the alloying tool and immersing it just below the surface of the melt. Beryllium is added in the same manner and at the highest possible temperature. About 50% of the beryllium is recovered when proper amounts of a 5% Be aluminum master alloy are added in order to obtain a 0.0005% Be content in the melt. Calcium is introduced into the melt 15 to 30 min before casting is started, in order to avoid excessive losses. It may be introduced as a master alloy of 20% Ca in magnesium or in the pure form. Good uniformity of calcium throughout an entire cast is difficult to obtain; however, with close control, maximum variations of 0.015% and recoveries of 75% are obtainable. Recovery will be decreased by increase in temperature, holding time, and the amount of flux present.

* For nominal compositions of these alloys, see page 968.

Refining, Settling and Sludging. Refining is performed by the introduction of a manganese flux to condition the melt for the removal of iron in settling, and to agglomerate oxides and other impurities. When the temperature of the melt is between 1360 and 1400 F, a manganese flux is sprinkled on the bath and stirred simultaneously. The addition is made in order to produce in the melt, before settling, the percentage of manganese given in Table I, and is based on an 80% recovery of the manganese contained in the flux (*see also* Table II).

Table I. Refining and Settling

Alloy	M1	AZ31X	AZ51X	AZ61X	AZ80X
Required percentage manganese	1.50	0.75	0.60	0.60	0.50
Settling temperature, °F max	None	1275	1250	1250	1240

After refining, settling is performed to precipitate iron, the agglomerated oxides and other impurities. For a minimum of 30 min the temperature is reduced below the limits specified in Table I. In order to decrease the temperature as rapidly as possible, heavy preheated low-iron scrap is sometimes added to the melt; this practice is known as "seeding".

During the melting, refining and settling processes, oxides and impurities settle to the bottom of the pot, intermingle with excess flux and form sludge. In the transferring or casting, care is taken not to transfer or disturb this heel of sludge; after the transferring operation the heel is removed. Prior to sludging, the walls of the pot are scraped clean to prevent a build-up of magnesium oxide, which would reduce melting efficiency.

Fluxes. All processes for the production of magnesium ingots require the use of fluxes, and a proper selection is of prime importance if a product of high quality is to be obtained. Table II gives the approximate composition of various fluxes employed.

Table II. Composition of Fluxes for Melting and Refining Magnesium[1]

Dow Chemical Co. Number	Percentage					
	KCl	$MgCl_2$	MgO	CaF_2	BaCl	$MnCl_2$[a]
230	55.0	34.0	...	2.0	9.0	...
232	37.5	42.0	7.5	8.5	4.5	...
250	23.0	...	...	2.5	2.5	72.0
310	20.0	50.0	15.0	15.0	...	...
320	...	...	11.0	13.0	...	76.0

(a) $MnCl_2$ contains 44.0% Mn

The fluxes Dow 230 and 232 are generally used in melting operations where two or more pots are employed in the operating cycle and where transferring is performed by pumping. Both fluxes offer good protection during melting, have good refining characteristics, and are self-healing when tools are inserted. The consistency of the sludge ordinarily determines the choice of flux. If the sludge is too fluid, Dow 232 or perhaps even 310 may be employed to increase the viscosity. Formation of a heavy crust on the walls of the pot and difficulty in loosening the sludge indicate that a more fluid flux is needed.

When all operations are performed in one pot and casting is done by pouring, it is essential to use Dow 310, which remains fluid for melting and then dries while standing, forming a crust that may be skimmed off or held back during casting. However, tools cannot be inserted after the crust has formed, because then the crust would be broken, the protection lost, and the flux carried into the cleansed metal.

Casting. The freezing rate, perhaps the most important factor in direct chill casting, is governed by casting temperature, rate of withdrawal, and application of cooling water. Casting temperatures and rates that have proved satisfactory are shown in Table III; proper spray locations

are indicated in Fig. 1. Application of water should be uniform around the mold and ingot, and impingement should not be so strong that water will rebound from either the mold or the ingot.

Table III. Casting Temperatures and Lowering Rates

Alloys	Temperature, deg Fahr		Rate of Lowering, inches per minute	
	min	max	First 6 in.	Remainder
M1	1260	1275	2.50	3.00
AZ31X	1250	1260	2.25	2.75
AZ51X	1250	1260	2.00	2.50
AZ61X	1240	1250	1.75	2.25
AZ80X	1240	1250	1.25	2.00

Underpouring is always performed so that the sulfide skin in the mold or distributing pan is not broken; otherwise the protection would be lost, and both sulfides and oxides would be incorporated into the ingot.

Common Defects. Some of the most common defects found in magnesium ingots are outlined below, together with some possible causes.

Flux Inclusions. These often result from (1) improper balance of flux causing too fluid a sludge; (2) transfer or disturbance of the flux heel during casting; or (3) too large a heel of sludge in the casting pot because of transfer from other pots, improper sludging, or excessive use of flux.

Oxide Inclusions. These inclusions are generally caused by (1) dirty casting equipment, including transfer pipes; (2) turbulence and insufficient sulfur dioxide for covering the metal at the casting unit; or (3) inadequate refining.

Segregation. Manganese segregation is ordinarily caused by an excessive amount of manganese in the melt, after the settling. A settling temperature that is too high may fail to precipitate the excess manganese, or reheating in the same pot after settling will redissolve manganese and produce an excess. Segregation of magnesium-aluminum compound is less prevalent in direct chill ingots and may be somewhat relieved by homogenizing. This segregation is often caused by improper freezing as a result of high temperatures during casting or insufficient chilling.

Folds. These defects are prevalent in direct chill casting and are often caused by (1) peripheral skin formation in the mold or (2) deep-seated freezing at the crater top.

Splitting. This defect generally results from an excessively rapid rate of lowering.

The Extrusion of Magnesium

By G. Ansel*

MAGNESIUM rods, bars, shapes and tubing can be produced in many sizes and shapes by the extrusion process. Square and round rods and bars are obtainable in sizes as large as 8 in.; rectangles, angles, channels, I-beams and special shapes are available in sizes as large as 14.75 in. Tubing is made in diameters ranging from 0.25 to 12 in., and in many wall thicknesses.

The properties and compositions of magnesium alloy extrusions are presented in the data sheets, page 1013. Various alloys are available for different purposes. M1 (1.5% Mn) is used where a low-cost, weldable alloy of moderate strength is desired. The largest single application of magnesium extrusions to date has been in making rocket-launcher tubes of M1 alloy. The alloys that contain aluminum as the chief alloying ingredient, plus a small amount of manganese and zinc, increase in strength as the aluminum content increases. The strongest commercial magnesium alloy AZ80X HTA (8.5% Al, 0.5% Zn), has found considerable use as structural material for aircraft.

Both direct and indirect extrusion presses are used for the hot extrusion of magnesium alloys. Such presses vary in size from 250 to 5500 tons. The majority are of the horizontal type, though some vertical presses are employed. Either direct pumps or accumulators are used to produce the required pressures.

Billets for the extrusion process are cast either by the direct chill process or in permanent molds. General practice is to extrude M1 alloy in the unscalped condition, whereas the alloys that contain aluminum are usually scalped prior to extrusion to prevent feed-in of the aluminum-enriched cast skin. The largest billet in commercial use is 16 in. in diam by 40 in. long, weighing 500 lb. Billets of small diameter are often cut from extruded bar stock.

The billets are preheated in electric or gas-heated furnaces. No special atmospheres are employed, although extra long heating, which may cause excessive oxidation, is to be avoided because die loading will be increased. Suitable temperatures for heating billets range from 650 to 850 F, depending on the alloy and the section to be extruded.

A brief summary of the extrusion conditions for the various alloys is presented in Table I. It is necessary to include a range of temperatures and speeds to cover individual die characteristics.

* The Dow Chemical Company, Midland, Mich.

Prepared for the Magnesium Committee

It will be noted that containers are generally maintained at somewhat lower temperatures than the initial metal temperature. This combination of temperature is used to ensure easy starting and yet achieve a low effective working temperature, so that the "hot shorting" tendency will be greatly reduced and desirable properties maintained.

Table I. Extrusion Data for Magnesium Shapes

Alloy	Metal Temperature, deg Fahr	Container Temperature, deg Fahr	Speed of Extrusion, fpm
M1	780 to 820	680 to 730	20 to 100
AZ31X	700 to 750	450 to 600	15 to 40
AZ61X	700 to 750	450 to 550	7 to 20
AZ80X	680 to 750	450 to 550	4 to 7

Containers are heated either electrically or by gas. Uniform circumferential heating helps to produce straight extrusions. Die and head are usually heated during operation.

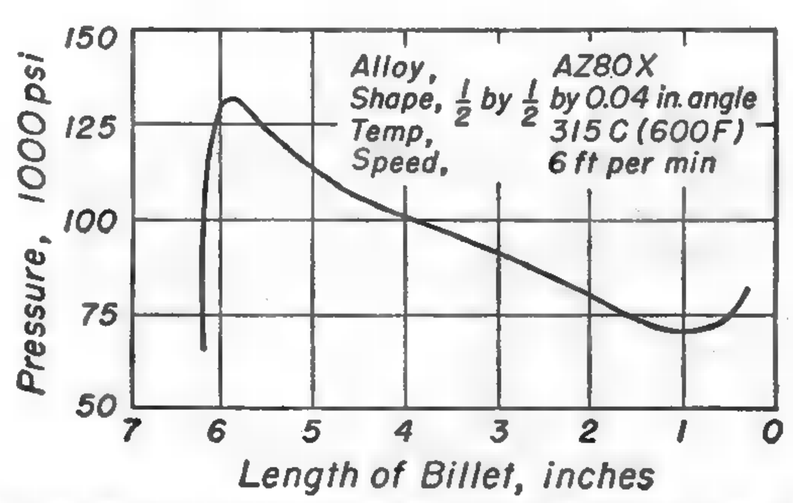

Fig. 1 Extrusion pressure-stroke diagram (Reduction, 184 to 1)

Pressure. Metal pressures used for extruding magnesium alloys vary from 50,000 to 100,000 psi; some jobs require as much as 135,000 psi at the start of a push. Figure 1 is the pressure-stroke curve for an angle ½ by ½ by 0.040 in., extruded from a 3-in. container—a reduction of 184 to 1. Extrusion pressures depend on composition, temperature, speed, length of billet, diameter of container, and the amount and complexity of reduction. Composition,

temperature and speed affect the resistance to deformation. The length of the billet and the diameter of the container affect the friction in direct extrusion.

The factors mentioned above cannot be varied at will, since the properties of magnesium alloy extrusions are determined by the conditions of fabrication. Speed, reduction and temperature affect grain size and orientation and

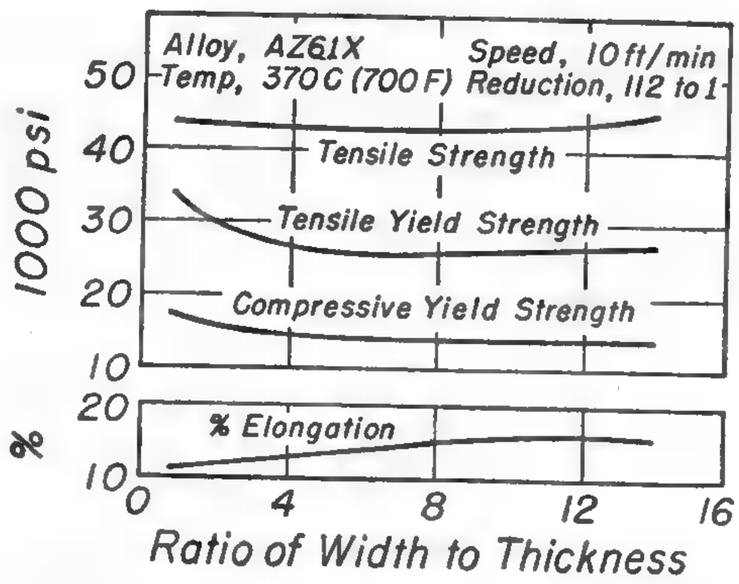

Fig. 2 Effect of the ratio of width to thickness (at constant reduction) on mechanical properties

thereby the mechanical properties. The orientation of magnesium extrusions can be described approximately as one with the basal plane nearly parallel to the direction of extrusion. More will be said later about the way orientation influences properties. The effect of the ratio of width to thickness on the properties of bars extruded at a constant reduction is presented in Fig. 2. The effects here are those of orientation and of temperature developed at the die. The amount of reduction has a considerable influence on properties, and to ensure good grain refinement, the ratio of reduction (ratio of areas) should be at least 10 to 1 and preferably 20 to 1. A great many shapes are made in the region of area reductions ranging from 50 to 1 to 150 to 1, although some bar stock is made with reductions as low as 4 to 1. This latter type of material will show a variation in properties from surface to center.

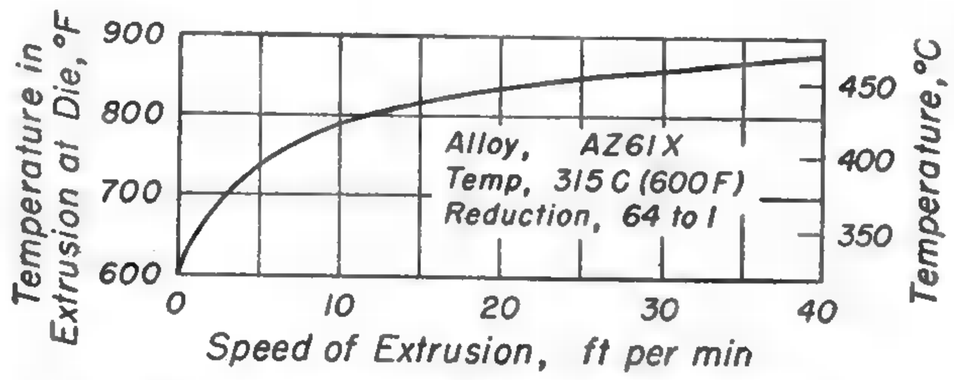

Fig. 3 Effect of speed on the temperature developed during extrusion

Speed of Extrusion. The influence of speed of extrusion on properties is determined largely by the temperature developed in an extrusion at the die. The effect of speed on the developed temperature is shown in Fig. 3. At slow speeds, great changes in temperature take place with relatively small increases in extrusion speed. At low billet temperatures, when the metal is work hardened and the grain size small (as demonstrated in Fig. 4), the rapid increase in temperature produces a change in properties with relatively small increases in speed of extrusion. This is because of relief of work hardening and increase in grain size.

At the higher extrusion temperatures (as illustrated in Fig. 5), changes in properties with variation in extrusion speed are not so pronounced, because the change in temperature with speed is less, and because the effects are mainly those of a moderate enlargement of the hot worked grain size. The speed of extrusion in production varies from 4 to 100 fpm, depending on composition and shape.

Temperature. The effects of billet temperature can be associated with changes in grain size and orientation. The influence of temperature of extrusion on M1 alloy is illustrated in Fig. 4. This figure exaggerates the effect because it was carried out at low speeds. Commercial extrusions, however, exhibit the trends shown. The combination of high strength and ductility at low temperatures is associated with fine grain size, cold work and a more random orientation. As the temperature of extrusion is increased, the influence of cold work decreases, the orientation becomes sharper, and grain size increases. Finally, at very high temperatures, the orientation becomes so sharp that both tensile strength and yield strength rise in spite of increased grain size. Compressive yield strength and elongation continue to decrease as the temperature rises.

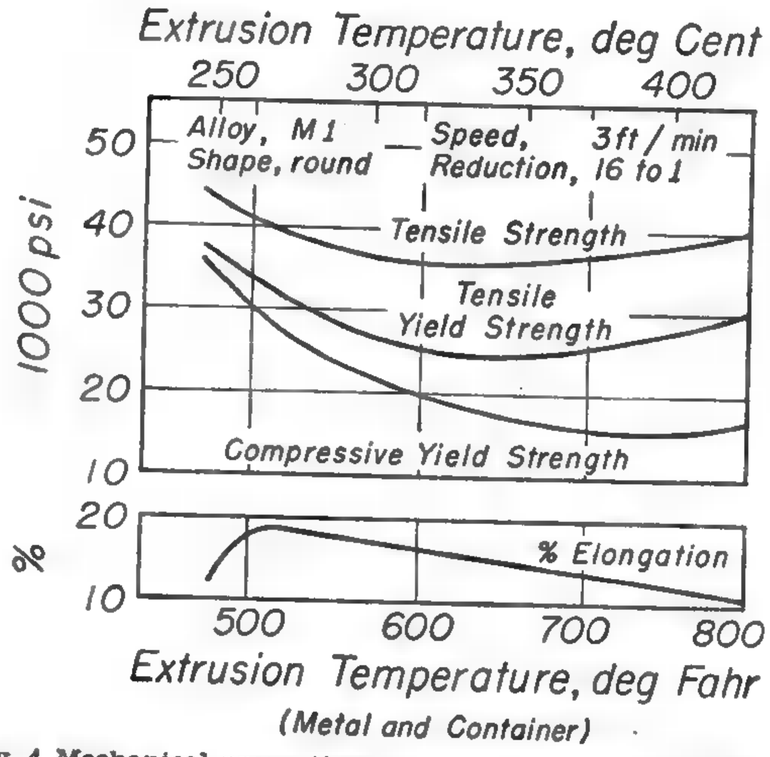

Fig. 4 Mechanical properties versus temperature of extrusion

Compressive Yield Strength. The compressive yield strength of extruded magnesium is important when the material is to be used for structural purposes. The ratio of compressive yield strength to tensile yield strength is often considerably less than 1; in fact, this ratio is about 0.7 for most alloys, but decreases to 0.5 occasionally. The cause of this phenomenon is related to the orientation in the extrusion and the mechanisms of deformation in magnesium. As previously indicated, the basal planes of the magnesium lattice are approximately parallel to the direction of extrusion. In flat shapes, the basal plane is parallel to the extrusion surface also.

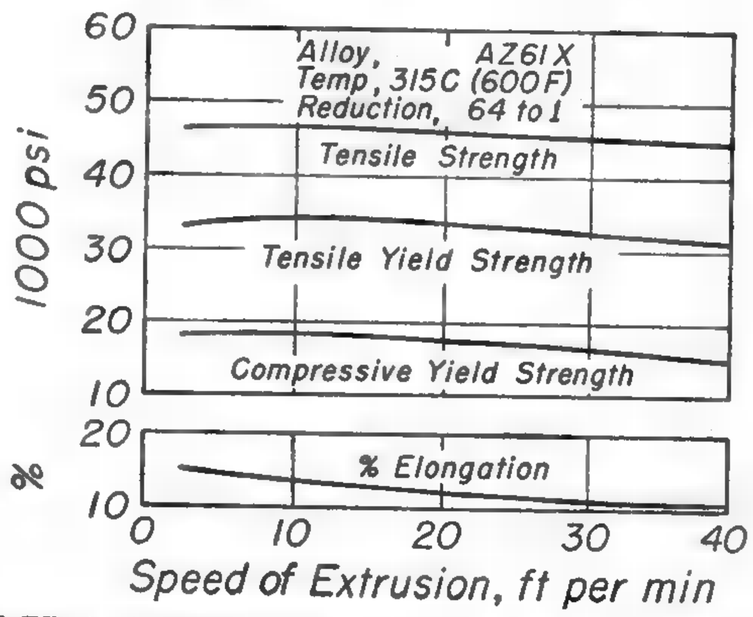

Fig. 5 Effect of speed of extrusion on the mechanical properties

Mechanism of Deformation. At room temperature the mechanisms of deformation in magnesium are mostly slip on the basal plane and twinning on the second-order pyramidal planes. In an extrusion, because of the orientation, the stress to cause yielding in tension is relatively high as a result of the unfavorable orientation of the basal slip planes. Twinning is not likely to occur in tension. In the compression of an extrusion, the crystallographic arrangements are favorable for twinning at relatively low shear stresses, while the stresses required for slip are too high for slip to take place.[1,2]

The stress to cause twinning can be increased by decreasing the grain size. In AZ80X HTA fine grain size and aging combine to make a high-strength extrusion alloy, with a ratio of compressive yield strength to tensile yield strength of about 1.

Methods. Magnesium tubing and hollow shapes are produced by two methods: the rod mandrel, and the porthole or supported-mandrel method. The rod mandrel method uses a bored billet. In the porthole or supported-mandrel method, solid billets are extruded through chambers in the male portion of the die, and the various segments are rewelded under pressure to form a tube.

Sections of magnesium are frequently guided by tension devices during extrusion, in order to maintain straightness. Extrusions can be straightened by stretching or roller straightening. The roller method must be used with caution because excessive bending can produce twinning, which will lead to a decreased tensile yield strength.

Besides the common defects that may occur in extrusions, such as hot shortness, die scores, and piping, other defects may develop, such as incipient fusion, "orange peel", and coarse grain. Incipient fusion, caused by a low-melting phase becoming liquid, most frequently affects elongation. A roughness similar to "orange peel" is found, generally in the softer alloys, and is associated with a difference in metal flow between surface and center of an extrusion.

The Rolling of Magnesium Sheet

By R. T. Myer*

MAGNESIUM sheet and plate are produced in thicknesses from about 0.016 to 2 in., widths as great as 60 in., and lengths as great as 144 in. Both annealed and hard rolled material are available. The typical properties of rolled products are given on pages 1020 to 1022.

Magnesium alloys for sheet products are melted according to practices much the same as those commonly employed for remelting magnesium for other products, such as castings. The use of manganese chloride or zirconium chloride flux as a means of reducing the maximum iron content to less than 0.005% in certain sheet alloys is an accepted practice in order to improve their resistance to corrosion in salt water. Calcium has been added in amounts up to 0.3% to control the grain size of the ingot, for improved hot and cold rolling characteristics and ductility. The calcium content is controlled preferably within very close limits, because in some alloys excessive amounts of calcium are considered detrimental to welding characteristics. In M1 alloy (1.5% Mn), for example, amounts in excess of 0.15% Ca are reputed to increase the incidence of cracks when restrained welds are being made. In this same alloy, a calcium content of less than 0.08% may lead to difficulties in rolling and to low mechanical properties.

In this country most ingots for magnesium sheet are cast by some type of continuous casting process. Between the melting and casting operation the metal is best transferred by pumping. This method serves the dual purpose of reducing the number and size of inclusions by improving the metal transfer, and refining the grain size, as a result of the agitation involved.

The alloys that contain aluminum may be homogenized in cast form. Temperatures for this operation are in the range from 700 to 800 F. The use of some form of protective atmosphere is necessary, according to some producers, to prevent combustion caused by ignition of the segregated exudation product on the surface of the ingot. Contact between the ingots and iron scale, aluminum, zinc, cadmium, or lead alloys should be prevented during heating, because such contact would initiate a reaction that would cause combustion at the homogenizing temperature.

Most magnesium alloy sheet and plate are produced from extruded slab. A round ingot 14 or 16 in. in diam is used; the ingot may be machined to remove the cast surface, depending on the composition of the alloy involved. Such ingot is then extruded into 3 by 9 in. or 4 by 12 in. in order to work the cast structure as thoroughly as possible under the conditions of compression that exist in the extrusion process before beginning the more critical rolling operations. One producer has used cast ingots successfully for the production of the more readily rolled compositions, and further progress in this direction may be anticipated.

* Chief Metallurgist, New Kensington Works, Aluminum Company of America

Prepared for the Magnesium Committee

The two factors that have the greatest effect on magnesium rolling practices are these: (1) A much greater amount of deformation can be taken hot than cold; and (2) the maximum hot rolling temperature is relatively low and the safe working range is narrow.

Amount of Deformation. The permissible amount of cold rolling varies from 16% on heavy gages of AZ51X alloy (5% Al, 1% Zn) to more than 50% on the thinner gages of M1 alloy. The comparatively low reductions in cold rolling are accounted for by the hexagonal crystal structure of magnesium alloys as compared with the cubic structures of the more readily workable alloys of aluminum, iron and copper, and the pronounced tendency for the occurrence of twinning in magnesium alloys.

Mechanism of Deformation. The deformation of the hexagonal structure of magnesium solid solutions at room temperature is believed to occur originally by slip along a single set of slip planes, the (0001) planes. As deformation proceeds, the grain fragments rotate so that the slip planes tend to become parallel to the surface of the sheet. Eventually, as rolling continues, shear stress on the slip planes decreases to the point where twinning becomes the principal means of deformation. Although twinning is not so effective in allowing deformation of magnesium as it is for zinc or cadmium, because twinning produces an extension along the [0001] direction, instead of compression, it does result in reorientation of the (0001) planes in the twinned regions so that further deformation by slip can occur. Cracking—known as "shear failure"—takes place when these planes of slip are exhausted.

The higher reductions during hot rolling are accounted for by the decreased rate of work hardening as a result of the higher temperature, as well as the fact that slip can occur on an additional set of planes, the $\{10\bar{1}1\}$ planes, at temperatures higher than about 450 F. When deformation by slip along the (0001) planes becomes more difficult, slip on the $\{10\bar{1}1\}$ planes, rather than twinning, is initiated. Thus, hot working involves uniform deformation as long as the temperature is kept sufficiently high.

Hot Rolling. Magnesium plate (0.250 in. and heavier) is hot rolled to gage. Practices for the fabrication of magnesium sheet (lighter than 0.250 in.) are based on the greatest possible use of hot rolling to take advantage of the economies of larger reductions. Cold working is introduced as the final gage is neared, in order to control flatness and improve mechanical properties, or as the gage becomes too light to hot work well by existing procedures.

Two different types of practices are used for hot rolling magnesium. One method calls for the use of cold rolls (operating at 250 F or less), with the result that metal temperature drops rapidly during rolling, so frequent reheating of the slab is required. However, because of the cool rolls, little or no lubrication of the slab is required, which is beneficial to the surface quality of the slab. On

the other hand, one producer uses heated rolls operating at 400 to 600 F. This has the advantage of maintaining the temperature of the slab at a higher level, making possible the use of greater reductions between reheatings. The higher temperatures for the rolls necessitates the application of lubricant to the slab. The lubricant must be applied evenly for uniform working; otherwise cracking may result, in a direction perpendicular to the direction of rolling. The use of elevated temperatures for the rolls accentuates the problem of maintaining satisfactorily uniform control of gage, and introduces a cleaning problem because no satisfactory lubricant is known which does not leave a residue on the slab. Temperature of the metal during hot rolling is between 575 and 850 F, depending on the alloy and the gage at which the reheating occurs. Reductions per pass vary greatly, depending on the alloy and hot rolling conditions; but, as an example, a 2.6-in. slab of AZ31X (3% Al, 1% Zn), prepared by hot rolling a cast ingot to 3-in. thickness, followed by a machining operation, would normally be rolled to 0.300-in. slab in ten passes starting with a metal temperature of 750 to 800 F and using heated rolls.

Cold Rolling. Wherever possible, cold rolling operations are performed using 4-high rolling mills because of the importance of uniformity of gage and because of the increased reductions that are possible in each pass. However, it is difficult, particularly in the lighter gages, to obtain satisfactory flatness when using 4-high mills for finish rolling. Therefore some producers may take the last stage of cold reduction on 2-high mills in spite of the higher costs involved. The practices in application of 4-high as compared with 2-high rolling vary greatly among the producers.

Almost all rolled magnesium is fabricated as flat sheet. Coiled sheet made of pure magnesium is available in widths as great as 8 in. Despite early experimental difficulties, it is quite probable that wide coiled sheet can be rolled in production if all the characteristics of the metal are taken into consideration.

Annealing operations are necessary between successive stages of cold rolling, and may also be used after hot rolling, although not always necessary at this point, since the hot rolled slab is usually recrystallized. Annealing temperatures vary from 600 to 800 F, depending on the alloy and the purpose of the annealing operation.

Cleaning. Because of the general high standards for surface quality required of magnesium sheet in most applications, cleaning procedures have been devised to remove mill scale and other surface contamination. These procedures involve dipping the surface in acid or cleaning mechanically by scratch brushing. The cleaning is usually performed after the last stage of hot rolling; however, at times such a procedure must be introduced at more than one point during fabrication. Acid dipping is generally used, although undesirable variations in gage may be introduced as a result of uneven etching. Scratch brushing is also employed after acid dipping, or after annealing, to remove oxide coating.

Flattening. Mechanical means of flattening magnesium sheet and plate, such as roller leveling, must be used with care. The accepted practice adapts thermal treatments for flattening the product. The sheets are loaded in horizontal stacks under pressure of approximately 100 lb per sq ft. They are then either annealed or given a much milder stress-relief treatment, depending on whether the final specification calls for "annealed" or "hard rolled" sheet. Ordinarily the temperature for thermal flattening is 300 F for alloys AZ31X and AZ51X, 400 F for M1 alloy; the alloys are held at temperature for ½ hr. Some slight sacrifice in strength is brought about in thermal flattening the hard rolled sheet, but elongation is improved considerably and there is evidence that the resistance to stress-corrosion cracking is improved in the alloys that contain aluminum.

Finishing.* Before shipment, finished magnesium sheet and plate ordinarily are dipped into a bath of chromic acid or sodium dichromate with nitric acid. Such a dip removes or passivates any small particles of the heavy metals—principally iron that may have become embedded in the surface—thus increasing the resistance to corrosion. The treatment also gives a coating that serves as a protection for the finished article. Magnesium sheet is sometimes coated with oil before shipment. Such a coating gives sufficient protection against corrosion for shipment under mild conditions and is removed more easily than the chrome pickle. This ready removal is of greatest importance when the material is to be spot or seam welded, because then chrome pickling interferes. Oiled sheet is also frequently preferred by users performing severe forming or drawing operations. The preference for oiled sheet over that with the chrome pickle coating is increasing, and oiling is now the standard method of protection employed by at least one producer.

* *See also* "The Surface Protection and Finishing of Magnesium Alloys", page 991.

The Forging of Magnesium Alloys

By A. L. Rustay* and F. B. Rote*

IN GENERAL, it is best to forge the magnesium alloys of higher strength, AZ61X (6% Al, 1% Zn) and AZ80X (8.5% Al, 0.5% Zn), in hydraulic or slow-stroke mechanical presses. A few parts have been made successfully by first preforming or blocking the stock in a press to place most of the metal in the desired position, and then finishing under a hammer to fill difficult sections that otherwise would require presses of large capacity. Some of the newer, rapid-stroke vertical and horizontal presses are not suitable for forging alloy AZ80X. These presses, like hammers, cause shearing and cracking of the metal during forging, if considerable movement is involved, because the metal flows too rapidly.

Alloy TA54 (5% Sn, 3% Al) may be successfully forged on hammers, presses, and other equipment that is satisfactory for aluminum. The mechanical properties are somewhat lower than those of alloy AZ80X. In common with all magnesium alloys, TA54 tends to move laterally instead of longitudinally when forged. "Drawing out", "fullering" or "rolling" operations must be performed under carefully controlled conditions. These require that the dies for such operations have radii adjusted to the stock size, and that the contour of the dies be carefully proportioned in such a manner that the metal is forced to move longitudinally. This results in a rather lumpy preformed blank, which sometimes requires smoothing dies to shape the piece before it is placed in an impression die.

* Chief Metallurgist, Wyman-Gordon Company, Worcester, Mass.
* University of Michigan, Ann Arbor, Mich.
Prepared for the Magnesium Committee

Temperature for Forging. Forging stock may be heated in electric, gas or oil-fired furnaces without an atmosphere of SO_2. The forging temperature of magnesium alloys is considerably lower than the melting point, so that the danger of fire during heating for forging is slight provided adequate furnace controls are employed. Further, since small, easily ignited sections are seldom produced during forging, the fire hazard is essentially no greater than that encountered in the heating of other metals for forging. Temperatures used for forging magnesium alloys vary from about 650 to 850 F, depending on the type of alloy, the section size of the forging, and the method of forging. Alloys AZ61X and AZ80X are usually forged at about 725 F, and the temperature should be held within plus or minus 25 F for best results. At lower temperatures the dies may be difficult to fill and the metal may crack. When forgings are made in several operations and difficulties with grain growth are encountered, it is considered good practice to lower the temperature with each subsequent operation.

Dies. Up to the present time, the dies customarily used

for magnesium forgings have been made from standard blocks carried in stock by die block manufacturers. It should be possible, however, to make press dies from cheaper materials and by cheaper methods; for instance, by casting the impressions to approximate size. Such a process, or any other process that lowers die costs, is attractive, especially for short production runs.

It is essential that the temperature of the die be relatively high in order to avoid chilling the stock as it flows. Generally the die temperature to be used for a given job will be adjusted for the type of alloy to be forged, the number of operations to be performed in a given heat, and the properties desired in the final forging. If multiple operations are to be performed, the preblocker and blocker dies should be operated at about 550 to 650 F, which permits the production of thin sections without danger of excessive cooling and, hence, cracking and underfilling.

The finish die may be operated as high as 600 F, if the section is thin and its projected area is large in comparison with the size of the equipment available for the production of the forging. However, if adequate power is available, it is desirable to operate the finish die at a low temperature, in order that the forging may benefit from strain hardening during the finishing step. In this operation the finish die may be operated at 400 F for thin sections and as low as 200 F for heavy sections to be "cold worked".

Dies for magnesium alloys should be designed according to the practice employed for dies used in forging aluminum, except for a few minor changes intended to make the dies easier to fill. Corner radii and fillets on magnesium forgings should be made as generous as possible, particularly when forging is done with a press. The use of large radii and fillets allows easier filling of a die.

The blocker dies for magnesium alloys should be held inside the finish die contours as much as possible, in order that the flow of metal during finishing can be simultaneously outward and upward. For example, in filling a high rib, magnesium tends to flow laterally rather than upward.

Dies are heated by encircling manifolds that carry gas burner tips which may be fastened on the dies during operation, if the forging is done in a hydraulic or mechanical press. In hammer forging it is unsafe to attempt to hang a manifold on the top die.

Lubrication. The lubrication of the dies in the production of magnesium forgings presents many problems not encountered in the forging of other materials. The best lubricants available at present contain graphite, either in flake or colloidal form, suspended in a mineral or animal oil, or occasionally in water. When considerable graphite is used to help a magnesium forging fill the dies, the deposits of graphite that adhere to the forging are difficult to remove by any but mechanical means, such as sandblasting. If the adhering graphite is relatively thick, attempts to remove it by chemical action result in severe pitting and surface deterioration and, usually, incomplete removal. Small forgings may require only sparing applications of die lubricant, and in these instances a chromic acid pickle will remove the graphite satisfactorily. The development of an improved lubricant that contains no graphite but that has adequate lubricating qualities is one of the problems now facing the magnesium forging industry. There is a possibility that some of the high-temperature, high-pressure lubricants developed for wartime applications may serve this purpose when their properties become well known and the products become easily available.

Wherever possible, the use of die lubricants that contain no graphite is desirable.

Trimming Forgings. Considerable care must be used in the trimming of magnesium forgings, because of the tendency to crack or tear if the trimming temperature is not within the proper range. The safe limits for most of the alloys are from about 300 to 500 F. For trimming forgings of alloy AZ80X, the temperature should not exceed 375 F and the time at temperature should be short if aging is to be avoided. At higher temperatures the metal is more likely to tear; at lower temperatures it may crack along the flash, into the forging. Dies for trimming must be made to close tolerances, if clean trims are to be obtained. Properly designed punch-out trimmers may be used satisfactorily, although trimmers that have a shearing action are usually more desirable for large forgings that have a relatively heavy flash. For short forging runs it is more economical to saw off the flash with a band saw and smooth the rough sawed edges with a rotary burr or file.

Heat Treatment. Of the standard forging alloys, only AZ80X may be benefited appreciably by aging, or by solution and aging heat treatments. The primary purpose of such treatments is to improve the tensile yield strength, and frequently more important, the compressive yield strength. The other alloys either contain insufficient amounts of hardening compounds for much improvement during aging, or the hardening compounds are insoluble at the forging temperature. Under optimum conditions AZ80X, after trimming, subsequent to finish forging, will have virtually all of the magnesium-aluminum compound in solid solution as a result of adequate homogenization at a sufficiently high temperature during heating for forging, and the maintenance of sufficiently high temperature during the forging operations. After forging or trimming at forging temperature, the alloy may be quenched in water if necessary to prevent grain-boundary precipitation of the magnesium-aluminum compound, which results in the loss of a certain amount of this compound to subsequent age hardening heat treatment. After quenching, a uniform solid solution is retained, recrystallization and grain growth are halted, and the structure is characteristically fine-grained with uniform straight grain boundaries free from high-temperature precipitate.

Alloy AZ80X may be fully aged by heating at a temperature of 350 F for 24 hours. This will result in maximum tensile properties, maximum compressive yield strength, and maximum hardness. Variations in properties can be obtained by aging and underaging.

Where resistance to creep at elevated temperatures is of primary interest, the forgings should be given a solution heat treatment before aging. The solution heat treatment consists of heating the forging at 725 F for ■ hours. This temperature should not be exceeded or excessive grain growth may result. The solution treatment may also be necessary where inadequate solution was achieved in heating for forging, or where some precipitation occurred during cooling after trimming. In general, forgings solution-treated and aged have somewhat lower tensile properties and ductility than those properly handled during heating and forging and then subsequently aged without an intermediate solution heat treatment.

Mechanical Properties. The typical mechanical properties obtained in the standard forging alloys are given in Table I, page 1000 in this Handbook. The minimum specification or design values for the mechanical properties are given in Table II, page 1001. Sections, forged from extruded stock 3 in. in diam, or smaller, usually possess tensile and compressive yield strengths greater than the design values. Forgings made from larger stock that undergoes considerable movement of metal may also exceed the design values, but usually by a lesser amount than do small forgings. However, heavy, chunky forgings made from 6-in. or 8-in. extruded rod or cast billets may have properties considerably less than average because of the difficulty of producing adequate mechanical work during either extrusion or forging. Designers planning to utilize magnesium forgings should consult with the forge shop regarding the properties that may be obtained in a particular forging, since the properties of the magnesium alloys may be changed considerably by variations in the amount of mechanical work or the working procedure.

The Press Drawing, Forming, Spinning and Bending of Magnesium Alloys

By J. V. Winkler*

SINCE magnesium sheet and extrusions are "formed" in much the same manner as other common metals, the same type of fabricating equipment is used. Most operations are performed hot, particularly those requiring bends of small radius and deep draws. Both the tools and the work material are heated; consequently deformation is easy, with little or no spring-back. Methods of applying heat vary with the type of operation used and depend also on the number of parts required.

Press Drawing. *Equipment.* Both hydraulic presses and mechanical presses are used for drawing magnesium sheet. Hydraulic or pneumatic devices for applying pressure to the blank-retaining portion of the die are essential where maximum draws are required. Single-action presses are sometimes used for hot drawing magnesium; springs or C-clamps restrain the sheet in the blank-holder. Control of clamping pressure is inferior, but the equipment is adequate when moderate draws are to be made or when a small number of parts is required. When springs are used, they should be located away from the die, and pressure should be exerted through pressure pins to eliminate the danger that the springs may become hot enough to be deformed plastically.

Materials for dies used in hot forming must obviously be able to withstand the temperatures employed in the drawing operation, without ill effect. Pressure rings and draw rings are usually made of mild steel. It is important to stress relieve the steel before the final machining, in order to remove strains that would warp the die in service. Plate thicknesses recommended for mild steel draw rings and pressure rings are given in Table I. Gray iron is also

Table I

Plate Thickness for Die Rings

Largest Blank Dimension, inches	Minimum Plate Thickness, inches
0 to 14	1.5
14 to 22	2.0
22 to 30	2.5
30 and more	3.0

used, as well as certain alloy cast irons that have the advantage of exhibiting little or no growth when long production runs are made. Steel, cast iron, aluminum alloys and magnesium alloys are used in making punches. Zinc alloy diestock (*see* Zinc Section for compositions of the alloys) may be used where the temperature does not exceed 450 F. The supporting structure for a built-up die is invariably made from mild steel. If welding is required, the structure should be stress relieved before final machining, in order to ensure parallel surfaces.

In designing dies for materials that have a coefficient of thermal expansion different from that of magnesium, allowance must be made to obtain accurate dimensions of parts. Steel and cast-iron die parts should be increased in size 0.0008 in. per in. for each 100 F above room temperature required for the operation of the die. The factor for aluminum die parts is 0.0004 in. per in.

A drawing of a conventional built-up die is shown in Fig. 1. This open type of die is desirable for reducing the transmission of heat to the press. Where solid cast dies are used, asbestos sheet should be placed between them and the press as insulation to conserve heat in the die.

For maximum drawability, the entering radius on the draw ring or female die should be from five to seven times the thickness of the sheet being worked. When only a small number of parts is required, dies can be heated either by playing a hand torch over them or by placing them in ovens, where temperature can be checked by means of a contact pyrometer. For production work, dies are heated by electricity or gas, and the temperature is controlled by automatic instruments.

Either electric-cartridge heaters inserted in holes drilled in the die, or strip heaters clamped to the die surface, are used for small dies. Large dies may also be heated by such means where an open gas flame is undesirable, and the increased cost is therefore warranted. The temperature is controlled by means of a controlling pyrometer that operates a magnetic contactor.

Gas and compressed air, mixed by means of suitable equipment, are conveyed to the die burners through a rubber hose. The die burners are made of ¾-in. or 1-in. steel pipe, bent to shape as required. Burner ports in the pipe are No. 40 drilled holes, spaced about ½ in. apart. The burner is mounted ⅝ in. from the die, so the flame impinges on the surface to be heated. A controlling pyrometer regulates the amount of gas burned, by operating a solenoid valve.

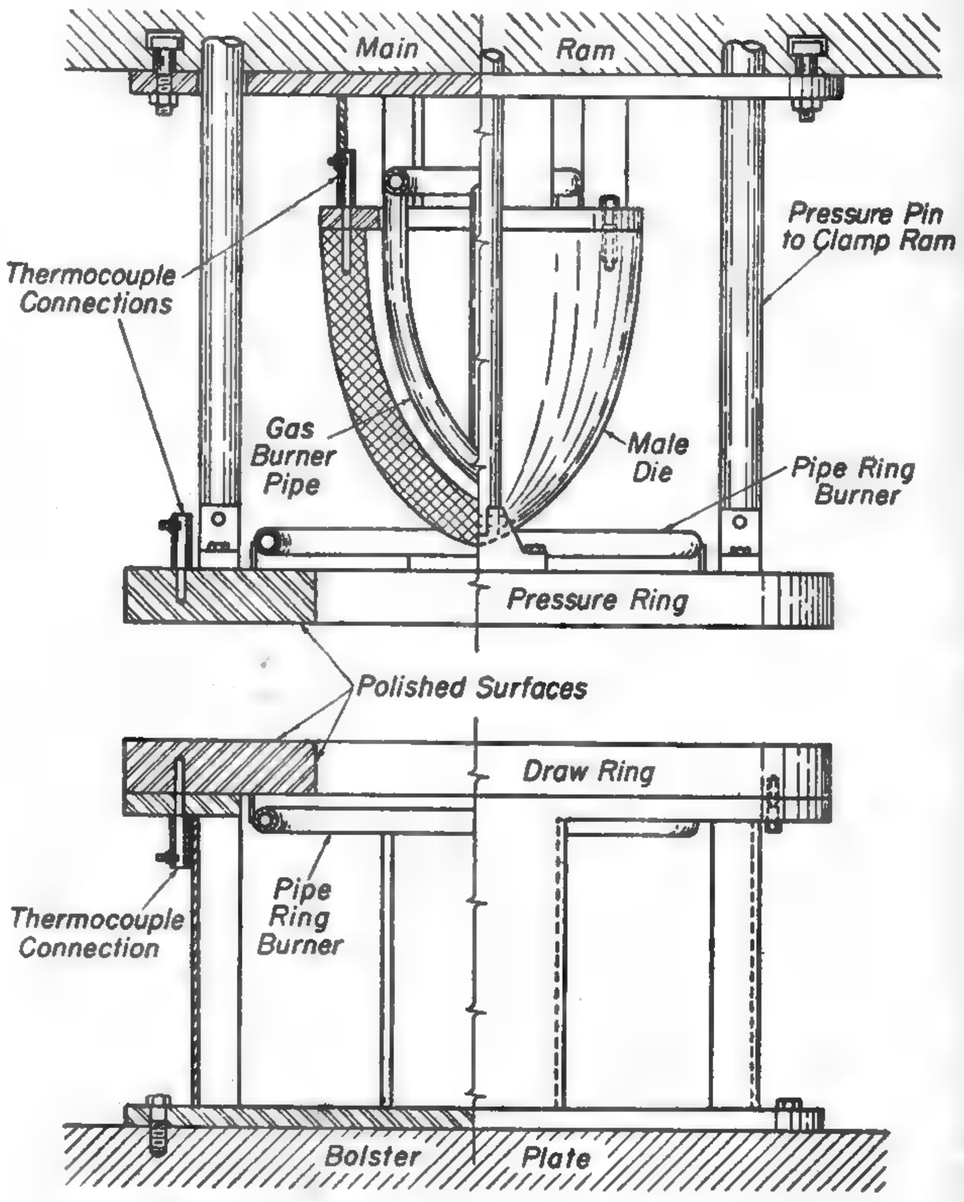

Fig. 1 Typical die for hot drawing magnesium alloy sheet

Burners should be located so that the magnesium sheet will not be subjected to an open gas flame. General arrangement of the burners and thermocouples may be seen in Fig. 1.

Two types of oven are used for heating the sheets. A contact-plate heater is preferred, in which the sheet is pressed between two steel or cast-iron plates heated with electric strip-heaters. Standard air ovens are also used for flat sheet, although the operation is slow because a waiting period is required to bring a new stack of sheet to temperature. The air oven is essential where heating of formed sheet is required for subsequent operations.

Operation. Graphite is used for lubricating sheet to be hot formed at about 260 to 343 C (500 to 650 F). The material most commonly used is a colloidal graphite suspended in a volatile carrier. When this material is sprayed on the sheet, the carrier evaporates, leaving a thin film of graphite that clings tenaciously. This coating prevents scoring while

* The Dow Chemical Company, Midland, Mich.
Prepared for the Magnesium Committee

the sheet is being formed, and stays on the sheet during the drawing operation, protecting the die from being fouled.

Graphite coatings are removed by a ½ to 2-min immersion in an aqueous solution that contains 15 to 20% chromic acid and 3% sodium nitrate. The bath is usually operated at room temperature.

A number of factors determine the temperature to which a sheet must be heated to provide sufficient ductility for forming. The alloy and temper of the sheet must be considered. Hard rolled sheet is usually limited to parts in which a moderate amount of shaping is required, since the forming temperature must be limited to prevent excessive loss of mechanical properties as a result of annealing. Generally the maximum temperatures used on hard rolled sheet are 163 C (325 F) for AZ31Xh sheet (3% Al, 1% Zn); 204 C (400 F) for AZ51Xh (5% Al, 1% Zn); and 260 C (500 F) for M1h (1% Mn). The temperature required to form annealed sheet for draws of various depths is shown in Fig. 2. Here the drawability factor $(D - d)/D$ is the ratio obtained by dividing the blank diameter minus the draw diameter by the blank diameter. For production

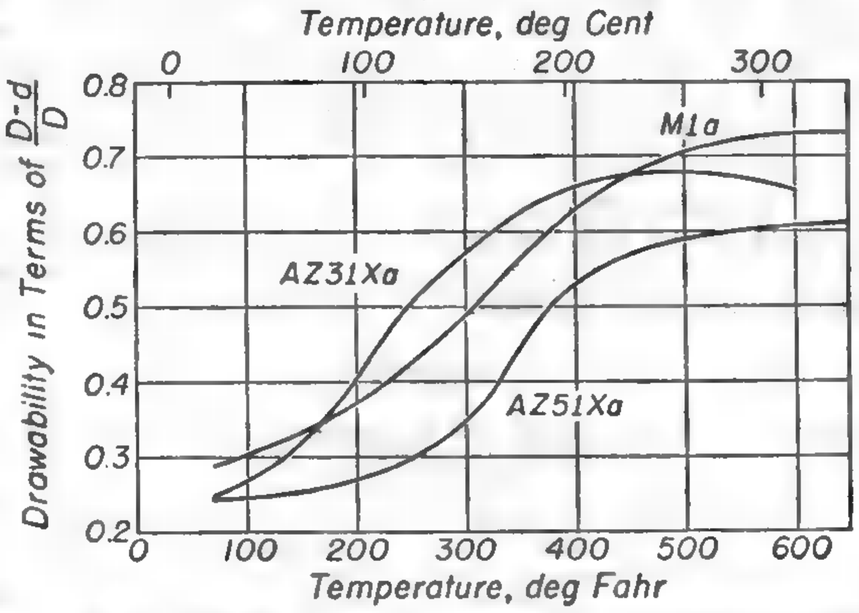

Fig. 2 Drawability limits for hot working annealed magnesium alloys in a single operation

design, maximum single draws should be held somewhat lower than the top limits shown on the curve, since these draws can be obtained only with very accurate control.

The shape of the part often dictates the temperature requirement, especially for the punch. In ordinary draw work, a punch will absorb sufficient heat from gas burners on the draw ring and pressure pad. Where the sheet must be stretched sufficiently to allow it to shape to the punch (for instance, in a hemisphere) the punch must be heated so that the sheet can be kept hot enough during the operation to preclude puckering. When draws of maximum depth are required, the punch is sometimes cooled by water to a temperature of 150 to 200 F. This permits the sheet between the holding plates to be heated high enough for compression without forming wrinkles, while the sheet drawn over the die radius is cooled by contact with the punch so that the strength is raised to permit drawing from between the plates. A working rule is to provide the amount of heat required for making a straight bend in the sheet, as shown in Fig. 3 in the section on bending sheet. A temperature of 316 C (600 F) may be used for drawing all annealed sheet. In the drawing of hard rolled sheet, the temperature should not exceed 149 C (300 F) for AZ31Xh, and 204 C (400 F) for M1h and AZ51Xh sheet, to avoid a loss in mechanical properties as ■ result of annealing.

Speed of draw and sheet thickness must be controlled, as well as any tendency of the sheet to be locked so that the shape is obtained in stretch rather than draw. In general the ram speed of 2 to 4 fpm, obtained with typical hydraulic presses, is the most satisfactory range for drawing magnesium. Faster speeds obtained on mechanical presses permit greater production, when requirements for deep draws, small bends, or excessive stretching do not prohibit their use. Where water-cooled punches are used for very deep draws, ram speed must be slow enough (usually 1 fpm or less) for the punch to cool the sheet.

Forming. *Forming in Rubber.* Flanged parts, lightly contoured parts, and other shapes that do not require drawing action are often formed by means of the Guerin process, as developed by Douglas Aircraft Company, for producing shapes such as ribs, fuselage frames, beaded panelings and fairings. Cost of labor is higher, but where a small number of parts is required, the advantage of low cost for dies and speed of producing or revising dies, will offset this disadvantage. In this process, sheet to be shaped is placed on forming blocks and a rubber pad about 6 to 8 in. thick is forced down on the sheet. The sides of the pad are confined in a steel box and the forming blocks are

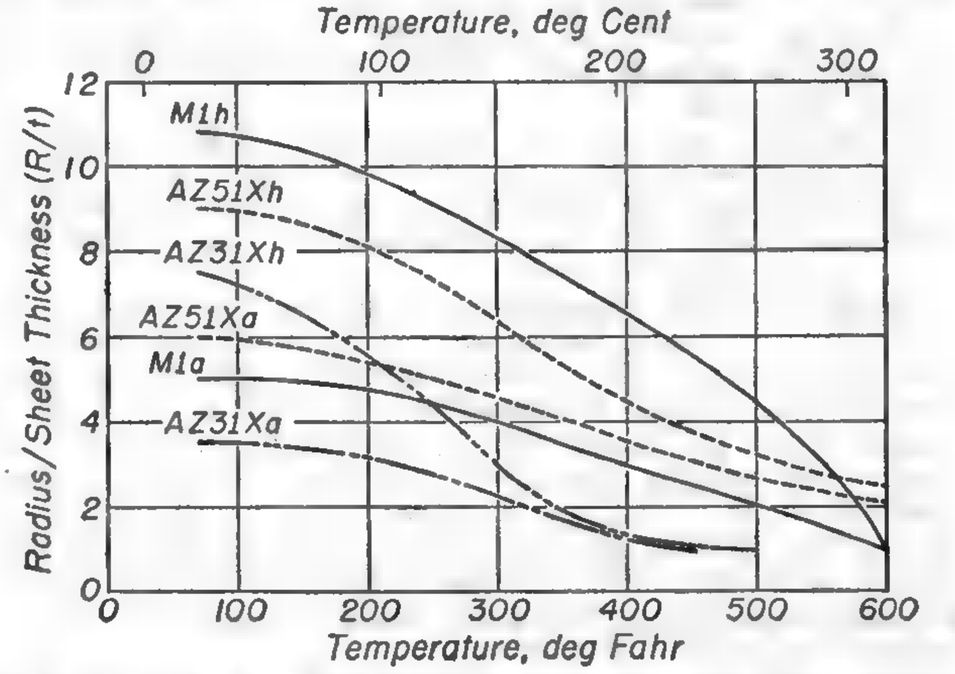

Fig. 3 Die radii for 90-deg bends. Heated punch and rubber bottom die. (Rubber retained in conventional U-shaped press-brake die.)

placed on a steel plate, which enters the rubber box. Pressure developed in the confined rubber is therefore applied to press the sheet to the shape of the form block.

This type of forming is normally limited to hydraulic presses, since form blocks of different sizes result in varying ram travel. On mechanical presses, this method would require excessively careful adjustment of ram travel in order to develop sufficient pressure for forming, without danger of overtravel, which might harm the press or even cause failure in the rubber box, with possible injury to workmen in the vicinity. The size of the rubber box for forming magnesium should be limited so that a minimum pressure of 1000 psi will be developed on the entire pad.

Form blocks are made from aluminum or magnesium, either machined from plate or produced as castings. Better forming characteristics are obtained by use of external rather than internal beads, lightening holes and stiffeners. ("External" means that the portion of the die to form these elements projects from the surface of the block, as opposed to "internal", where the sheet is pressed into cavities cut into the block).

Rubber forming for magnesium is usually conducted at temperatures between 149 and 232 C (300 to 450 F). Compounded heat-resistant natural rubber or synthetic rubber is employed either as a facing on a natural rubber pad or as the entire pad. This material withstands temperatures developed when dies are used at 232 C (450 F).

Ordinarily an oven provides the necessary heat. The blank is placed on a forming block, is brought up to the forming temperature in the oven, and is then transferred to the press for forming.

Forming Under a Drop Hammer. Under a drop hammer, magnesium sheet can be formed into shapes as complicated as those produced in other metals. Comparatively recent experience has established this process as an economical means of forming magnesium sheet.

Zinc-base alloys with melting points from 371 to 380 C (700 to 725 F), normally used in making drop-hammer dies, have proved satisfactory for forming at temperatures as high as 232 C (450 F). Antimonial lead (which usually serves as a punch, since it may be cast into the die, thus eliminating the necessity for a pattern) has been used at temperatures as high as 204 C (400 F).

The dies must be heated so that hot sheet will not be

chilled too rapidly to permit forming. Heating is accomplished by means of a hand torch or by means of pipe burners mounted on the sides of the die. When a torch is used, the flame should be moved continuously to prevent local rise in temperature. Flames from pipe burners produce heat less intense than the heat of a torch, and may be mounted on zinc alloy dies, since the conductivity of such dies is high enough to prevent local melting.

Sheet may be preheated in an oven or it may be heated by contact with the heated dies. When the dies serve as heating mediums, restraining rubber placed at the edge of the die, supports the punch so that its weight will not deform the sheet, while it is still relatively cold, sufficiently to cause a fracture. A one-minute pause is required for allowing the sheet to heat, before the punch is raised and a blow delivered.

When lead punches are used, provisions must be made to prevent lead from contaminating the magnesium sheet, or corrosion may be encountered. A thin sheet of steel or aluminum placed on the punch affords adequate protection.

Hand Forming. Because of the heating requirement, the hand forming of magnesium is more difficult than the hand forming of other metals, which is possible at room temperature. When the material is clamped to a block, simple bends are made with a soft hammer. Metal form blocks are usually employed, although a heat-resistant wood, such as birch, may be used for a small number of pieces. For making contoured shapes, simple dies are used with magnesium more extensively than with other metals, because such dies permit more rapid forming and thereby reduce the heating problem.

Heating is usually accomplished with a hand torch and temperatures are checked with a hand pyrometer. Metal dies and form blocks may be heated by placing them in an oven, or by attaching electric heaters to them.

Although heating does present a problem in the hand forming of magnesium, when the material is hot it forms so readily that much less force is required to produce a desired shape than is required for other materials. This factor is so important in many instances that it alone warrants the use of heat.

Stretch Forming. The excellent elongation of hot magnesium sheet permits the production of very complex shapes by stretch-forming operations. Forming is possible at room temperature, but severe working must be done hot. A hand torch playing over the surface will heat magnesium sheet or, if production parts are being run, the heated punch will convey enough heat to the sheet to facilitate forming.

Punches for hot stretch forming can be made from a zinc-base alloy if the temperature is limited to 204 C (400 F). Aluminum or magnesium castings are used at higher temperatures. The punch is heated by means of gas and the sheet is heated by contact with the punch. Graphite-tallow mixtures are most satisfactory for punch lubrication, because they provide adequate body to eliminate slip chatter.

Bending. *Bending Sheet.* Figure 3 shows the bends that may be obtained in magnesium sheet alloys as a function of temperature. These curves represent values obtained from bend tests on sheet that has typical forming properties, but they are not recommended as minimum bends.

Press-brake dies are heated by electric strip-heaters. A holder for the upper brake blade, as shown in Fig. 4, incorporates heaters, so it is unnecessary to attach heaters to each blade. This holder includes insulation. With lower dies the insulation is placed between the press bed and bed rail. Temperature is usually controlled manually and checked by a contact pyrometer, or it may be controlled automatically.

Bending Extrusions. An extrusion may be formed by clamping one end and bending it to a form block by hand or with a soft hammer. If heat is required, a hand torch is played on the extrusion while the bending is in progress. In addition to permitting smaller bends, use of heat reduces the work required to complete the bend and reduces the spring-back—a definite advantage where the extrusion must conform to a form block, or where a bend through 360 deg is required.

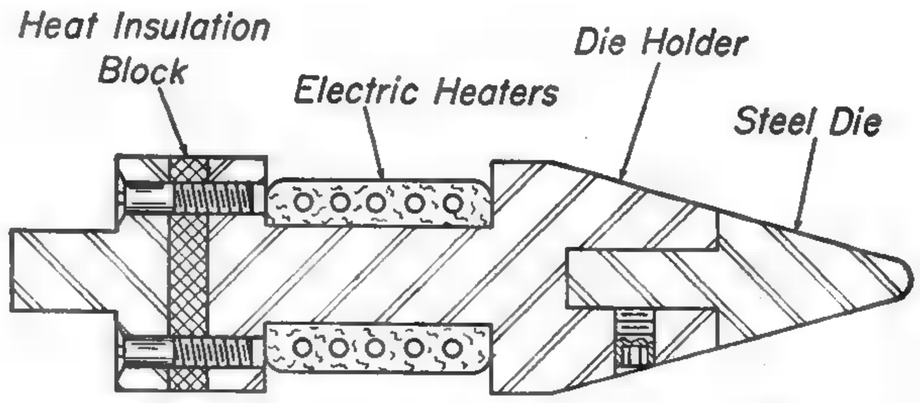

Fig. 4 Electrically heated press-brake blade holder

Angle rolls, mating dies, stretch-forming presses, and specialized bending machines are employed where production quantities are required. Heating, when necessary, is accomplished by placing the stock in an oven. Dies are heated by placing electric elements in them or by attaching gas burners in such a manner that the flame may be directed against the die.

Table II shows the radius to which a rectangular section can be bent at room temperature and at the highest temperature that may be used.

Table II

Minimum Bend Radii for Extruded Strip in Terms of Strip Thickness, t

Alloy	Room Temperature Bend	Elevated Temperature Temperature[a]	Elevated Temperature Bend
AZ80X HTA	7 to 9 t	193 C (380 F)	1.5 to 2.5 t
AZ80X	2 to 3 t	316 C (600 F)	1 t
AZ61X	1.5 to 2.5 t	316 C (600 F)	1 t
M1	4.0 to 5.5 t	371 C (700 F)	1.5 to 2.5 t
AZ31X	2 to 3 t	316 C (600 F)	1 to 2 t

(a) The maximum permissible forming temperature for each alloy is listed. Exceeding this temperature will result in excessive loss of strength, and also reduced ductility in AZ80X, AZ61X, and AZ31X.

Spinning. The spinning process for magnesium has proved very successful. Small quantities are produced at an appreciable saving because of the lower cost of tooling. Where the shape of a part is such that press-tooling would be very complex, spinning may be employed to advantage for making even a large number of parts.

Spinning at room temperature is limited to shallow parts that do not require bends of small radius. Heating the sheet permits it to be spun as readily as any other material.

Heat is normally applied by playing a torch on the rotating part. The spinner can regulate the heat applied, according to the "feel" of the material. Chucks for spinning may be made of maple or of metal, but aluminum or magnesium is preferred. Maple chucks are satisfactory for a small number of parts; metal chucks may be heated by playing a gas flame on the base of the chuck, thus reducing or eliminating the necessity for playing a torch on the sheet while it is being spun.

The spindle speed should be selected so that the peripheral speed of the outside of the blank will be about 2000 fpm.

Standard spinning tools are satisfactory. Brown laundry soap or a paraffin-tallow mixture is the usual lubricant, except in the spinning of certain shapes where high temperatures are required. In such instances a graphite-tallow mixture is applied.

Joining Magnesium Alloys

By Thomas E. Piper*

MAGNESIUM alloys may be joined by welding, riveting, bonding and soldering.

Welding

The principal methods employed are gas welding, arc welding and electric-resistance seam and spot welding. Magnesium alloys cannot be satisfactorily welded to other metals.

Gas Welding. Most of the wrought and some of the cast magnesium alloys can be joined by gas welding. Oxyacetylene, oxyhydrogen and oxycarbohydrogen gases may be used; however, oxycarbohydrogen gas is recommended, because the flame is cooler and is more easily seen. The filler rod should either be of the same composition or have a lower melting point than the parent metal. Table I gives information about the selection and regulation of equipment for the acetylene welding of magnesium alloys. For oxycarbohydrogen welding, a somewhat larger orifice is used, and the carbohydrogen gas pressure is somewhat increased for the thinner metal sections.

Table I. Data for Oxyacetylene Welding Magnesium

Metal Thickness, inch	Welding Rod Diameter, inch	Orifice Diameter, inch	Drill Number	Oxygen Pressure, psi	Acetylene Pressure, psi
0.020	1/16 to 3/32	0.035	65	1 to 4	1 to 3
0.032	1/16 to 3/32	0.035	65	3 to 5	1 to 3
0.040	3/32 to 1/8	0.035	65	3 to 5	1 to 3
0.051	3/32 to 1/8	0.035	65	3 to 5	1 to 3
0.064	3/32 to 1/8	0.040	60	3 to 5	3 to 5
0.072	3/32 to 1/8	0.040	60	3 to 5	3 to 5
0.081	3/32 to 1/8	0.046	56	3 to 5	3 to 5
0.091	1/8 to 5/32	0.046	56	3 to 5	3 to 5
0.128	1/8 to 5/32	0.059	53	3 to 5	3 to 5

Commercial fluxes are available for torch welding magnesium alloys.

The composition of a typical flux is as follows:

Compound	Percentage (by weight)
Potassium chloride	45%
Sodium chloride	25%
Lithium chloride	25%
Sodium fluoride	5%

Total impurities — carbon, oxygen, sulfur, iron or silicon — should not exceed 0.15%. The fluorine content should not be less than 2%.

Welding fluxes are generally supplied as a dry powder which is hygroscopic and should be stored in tightly sealed containers. Preparatory to welding, the powder is mixed with water to form a thin paste, in a glass or porcelain container. Containers made of iron, brass, or other materials that might react with the flux should not be used.

The material to be welded should be cleaned with gasoline, naphtha, carbon tetrachloride or hot alkaline cleaners. The joint area should be cleaned with a fine steel brush made of wire 0.003 to 0.006 in. in diam; with steel wool; or by chemical means.

A flanged joint 1/16 to 1/8 in. high is desirable for sheets thinner than 0.040 in. Sheets 0.040 to 0.125 in. thick can be welded with a butt type of joint. Sheets thicker than 0.125 in. should be beveled to an included angle of 90 to 120 deg, with a root face of approximately 1/16 in. The maximum thickness for a single-pass weld is usually 1/4 in. Gas welding is restricted to butt-joint and single-pass welds to avoid corrosion by entrapped flux.

The flux should be brushed on both sides of the joint and the rod. A neutral flame is recommended for all types of gas.

* Chief Process Engineer, Northrop Aircraft, Inc., Hawthorne, Calif.
Prepared for the Magnesium Committee

The material should be preheated slowly until the flux fuses. Then the torch is moved forward in a straight line with no rotary motion. As the puddle forms, the rod should be dipped into it intermittently and the torch should be moved forward, inclined toward the work material at an angle of about 45 deg.

As soon as the welded parts are cool, the flux should be removed by a thorough cleaning with hot running water and a bristle brush. The part should then be given a chrome-pickle treatment for one minute at 70 F in the following solution:

Sodium dichromate ($Na_2Cr_2O_7.2H_2O$)	1.5 lb
Concentrated nitric acid (sp gr 1.42)	1.5 pt
Water	to make 1.0 gal

After treatment, the parts should be washed in cold running water, then boiled for two hours in the following solution:

Sodium dichromate ($Na_2Cr_2O_7.2H_2O$	0.5 lb
Water	to make 1.0 gal

The assembly should then be rinsed in cold running water and dipped in boiling water.

If an assembly is too large for immersion, it should be cleaned and heated to about 150 F; then a chrome-pickle solution should be brushed over the seam and allowed to remain for one minute, after which the assembly should be thoroughly rinsed in hot water. This treatment does not afford the same protection against corrosion as the preceding method.

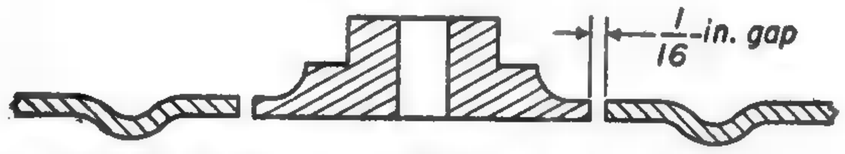

Fig. 1 Heavy section tapered to thickness of sheet before welding

Extrusions and castings can be welded to sheet stock. The edges of both should be beveled so as to be near the thickness of the sheet material, as shown in Fig. 1. More heat should be directed on the area having the greatest mass in the vicinity of the weld.

Shielded Arc Welding. Magnesium sheet, extrusions, forgings, sand castings and permanent mold castings can be welded by the gas-shielded arc method. The torch employs a tungsten electrode shielded by an inert gas, such as argon or helium. This method requires no flux; therefore, all types of joints commonly employed on steel can be welded with magnesium.

To weld magnesium by an automatic machine is practicable when production methods warrant the expense of the machine. Welding speeds of 12 to 40 in. per min are possible with such equipment. Higher mechanical properties and more uniform welds are thus obtained.

A standard d–c arc–welding generator or rectifier equipped with a variable current control is satisfactory for welding magnesium. An a–c transformer type of machine with high-frequency unit is also satisfactory. Commercial torches are supplied in various sizes and tip angles. A conventional welder's helmet for the face and suitable protection for hands and arms should be used to prevent exposure to the radiation from the arc.

A pure inert gas is essential for sound welds. Impurities in amounts greater than the following will cause welding difficulties:

Helium		Argon	
Helium	97.8 %	Argon	99.8% min
Carbon dioxide	0.2 %	Nitrogen	
Nitrogen	1.6 %	Neon	
Water	0.029%	Xenon	
Hydrogen	0.2 %	Helium	0.2%
Hydrocarbons	0.0 %	Oxygen	
		Hydrogen	

Water vapor decomposes in the arc and yields hydrogen and oxygen. Hydrogen, very readily absorbed by the molten metal, produces porosity. Oxygen reacts to form magnesium oxide, resulting in poor fusion and inclusions. Nitrogen reduces the welding speed.

Electrodes are manufactured in sizes from 3/32 to 1/2 in. in diam. The filler rod should have the same composition as the parent metal or should have a lower melting point than the parent metal. Selection and regulation of arc-welding equipment is shown in Table II. Alloy M1 (Mg – 1.5% Mn) requires somewhat more current than is indicated in Table II.

Table II. Data for Arc Welding Magnesium

Metal Thickness, inch	Current, amperes	Filler Rod Diameter, inch	Helium Flow, cu ft/min	Helium Pressure, oz/sq in.	Tungsten Diameter, inch
0.030	20	1/16	0.3	6	3/32
0.040	30	1/16	0.3	6	3/32
0.050	35	3/32	0.3	6	1/8
0.060	45	3/32	0.3	6	1/8
0.070	55	1/8	0.3	6	1/16
0.080	60	1/8	0.3	6	3/16
0.090	65	1/8	0.3	6	3/16
0.100	70	1/8	0.3	6	3/16
0.125	75	1/8	0.3	6	3/16
0.150	80	5/32	0.3	6	3/16
0.200	90	5/32	0.5	12	1/4
0.250	100	5/32	0.5	12	1/4
0.500	115	5/32	0.5	12	1/4
1.000	130	5/32	0.5	12	1/4

The first and most important operation in welding is to clean the material thoroughly of all paint, coatings, oxides, grease and other foreign matter. Naphtha or carbon tetrachloride can be used for removing oil and grease. For removing oxides and chemical coatings previously applied, a hand or rotary brush is recommended, made of wire 0.003 to 0.006 in. in diam. Steel wool or abrasive cloth (not emery cloth) may also be used. If the butting edges are rough, they should be smoothed by filing or grinding.

The arc is started by brushing the tungsten electrode lightly on the metal and then raising the electrode to a minimum arc length. As the metal becomes molten the filler rod is advanced into the arc, which rapidly bites off small pieces of the rod. The rod should not be pushed into the molten metal, but rather into the arc. The torch should be held close to the surface to maintain a short arc and at an angle of not more than 60 deg to the work. The filler rod should be held at an angle of not more than 30 deg to the work, and in such a way that the torch and filler rod make an angle of 90 deg to each other. For good sound welds, it is recommended that the entire weld be made with as few stops as possible. When stops are necessary, the weld should be wire-brushed before continuing.

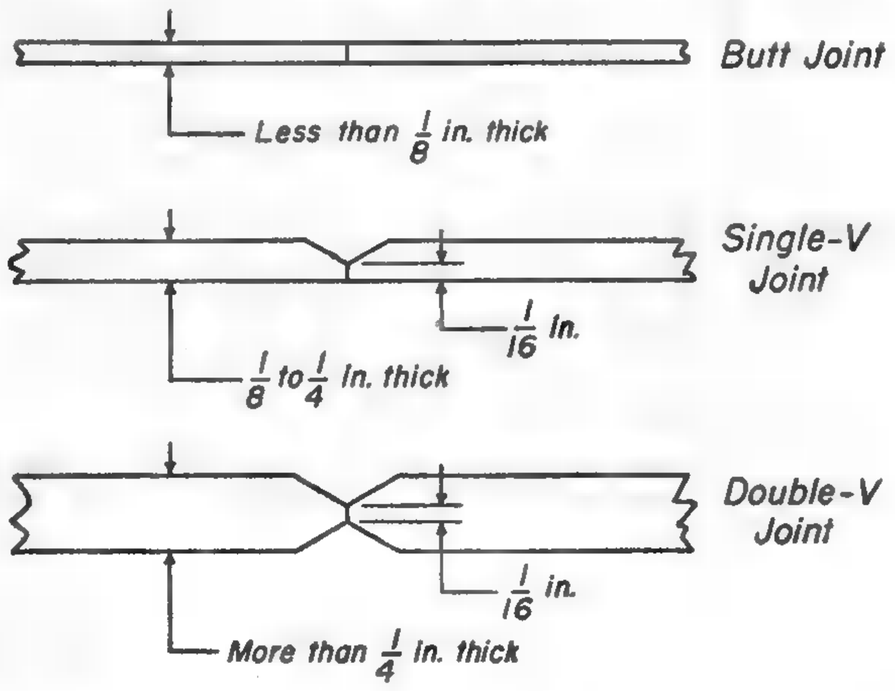

Fig. 2 Preparation of joints for arc welding

The recommended preparation for joints of various thicknesses is shown in Fig. 2.

When no backing plate is used with metal 0.125 in. thick or less, the metal drops through on the under side, permitting 100% penetration; however, a good fit is necessary when this method is followed.

Sometimes it is necessary and advantageous to use a backing plate that has a small groove directly below the seam. The groove allows a smooth cast through on the under side. Dimensions for the groove vary with sheet thickness. For sheet 0.064 in. thick, a depth of 1/16 in. and width of 3/16 in. are suitable. For sheet 0.125 in. thick, a depth of ⅛ in. and width of ¼ in. are required. More uniform penetration and greater ease of welding are two advantages of this method.

Steel, copper and magnesium can be used for backing plates on thin material. A magnesium jig is advantageous in reducing warpage and residual stresses, since the jig is heated during welding and the weld is permitted to cool slowly.

Warpage, residual stresses and cracking are reduced by preheating between 200 and 400 F. Preheating increases the speed of welding and permits the use of lower current.

Since no flux is necessary for arc welding magnesium the welds need only be wire-brushed to remove the gray powder deposited on the material. Parts can then be given the chrome-pickle or dichromate treatment, and if desired, painted for greater resistance to corrosion.

Stress Relieving After Welding. Residual stresses set up by arc welding range from 1,000 to 15,000 psi adjacent to the weld in a longitudinal direction, and therefore require a thermal treatment to reduce these stresses to a minimum. The parts should be placed in a jig and clamped to prevent any warpage during the thermal treatment. If possible, the entire jig should be placed in a furnace at the temperature and for the time indicated in Table III, which gives the recommended stress-relieving treatments for the weldable magnesium alloys. After thermal treatment, the parts should be left in the jig in still air until they are cool.

Table III. Recommended Stress-Relieving Treatments for Magnesium Alloys

Alloy	Temperature ±10 deg Fahr	Temperature ±6 deg Cent	Time at Temperature, minutes
AZ31X Annealed	500	260	15
AZ31X Hard Rolled.....	300	150	60
M1 Annealed	500	260	15
M1 Hard Rolled.....	400	204	60
AZ51X Annealed	500	260	15
AZ51X Hard Rolled.....	375	190	60

Resistance Welding. Most magnesium sheet, extrusion and casting alloys can be spot welded. The best spot welds are secured when alloys of the same composition are welded together, but reasonably good joints can be made between different alloys. When sheets of unequal thickness are to be spot welded, the ratio of sheet thickness should not be greater than 3 to 1. The recommended distance between the spots is at least 8 times, and preferably 16 times, the thickness of the sheet (minimum ¼ and preferably ½ in.). The recommended distance from the edge is at least 4 times, and preferably 6 times, the sheet thickness (minimum 3/16 and preferably 5/16 in.). The minimum shear strength required per weld for spot-welded specimens is given in Table IV.

Table IV. Minimum Required Shear Strength Per Weld for Spot Welds of Magnesium

Nominal Thickness of Thinner Sheet, inch	Shear Strength, pounds
0.020	75
0.040	202
0.064	357
0.081	472
0.125	800

Magnesium alloys are supplied with two different protective coatings, chrome pickle or oil. The oil-protected material is preferred for spot welding, because the neces-

sary removal of the chrome-pickle coating is difficult. Oiled sheet should be degreased in solvents or alkaline cleaners before either mechanical or chemical cleaning. Mechanical cleaning may be done with a wire brush, steel wool or abrasive cloth.

Welding tips and machines similar to those used on aluminum are satisfactory for spot welding magnesium.

To prevent corrosion, the spot-welded joint should be wire-brushed and chemically treated.

Seam welds, of either the continuous or the intermittent type made in magnesium alloys, develop strength comparable to that of spot welds.

Flash Welding. Hydraulic flash-welding machines with rapid burn-off and fast push-up are best suited for magnesium. Good welds can be made with 90% strength efficiency.

Riveting

Most conventional methods of riveting can be employed with magnesium. For best results, however, it is necessary that special consideration be given to selection of rivets, design of joints, driving techniques and protection of the assembly.

Rivet Alloys. Magnesium is not suitable for use as a rivet alloy because of its characteristically rapid work hardening at room temperature. Aluminum alloy rivets that contain 5.2% Mg (Alloy 56 S) cause almost no galvanic action on magnesium. Steel, brass or 17 S aluminum rivets are not recommended unless service conditions include no appreciable danger of corrosion.

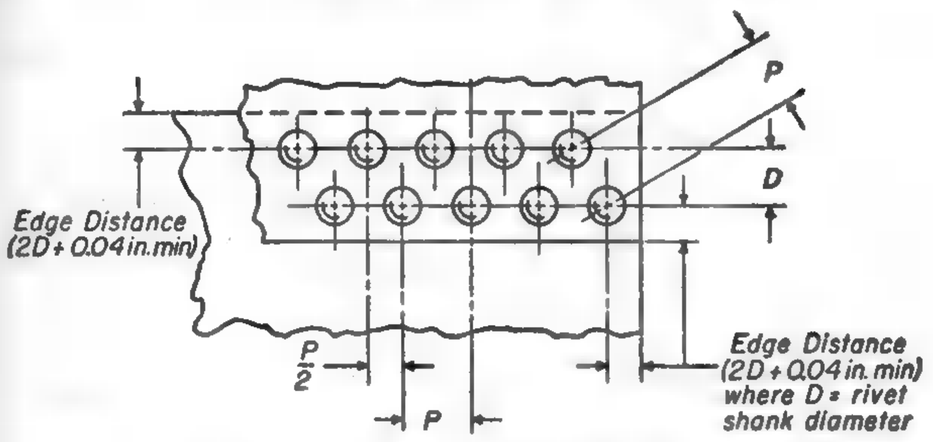

Fig. 3 Rivet spacing and edge distance

Design of the Riveted Joint. The selection of rivet size depends mainly on the rivet alloy, sheet alloy and thickness of sheet used.

The minimum normal rivet spacing or pitch, shown as *P* in Fig. 3, is four times the diameter of the rivet shank for all types of rivet. The absolute minimum spacing is three times the diameter of the shank for all types of rivets except those with flush heads. Flush-head rivets, when installed in dimpled countersinks, should not be spaced more closely than four times the diameter of the rivet shank. This minimum normal rivet spacing should be maintained whenever possible, since it permits drilling out an unsatisfactory rivet and replacing it with a larger size in order to salvage a part. Where the rivet spacing is too great, the sheet may warp or bow between rivets.

The distance between rows of rivets in a pattern should be approximately the same as the rivet spacing or pitch. If the rows are staggered, as shown in Fig. 3, the distance between rows can be less than the rivet spacing, but the diagonal distance in this instance should equal the rivet spacing *P*.

The minimum distance from a rivet to the edge, as shown in Fig. 3, should be limited to a minimum of twice the diameter of the rivet shank plus 0.04 in. Excessive distance at the edge should not be allowed where it would add weight unnecessarily or would form a moisture trap in horizontal parts (Fig. 4).

Types of Rivets. Most of the common types of heads supplied on aluminum rivets can be used for riveting magnesium alloy structures. Cone-shaped driven heads are less likely to cause damage to the magnesium sheet; first, because cone-shaped heads require less driving pressure and, second, because when a rivet is unintentionally driven at an angle, the rivet set is less likely to cut into the sheet.

Riveting Methods and Equipment. Driving methods for riveting magnesium are similar to those for other metals.

Squeeze-riveters are generally preferable to other machines for driving rivets in magnesium assemblies. Pneumatic hammers are suitable for riveting, provided they are large enough to upset the rivets properly.

Rivet Holes. Rivet holes in magnesium structures should be drilled or subpunched and reamed to obtain a smooth surface. Reaming reduces edge stresses and fatigue failures. Parts that are drilled together should be taken apart and all the chips should be removed from the joints before final assembly.

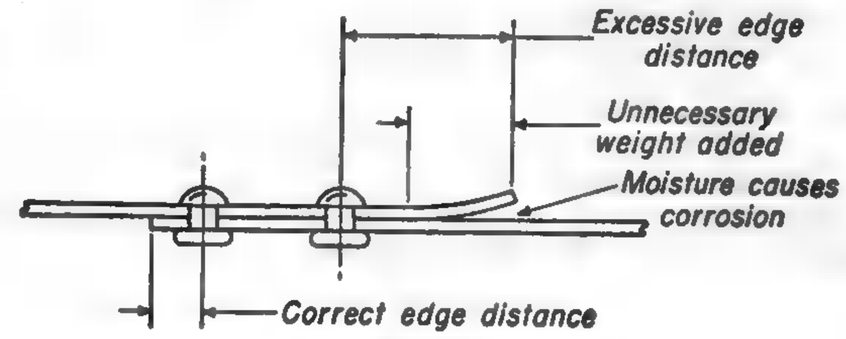

Fig. 4 Excessive edge distance with riveted joint

Flush Riveting (Dimpling). Several methods have been devised for dimpling magnesium sheet. Of the different processes, two seem the most practicable for production: first, resistance-heated dimpling, because of speed; and second, spin dimpling, because expensive equipment is not necessary. Another method is the use of heated dimpling dies.

Resistance-Heated Dimpling. In preparing the material for dimpling, any protective treatment must be removed around the area contacted by the dimpling sets, to prevent arcing or burning.

Before dimpling, it is essential that the holes be drilled several thousandths of an inch undersize so that they can be reamed to size after dimpling. Burring the holes is not necessary before dimpling, and in most instances is detrimental unless the holes are left smooth. The cutting edge of the burring tool leaves a sharp notch, which develops a crack when dimpled.

Spin Dimpling. The material to be dimpled is placed between two dies. The spinning male die is brought down on the metal, while the pilot indexes the material. Enough pressure is applied at first to create frictional heat; then pressure is increased until the dimple is formed.

Magnesium 0.050 in. thick or less can be dimpled satisfactorily. Heavier gages are countersunk by machine.

Prevention of Corrosion. The extent of the protection required for riveted magnesium joints depends on service conditions and on the composition of the aluminum alloy rivets that are used.

All parts to be riveted should be chemically treated in detail and given two coats of primer (Army-Navy Specification AN-TT-P-656b recommended) before assembly.

All rivets should be anodized or chemically treated to obtain good adhesion of paint. When the rivets have been driven, all the heads should be primed. Before a riveted structure is painted, all areas from which the surface-treatment chemical has been removed should be given the "brush-on" chrome-pickle treatment.

Exterior magnesium alloy surfaces that are assembled in contact with dissimilar metals should be insulated with high-pressure zinc chromate compound on the faying surfaces. Interior surfaces need only two coats of zinc chromate primer on each faying surface.

In assemblies requiring watertight joints, gasket material or heavy calking compounds offer the best means of sealing and preventing corrosion.

Adhesive Bonding

The numerous plastic and rubber compounds available for bonding magnesium surfaces, are generally classified as thermoplastic or noncuring, and thermosetting or curing types. The thermoplastic adhesives soften, become tacky

and dissolve when in contact with solvent or when heated; the thermosetting adhesives actually become a new and different compound when fully cured. The selection of the proper adhesive for a specific application depends on the conditions of service and stress to which the bonded magnesium will be subjected.

Magnesium surfaces to which adhesives are to be applied should be chrome-pickled, clean and free from grease. Cleaning may be done first with a fine wire brush, then with a strong alkaline cleaning solution. The sheet should not be "solvent cleaned" before cementing.

Thermoplastic adhesives may be applied as hot solutions or as solvent solutions and may be roller coated, brushed or sprayed. Sheet and strip film are applied by heat activation. Thermosetting adhesives are usually supplied in solvent solutions and may be applied by brush, roller or spray gun.

Most modern adhesives, when used for bonding magnesium, may be expected to be effective for about 10 years, under normal weather conditions and 50% stress. Sunlight and oxygen are probably the most detrimental conditions to the life of adhesive bonds.

Soldering

Soldering is ordinarily used only for filling imperfections in castings or sheet metal where a smooth surface is necessary. Soldering is not recommended where stresses are involved.

Two types of commercial solders have been developed especially for magnesium alloys. One type melts at 315 F and contains 60% Cd, 30% Zn and 10% Sn; the other type melts at 500 F and contains 90% Cd and 10% Zn. The area to be soldered should be preheated to approximately 350 F when the first type of solder is used, and to approximately 500 F when the second type is used.

The area to be soldered should be cleaned to a bright metallic luster so that a good alloying action can take place. Filing, wire-brushing and sanding with an aluminum oxide abrasive cloth are suitable methods.

A small amount of solder should be applied and the interface between the solder and the magnesium should be rubbed vigorously with a sharp pointed tool or brushed with a stiff wire brush continuously until the solder is alloyed. No flux is necessary or recommended for soldering.

Machining Magnesium and Magnesium Alloys

By H. Menking*

MACHINING TOOLS of standard design as used for other metals may, in most instances, be employed for magnesium. However, for maximum economy, tools for machining magnesium should be of slightly different design. The main factors governing the design of tools for cutting magnesium are: (1) the extremely low resistance of magnesium to cutting, (2) the comparatively low heat capacity of the metal, and (3) the large volume of the chips obtained because of the easy cutting. The low resistance to cutting leads to high speeds and heavy feeds; therefore the problem is to dispose of the chips quickly and smoothly, without jamming and subsequent development of frictional heat. The power required to remove a given amount of magnesium by machining is much lower than that required to remove an equal amount of any other metal used commercially. The power per cubic inch per minute normally required for machining magnesium varies from 0.15 to 0.3 hp. These basic factors have led to the development of tools with the following principal characteristics: smooth tool faces; large peripheral relief angles; large chip spaces and (in milling cutters) small number of blades; as well as comparatively small rake angles.

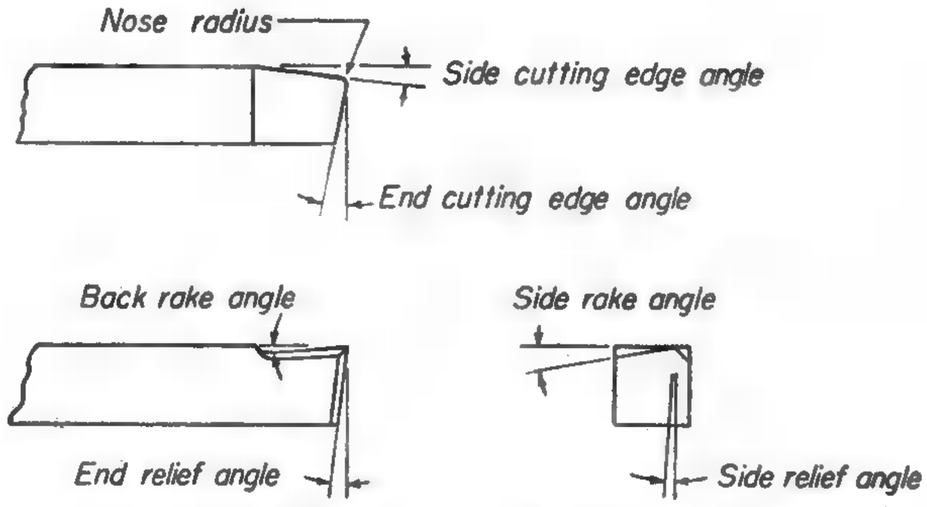

Fig. 1 Terminology of single-point tools according to the American Standards Association

In grinding the tools, it is most essential to keep the cutting edge as keen and smooth as possible and free from grinding wheel scratches, burrs or wire edges. In addition, the tools should be kept as smooth as possible wherever they come in contact with the chips, in order to facilitate chip flow. Keen tool edges and smooth tool surfaces are obtained best by finish grinding on a fine or very fine abrasive wheel, followed by a careful hand-stoning with a fine or extra fine oilstone when necessary. Tools previously used for other metals should always be resharpened before cutting magnesium, regardless of whether the cutting angles are changed or not.

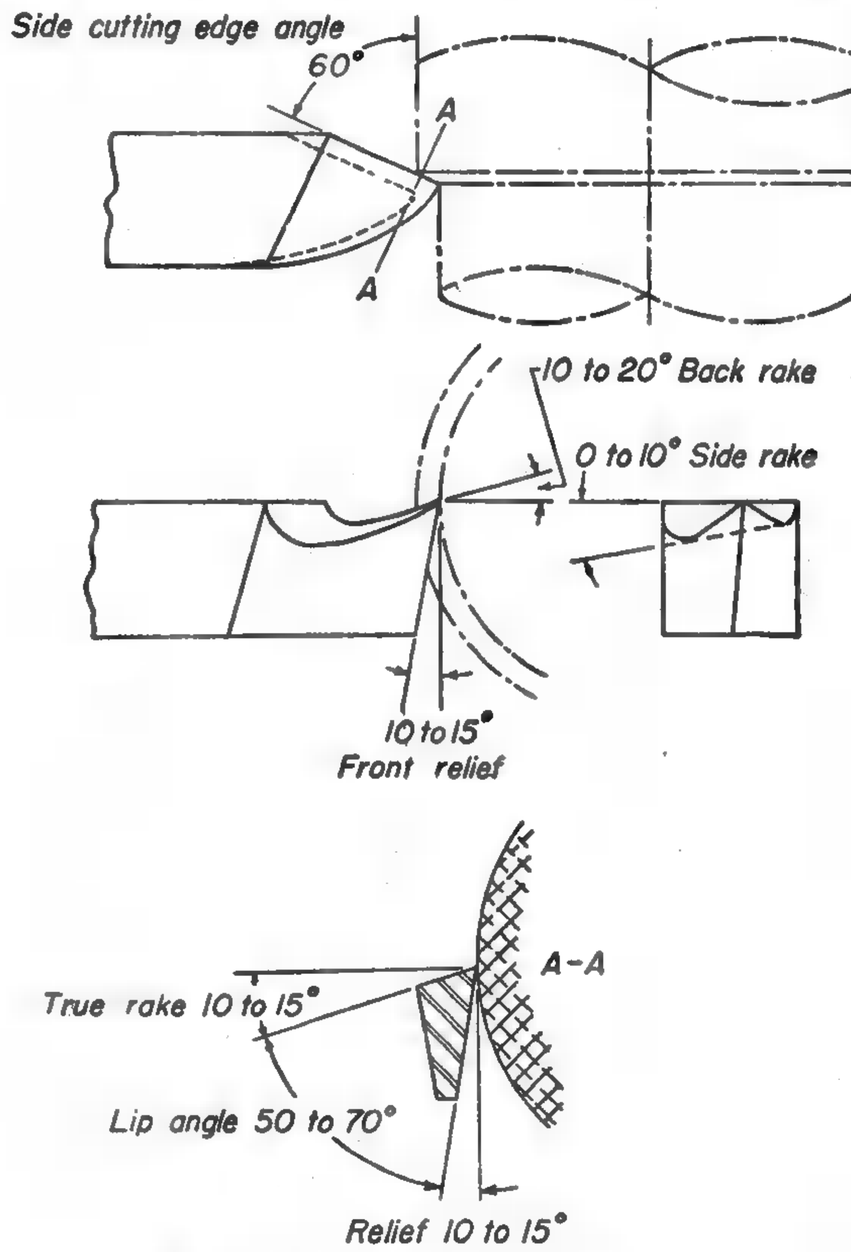

Fig. 2 Lathe tool for turning magnesium

Tools tipped with sintered carbide give considerably better results than tools made of high-carbon steel or

* Revised for this edition by the Magnesium Committee

high speed steel. Carbide tools are recommended for maximum efficiency, especially when extremely high cutting speeds are employed. The higher price of these tools is more than offset by their longer life, greater accuracy and greater operating economy, because of less frequent resharpening.

The terminology used in this article is in accordance with that advocated by the ASA. (*See* Fig. 1.)

Turning. Figure 2 shows a recommended lathe tool for rough cutting. The large relief (10 to 15 deg) and the small back rake (10 to 20 deg) are important. A larger back rake often causes feeding of the tool into the work. In some machine shops no back rake is used, an advantage in breaking up chips and preventing curling. Such a tool, however, is not generally recommended, since it reduces the smoothness of the machined surface slightly and increases the power consumption. The side rake may vary from 0 to about 10 deg.

The recommended finishing tool differs from the roughing tool by having a round nose on the tool tip, producing a smoother finish on the surface. General experience indicates that tool noses narrower than those used for aluminum are sufficient to obtain the same degree of smoothness for articles made of magnesium.

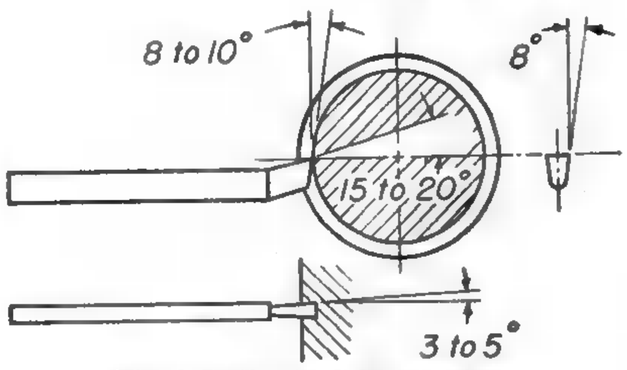

Fig. 3 Lathe tool for parting

Form tools (broad-nose tools) for taking wider cuts or turning specially shaped contours, should be designed along the same lines, except that the back rake should be reduced to about 3 to 8 deg to avoid chattering. Figure 3 illustrates a parting tool. The large relief angles are important to reduce friction and to avoid breaking the tool.

Recommended speeds, feeds and depths of cut for turning are shown in Table I.

Planing and Shaping. In principle, the same cutting angles are used as for lathe tools.

Table I. Recommended Speeds, Feeds, and Depths of Cut for Turning and Boring Magnesium

Operation	Speed, ft per min	Feed, in. per min	Maximum Depth of Cut, inch
Roughing	300 to 600	0.030 to 0.100	0.500
	600 to 1000	0.020 to 0.080	0.400
	1000 to 1500	0.010 to 0.060	0.300
	1500 to 2000	0.010 to 0.040	0.200
	2000 to 5000	0.010 to 0.030	0.150
Finishing	300 to 600	0.005 to 0.025	0.100
	600 to 1000	0.005 to 0.020	0.080
	1000 to 1500	0.003 to 0.015	0.050
	1500 to 2000	0.003 to 0.015	0.050
	2000 to 5000	0.003 to 0.015	0.050

Milling. Milling cutters for magnesium should be of the coarse smooth type. They should have considerably fewer teeth, preferably only one-half or one-third as many as are standard with conventional cutters used for steel and other metals. The larger chip space and the heavier cut resulting from the smaller number of teeth,

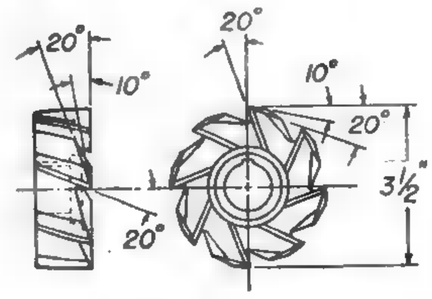

Fig. 4

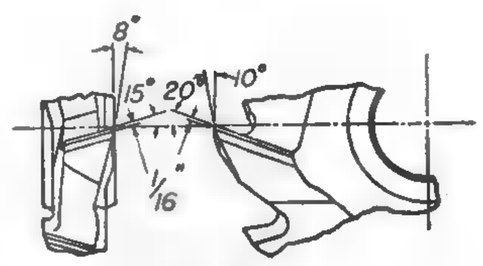

Fig. 5

Fig. 4 Face mill
Fig. 5 Staggered-tooth cutter. Recommended design of tooth

lead to a reduction of frictional heat, greater chip clearance, and consequently higher speeds, decreased distortion, lower power consumption and smoother finish. Unless otherwise stated, a relief angle of 10 deg, 1/16 in. wide, followed by a secondary clearance of 20 deg is common to all cutters illustrated.

Solid Cutters. Figure 4 shows a recommended type of face cutter. Figure 5 illustrates a staggered-tooth (slotting) cutter 6 in. in diam with 12 teeth. A helix angle of 15 deg, a rake of 20 deg, and relief of 8 deg on the side of the tooth are suggested for the latter type of cutter. Plain mills (Fig. 6) are recommended with 25-deg rake and 45-deg helix angle. On form cutters (Fig. 7) the rake is reduced to 5 to 8 deg, because of the heavier cutting pressure. A larger rake may result in chattering.

Inserted-Blade Cutters. These are less expensive than solid cutters of large diameter and offer a better chance to obtain large chip space. They are, therefore, used for high peripheral speeds. Figure 8 shows the design of an inserted-blade face mill 8 in. in diam with 6 to 8 blades. The blade design of a cutter 18 in. in diam, as used for extremely high cutting speeds (7000 to 8000 fpm), is shown in Fig. 9 and 10. Particular attention is called to the unusually small number of blades, the free unobstructed chip space between cutter body and work piece, the curved-out and polished face of the blade and the large relief (16 deg). All these features aid chip flow and reduce friction, thus making higher cutting speeds possible and increasing the life of the teeth.

A suitable type of shell-end cutter (Fig. 11) is designed similarly to the milling cutters described before.

With the type of machining equipment now used as standard, magnesium alloys, under ordinary conditions, can be machined at maximum spindle speeds and with feeds and cuts as great as the capacity of the machines. Recommended speeds, feeds and depths of cut for milling magnesium are shown in Table II.

Reaming. Reamers for magnesium should have a small relief (4 to 7 deg), a clearance of 15 to 20 deg and a small rake (5 to 8 deg) in order to secure a steady cut without vibration. A recommended reamer is shown in Fig. 12. The special steel and diamond boring tools often

Fig. 6 Plain mill. Fig. 7 Form cutter. Fig. 8 Inserted-blade face mill. Recommended design of blade

Table II. Recommended Speeds, Feeds, and Depths of Cut for Milling Magnesium

Operation	Speed, ft per min	Feed, in. per min	Feed, in. per tooth	Depth of Cut, inch
Roughing	Up to 900	10 to 50	0.005 to 0.025	Up to 0.500
	900 to 1500	10 to 60	0.005 to 0.020	Up to 0.375
	1500 to 3000	15 to 75	0.005 to 0.010	Up to 0.200
Finishing	Up to 900	10 to 50	0.005 to 0.015	Up to 0.075
	1000 to 3000	10 to 70	0.004 to 0.008	0.005 to 0.050
	3000 to 5000	10 to 90	0.003 to 0.006	0.003 to 0.030
	5000 to 9000	10 to 120	0.002 to 0.005	0.003 to 0.030

used for reaming are well suited for magnesium. A definite cut (minimum of 0.025 in. on the diam) should be taken with the reamer; otherwise the metal will compress, resulting in an undersize hole with poor finish.

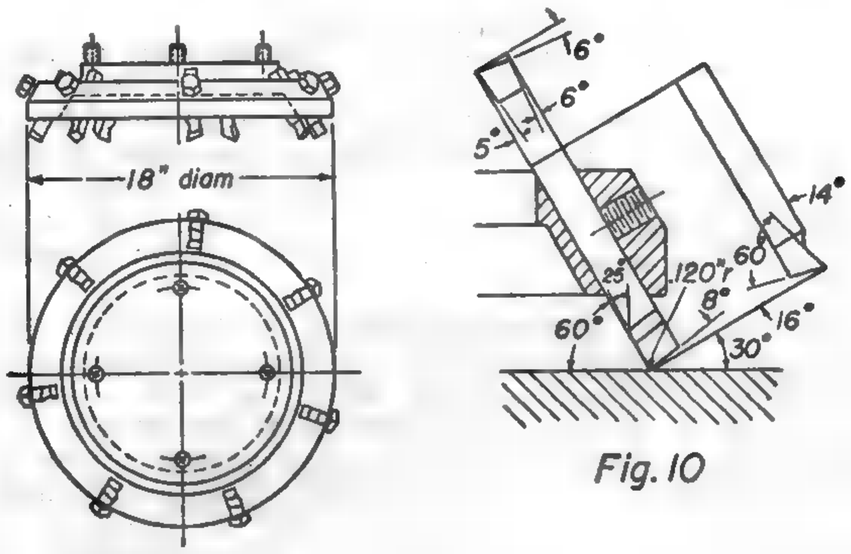

Fig. 9

Fig. 10

Fig. 9 Inserted-blade face mill for extremely high speeds
Fig. 10 Design of blade for inserted-blade face mill shown in Fig. 8

Drilling. The type of twist drill recommended for magnesium depends on the depth of the hole to be drilled. The speeds and feeds recommended when drilling magnesium are shown in Table III.

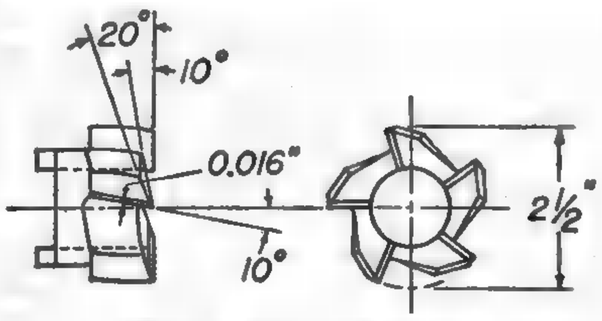

Fig. 11 Shell-end cutter

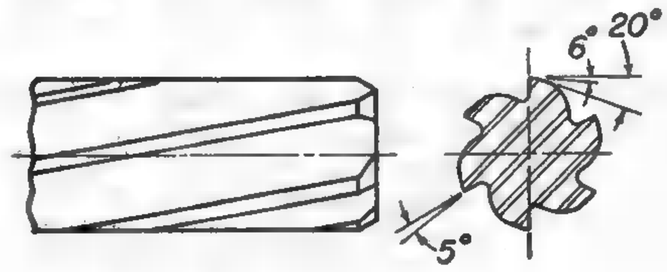
Deep Holes. A drill for deep holes (more than about four times the diameter) should have a helix angle of about 40 deg and smoothly polished flutes in order to ensure rapid flowing of chips. A web of uniform thickness is preferred. The clearance (relief behind land) should be twice as deep as with standard drills. The margin should be narrower than customary (one-half the standard width). A point angle of 110 to 120 deg and a lip relief of 15 deg is recommended. A drill of this design will cut freely and will readily clear out the chips. Raising the drill to remove the chips will be unnecessary unless the hole is deeper than about 20 times the diameter. A drill of suitable design is illustrated in Fig. 13. To prevent drill marks and to keep the drill straight, a spur or pilot may be ground on the point.

Table III. Speeds and Feeds for Drilling Magnesium

Diameter of Drill, inch	Speed, ft per min	Feed, inches per revolution — Sheet	Shallow Holes	Deep Holes
¼	300 to 2000	0.005 to 0.030	0.004 to 0.030	0.004 to 0.008
½	300 to 2000	0.010 to 0.030	0.015 to 0.040	0.012 to 0.020
1	300 to 2000	0.010 to 0.030	0.020 to 0.050	0.015 to 0.030

Insufficient distance between the drill jig bushing and the surface of the drilled part will prevent the chips from flowing out readily and will cause them to jam in the flutes. An approximate minimum distance of 1½ times the hole diameter is recommended.



Helix angle	0° (Straight) or 10°
Rake angle	5 to 8°
Relief angle	4 to 7°
Clearance angle	15 to 20°
Margin	0.010 to 0.025"
Flutes	4 to 6°

Fig. 12 Reamer recommended for use on magnesium

Shallow Holes. Drilling holes in magnesium to a depth less than about five times the diameter presents few difficulties and standard drills may be used. Polished flutes are recommended to aid in clearing chips and it is extremely important that the cutting edges be kept sharp. Dull drills result in poor surface finish, undersize holes, burrs and overheated work.

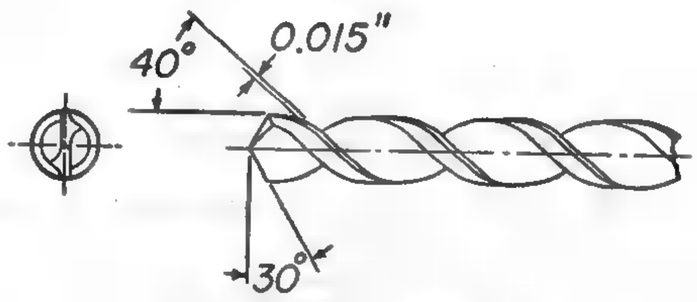


Fig. 13 Drill for deep holes

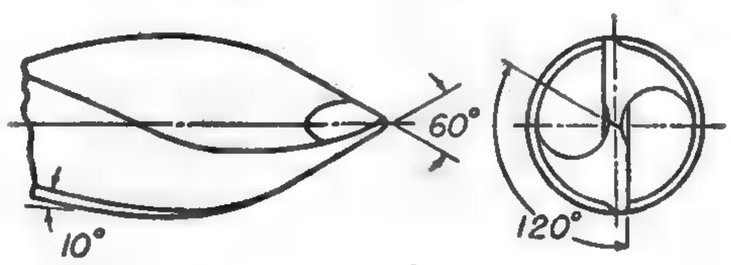
Drilling Sheet. Magnesium sheet can be drilled with a sharp, standard drill (118-deg point angle); but for high production of accurate holes with a good finish and minimum burn, a slightly modified drill may be used. The point angle should be reduced to approximately 60 deg to prevent "walking" of the drill, to reduce thrust and to prevent abrupt change of thrust when breaking through. The chisel-edge angle should be within the range of 120 to 135 deg. The web should be thinned and the ends of the cutting edges rounded. A thin web at the point helps to center the drill and reduce thrust; the rounded corners provide a smooth finish and reduce burrs. A helix angle of approximately 10 deg will prevent the work from climbing the drill on the break-through. Figure 14 illustrates a drill recommended for magnesium sheet.



Point angle	60°
Helix angle	10°
Chisel edge angle	120 to 135°
Web	Thinned at point
Corners	Rounded

Fig. 14 Data concerning drills for magnesium sheet

Counterboring. A recommended tool for counterboring is shown in Fig. 15. An important feature is the narrow cylindrical land, which is only about 0.015 in.

Tapping. A suitable tap design is illustrated in Fig. 16. The acute back angle of the land (3 to 4 deg) results in cutting rather than squeezing the metal when backing out of the tapped hole. The slightly greater spring-back of magnesium, as compared with other metals, makes this

precaution advisable. The lands should be shorter than usual and cylindrical; that is, there should be no clearance on the land. This will reduce the possibility of chips getting jammed in the clearance space and building up on the land. Taps for magnesium are usually not made oversize. A thread length of two to three times the diameter is recommended.

No trouble is encountered with the "seizing" of threaded magnesium parts, when in contact with magnesium, aluminum or any other metal. Steel or brass inserts should be used in assemblies where the screw bolt or stud is removed frequently.

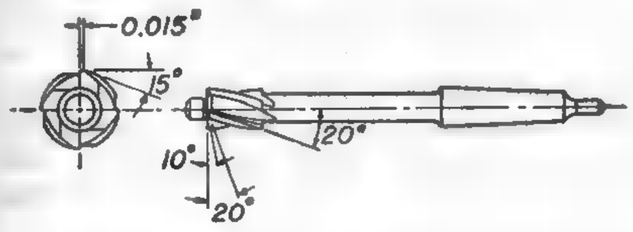


Fig. 15

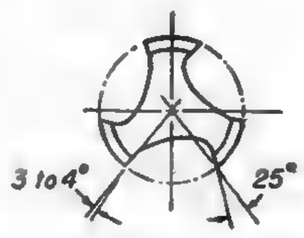

Fig. 16

Fig. 15 Counterboring tool
Fig. 16 Angles recommended for taps

Grinding. Finish grinding of magnesium is usually unnecessary because of the fine finish obtained by normal machining operations. Rough grinding or snagging is widely used, however, in foundries and for cleaning die castings and forgings. Grinding wheels should have a relatively coarse grain and an open structure in order to prevent loading. A grain size of 20 to 40 is satisfactory for rough grinding and a grain size of 40 to 80 should be used for finishing operations. The structures should be open with a rating of four to eight. Silicon carbide or aluminum oxide wheels with a vitrified or resinous bond are satisfactory for magnesium. Various types of abrasive cloths using fused alumina or silicon carbide abrasives are widely used on portable grinding units.

Magnesium dust creates a fire hazard and every precaution should be taken to ensure the proper collection and disposal of such dust.

Wet Grinding. If magnesium is to be ground wet on a belt sander or disk grinder, sufficient cutting fluid should be used to collect all the dust adequately and convey it to a central collecting point. At all times the dust should be wet with a copious supply of fluid and there should be no opportunity for dry or damp dust to collect on the machine. Water, soluble oil or mineral oil can be used as the cutting fluid. The magnesium sludge should be disposed of as discussed under Dry Grinding.

Dry Grinding. If magnesium is ground dry with a portable sanding unit or a grinding wheel, the magnesium dust created must be collected in an approved type of dust collection unit, in which a water or oil spray as near the dust-producing unit as possible, washes the dust from the air stream. Any ducts used should be short and as straight as possible. Multiple units, in which a number of dust-producing units are connected to a single exhaust system, are not recommended. The controls of such collecting systems should be interconnected so that they cannot be operated unless the water spray and the exhaust system are working. The dust collectors should be kept clean and ventilated to the atmosphere. The magnesium-water sludge should be collected at least daily, and more frequently if required, to prevent excessive accumulation. Such sludge should be stored under water and should be disposed of by burning or by mixing with sand and burying. The following additional precautions are suggested in order to ensure safe operation:

1 Wheels should be used for magnesium alloys only. Before wheels are dressed, the collector should be cleaned thoroughly.
2 Grinding operators should wear hard-finished clothing to prevent accumulation of dust thereon. Clothing should be brushed frequently.
3 The areas around grinding units should be kept free from magnesium dust. Rafters and ledges should be cleaned regularly.
4 An adequate supply of recommended extinguishing compound should be available.
5 Warning signs should be displayed in order to prevent unnecessary exposure to miscellaneous fire hazards.

Polishing. Sandpaper, fused alumina or silicon carbide cloths of a suitable grade should be used in polishing. Emery paper will tend to cause sparking and is therefore not recommended. In order to maintain a bright shine, the polished surface should be slightly greased with vaseline or an equivalent grease, or painted with a suitable clear lacquer. Polished surfaces will tarnish if not protected. For larger polishing operations, the same precautions as for grinding are recommended.

Sawing. Magnesium is readily cut by circular saws or band saws. Sharp blades are essential for satisfactory results. A tallow stick lubricant facilitates the work.

The following is recommended for band saws:

	Thickness of Blade, inch	Width of Blade, inches	Teeth per inch
For lighter work.....	0.030 to 0.040	$\frac{13}{16}$ to 1	6
For heavier work.....	0.045 to 0.050	1½ to 2½	4

The set of the teeth should be greater than standard to reduce friction. For circular saws, blades about 10 in. in diam and 0.040 in. thick with 3 to 7 teeth to the inch and a set of about 0.055 in. are satisfactory for cutting sections as large as approximately 2 in. in diam. Hack saws should have 14 to 18 teeth to the inch, every third tooth a clearance tooth without set. A satisfactory size is 0.025 to 0.030 in. thick and ½ in. wide. Power hack saws should have 2 to 10 teeth per inch, depending on the size of the work being cut.

Filing. For hand work, single-cut or double-cut files may be used, although single-cut files work better. Files with rasp cut produce too rough a surface. Depending on the smoothness desired, bastard, second-cut or smooth files are used. For rotary files, medium-coarse single-cut files are found best. Too coarse a cut causes chatter.

Cutting Fluids. Experimental tests and experience in many plants have shown that the purpose of cutting fluids when machining magnesium is primarily to cool the work and reduce the fire hazard. Any improvement in surface finish and increase in tool life obtained are minor.

Although less heat is generated in cutting magnesium than in cutting other metals, the high cutting speeds, the high thermal expansion, and the low heat capacity of magnesium make it necessary, in some machining operations, to dissipate the heat developed in cutting. Machining heat may be reduced by correct tooling and machining technique, but this heat is often of such intensity that application of cutting fluids is necessary.

Efficient machining practice demands that high cutting speeds be used wherever possible. When such speeds are used in machining magnesium, a fire hazard sometimes exists, particularly when fine chips are being produced. Although sharp tools greatly reduce this hazard and cutting feeds must be in the range of 0.001 in. or less to start fires, uncertainties in operations make it necessary to take precautions against fire. Iron or steel inserts and sand-cast surfaces, which are likely to spark when hit with a cutting tool, also add to the fire hazard. A stream of cutting fluid, of 4 to 5 gal per min per tool, will virtually eliminate the fire hazard. If a particular job or machine tool prohibits the use of a cutting fluid, cutting speeds should be reduced to less than 500 ft per min, and the recommendations regarding sharp tools and feeds should be followed rigorously.

A wide variety of mineral-oil cutting fluids will function satisfactorily on magnesium. Almost any oil will reduce the fire hazard materially if applied in sufficient quantities; but to secure adequate cooling, the cutting oil should have low viscosity. The chemical nature of magnesium makes it necessary that the free acid content of cutting fluids be less than 0.2% and that the use of vegetable or animal oils be restricted, since these may oxidize and increase the acid content.

Water-soluble oils, oil-water emulsions, or water solutions of any kind, although good coolants, should not be used on magnesium. Water will greatly intensify any chip fires that might accidentally be started and will also make the reclaiming of machine scrap very inefficient. The presence of moisture on turnings causes the generation of small amounts of hydrogen, a circumstance that presents

a definite hazard during shipment or storage. Experience has shown that the use of water-base cutting fluids on magnesium is inadvisable.

Prevention of Distortion. Occasionally, a slight distortion of magnesium parts is observed during or after machining. This is infrequent and can generally be attributed to one of the following causes.

Frictional Heat. This will often result in distortion. Magnesium has a high coefficient of expansion and is, therefore, likely to warp when heated locally by friction. Avoidable factors causing frictional heat include dull tools, improperly designed tools, very fine feeds and cuts, and slow speed. This last is likely to cause jamming of chips, especially in combination with small feeds. Fast speeds increase the centrifugal force and throw out the chips, thus reducing the tendency of chips to jam.

Improper Clamping or Chucking. Magnesium alloys have lower modulus of elasticity than most other alloys commonly machined. This may, at times, lead to somewhat greater deformation, when clamping pressure or spacing is excessive. Light sections may also deform under the pressure of the cutting tool if the work is not rigidly mounted.

Casting or Heat Treating Stresses. These stresses have seldom been found to cause distortion of magnesium castings during machining. Castings with a tendency to such stresses can be stress relieved thermally when necessary, before machining. In exceptional circumstances, however, this treatment may be ineffective and the casting stresses will be released only by the roughing cut. Complete relief of stress may require considerable time if it is allowed to proceed at room temperature. In such instances, the castings may be stress relieved between the rough and the finish cuts by heating from 1 to 2 hr at 500 F and then cooling slowly in still air.

Automatic Screw-Machine Work. *Speeds and Feeds.* Magnesium alloy screw-machine stock may be machined at higher speeds and feeds than are used for other metals. Because of speed limitations of the machine, however, the maximum economies offered in machining magnesium may not be obtainable in all instances. The possibility of using a feed heavier than that used for other metals will depend on the conditions; but a feed approximately 40% greater than is used on free-cutting brass may be considered an average figure. In general, better results are obtained with heavy feeds than with light ones.

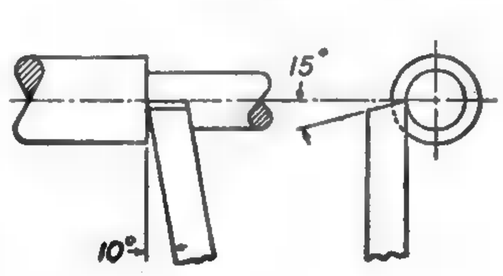

Fig. 17

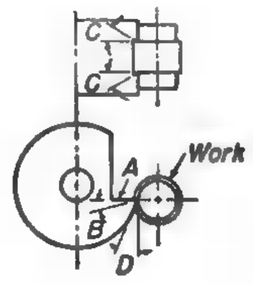

Fig. 18

Fig. 17 Box tool for screw-machine work
Fig. 18 Circular forming tool for screw-machine work

Box Tool. Tool angles recommended for box tools are shown in Fig. 17. A tool ground in this way will produce a satisfactory finish. The angle shown as 10 deg is to be considered an average and may vary within a relatively wide range (about 8 to 15 deg) depending on conditions.

Circular Forming Tool. The circular form tool shown in Fig. 18 is one of the types most commonly used for automatic screw-machine work. At *A* the tool is shown without back rake, which is satisfactory for magnesium. Frequently, it is necessary to grind the tool with a few degrees back rake, as shown at *B*, to correct a slight error in the steps of the tool. Back rake will produce satisfactory results, but no rake is preferable, giving better breakage of chips. The side relief indicated at *C* should not exceed one quarter degree. In most instances best results are obtained when the tool is without side relief or with a slight negative rake.

The front relief angle *D* is controlled by the design of machine and of toolholder. A standard relief angle has been determined for each type of machine and is considered satisfactory for all metals. This angle may vary slightly from one machine to another.

When a side forming tool is used without support, the ratio of the width of tool to the smallest diameter on the work should not exceed 2:1 for magnesium.

Chips. With light feeds in machining magnesium, the chips form in coils or ribbons. When the feeds are increased, the chips break up, and with relatively heavy feeds they are well broken. The chips produced in machining magnesium do not increase in thickness as they pass across the tool. Their thickness is about equivalent to the advance of the tool, indicating no adherence of metal.

Machine-Shop Scrap. Care should be taken to keep the magnesium scrap free from contamination with other metals, floor sweepings and the like, and as far as possible free from moisture. During accumulation, scrap should be stored in tightly covered metal containers, and grindings should be kept under several inches of water until disposed of. The disposal of grindings should occur daily in the manner recommended under Grinding.

Fire Precautions. Ordinarily, the fire hazard in machining magnesium is slight and, with sound knowledge of the correct machining practice, ignition of the shavings may be easily avoided. In order to ignite magnesium, it is first necessary for the metal to reach the melting point. Partial melting begins, depending on the alloy, at temperatures between 800 and 1200 F. In roughing operations, it is very difficult to attain such temperatures, for the high heat conductivity of magnesium rapidly dissipates any frictional heat generated.

In finishing operations, however, where light shavings are necessarily produced, temperatures sufficiently high for ignition may be reached under certain circumstances. Factors that will tend to produce such temperatures in the chips or shavings include very fine feeds or cuts, dull or chipped tools, tools with small relief angles and small chip space, and high cutting speeds in the absence of coolants.

A combination of two or three of the above factors may lead to the ignition of the shavings. Sharp tools with ample clearance will greatly reduce the fire risk. Coarser feeds, deeper cuts and lower speeds will act in the same direction; but where fine feeds and cuts and highest speeds are essential to quality and economy, a liquid coolant should be used.

In turning, ignition may occur if the cutting is interrupted and if the feed is stopped while the work still revolves. In these instances, the tool should be backed away from the work. In machining magnesium parts with an insert of ferrous metal, sparking sometimes occurs when the tool strikes the insert. In such instances, the use of a cutting oil has often been found advisable.

Under no circumstances should water or any other type of standard fire extinguisher (such as the pressure or liquid type) be used for extinguishing a magnesium fire, because such extinguishers will make the fire more violent instead of smothering it. An effective way to extinguish a magnesium fire is to cover the burning chips with dry graphite powder, dry cast-iron turnings or graphite-base proprietary compounds. It is suggested that a container full of one of the recommended extinguishers be placed at each machine and that the operator be trained in the application of the extinguisher. The smothering material should be applied gently to avoid scattering the fire.

In its initial stage, the fire should be localized by scraping away adjacent turnings. The accumulation of magnesium chips or turnings, on, under or around the machine, should be avoided. The danger of the spread of fire will be minimized if the quantity of chips near the machine is small. Avoiding the possibility of any accumulation of magnesium dust on the body or clothing of the operator is of particular importance. The chips should be removed from the machine at regular and frequent intervals and should be stored in tightly covered metal cans until reclaimed. Special fire precautions are discussed under Grinding.

Precautions During Machining. (1) Do not allow chips or dust to accumulate on the machine or clothing. (2) Store chips in covered metal cans. (3) Place a container of extinguisher at each machine. (4) Keep cutting tools sharp; use tools with proper relief angles. (5) Take heavy cuts. Back tool away from revolving work when not cutting. (6) Use a coolant when machining magnesium cast-

ings that have ferrous inserts, or when taking light cuts at high speeds. (7) Avoid generation of sparks; avoid smoking. (8) Grind with oil coolant or water or with dust-exhausting equipment that precipitates the grindings in water. (9) When grinding, wear a smooth and easily removable apron. (10) Do not grind steel or other metal on wheels used for grinding magnesium. (11) Store grindings under several inches of water and dispose of them as recommended.

Directions for Extinguishing Fires. Localize fire and scrape away adjacent turnings. Cover the ignited turnings with one of the following materials: cast-iron turnings, graphite, graphite-base proprietary compounds. DO NOT use water or any standard fire extinguisher.

The Surface Protection and Finishing of Magnesium Alloys

By W. S. Loose*

THIS ARTICLE describes the cleaning and finishing of magnesium alloys. Both mechanical and chemical methods for cleaning are discussed. Finishing processes include the chemical and electrochemical treatments that are in current use for providing surface protection for magnesium alloys. A brief discussion of painting is included also.

Cleaning

Mechanical Cleaning and Surface Conditioning. *Sandblasting.* Sandblasting is normally used as a cleanup method on sand castings and permanent mold castings. Shot or grit blasting is employed to a limited extent. For sandblasting, silica sand that has a No. 35 AFA rating is often employed with 70 to 90-lb air pressure. AFA No. 70 steel shot (approximately 0.07 in. in diam) has been used with 90-lb air pressure for shot blasting. For grit blasting, SAE No. 35 steel grit has been used with approximately 90-lb air pressure. Other blasting mediums —corncob grit, rice hulls and the like—have been used to a limited extent, mainly for surface appearance or for removing oxides and surface contaminants without affecting the surface dimensions appreciably.

Scratch Brushing. Scratch brushing has been used widely for removing mill scale from sheet or for improving the appearance of the surface. For removal of mill scale, steel wires approximately 0.010 in. in diam are preferred, but for surface appearance a finer wire, 0.003 to 0.005 in. in diam, is normally employed. Wheels 6 to 10 in. in diam with bristles 2 to 4 in. long are operated at approximately 1700 rpm. Long bristles are normally employed, because short bristles may pit the surface.

Grinding. Grinding is employed widely as a method of cleaning castings or wrought products and as a final finish. Built-up cloth wheels prepared with 100 to 200-grit abrasive and operated at peripheral speeds of 4000 to 6000 surface ft per min, are usually employed, but tend to become loaded with metallic particles. The most satisfactory grinding is accomplished with abrasive cloths containing 50 to 320-mesh abrasive, operated as either belt or rotating-disk sanders. The drum type of sanders that have sponge rubber backing for the abrasive cloth, may be used, but belt sanders are more satisfactory if they have sufficient length and cooling area to keep the abrasive cold so that loading of the abrasive is virtually prevented. These belt sanders operate at approximately 4000 to 6000 surface ft per min.

The grinding and polishing of magnesium produce highly flammable dust which, in the proper proportions with air, may ignite with explosive violence. It is essential, therefore, that this dust be removed immediately from the working area to prevent the formation of explosive mixtures. This can be accomplished effectively with a dust-collection system of the proper design. A system considered safe for the collection of magnesium dust from grinding and polishing, is one in which the dust is precipitated by a heavy spray of water or mineral oil of low viscosity, to form a sludge with a great excess of fluid. The equipment should be designed to prevent the accumulation of dust or sludge in any location where it could dry out to flammable composition. The collecting systems should be inspected periodically to ensure against such conditions. The best collectors for grinding stands are small units that serve one or two stands where the power supply for the grinder, water circulation, and air blower is interconnected so that the grinders cannot operate without having the collector in operation. The grinders are connected to the collector by short, straight ducts.

A central system that serves a large number of grinding hoods or stands can be operated safely if the dust is precipitated by heavy sprays at each booth or stand. The dust should be conveyed, by a flowing stream of water or oil, to a central settling tank from which it is removed. Such a system is safe if dust or sludge does not accumulate in the ducts. The power for the grinders, air blowers, and circulation of liquid, should be interconnected, as in the smaller unit systems.

Sludge pits should be ventilated adequately to prevent the accumulation of hydrogen gas. The sludge, which collects under the liquid in the pit, should be removed frequently. For disposal this sludge should be mixed with five parts of sand and buried or spread in thin layers on noncombustible surfaces. After draining, the mixture should be burned. The same principle of dust collection can be applied to grinding and polishing booths where the work is done on a grating. In the hood the air flows past the work material, through the grating and through a liquid spray that removes the dust. The hoods or booths should be designed to catch as much of the dust as possible, keeping it off the floor and workmen's clothes.

Central collecting systems in which the dust is passed through long, dry or partly dry ducts, and the conventional dry type of filter collectors are dangerous and emphatically not recommended for the collection of magnesium dust. Records of accidents in systems of these two types have proved them to be very hazardous.

Polishing. A finer surface finish may be obtained by the use of greases on the abrasive cloth or wheels. The greases act as lubricants and aid in preventing the wheel from becoming loaded with metallic particles. Before buffing, final polishing is normally accomplished with a greaseless polishing compound applied to sewed or string buffing wheels operated at peripheral speeds of 4000 to 6500 ft per min. Loose muslin buffs or loosely sewed muslin buffs are normally employed. For many products, greaseless polishing compounds are sufficiently abrasive to be used alone before the buffing operation.

Buffing. For the buffing of parts that require a high luster, tripoli composition is used on loosely sewed buffs. Hard sewed buffs may cause dragging. Best results are obtained by the use of approximately 74 to 82-count cloth wheels operating at a peripheral speed of 6000 to 8000 ft per min. Usually 10 to 14-in. buffs are employed. The tripoli should be free-cutting to avoid the need for high pressures, which may cause waviness and dragging. Coloring operations are performed through the use of dry lime compositions on 12 to 16-in. Canton flannel buffs operated at peripheral speeds of 8000 to 12,000 ft per min. Light pressures are sufficient.

Chemical Cleaning. *Alkaline Cleaning.* A satisfactory method of degreasing magnesium is alkaline cleaning, which removes not only oily matter but also previously applied chemical treatments. Proprietary cleaners of the strongly alkaline type, such as those commonly used on

* The Dow Chemical Company, Midland, Mich.
Prepared for the Magnesium Committee

steel, are the most desirable for magnesium. The milder type of aluminum cleaners are satisfactory in some instances but should be tested before using. An alkaline cleaning solution should have a pH value greater than 11 for best results. Alkaline cleaners containing pyrophosphate may be employed with a bath of high pH.

A satisfactory bath that can be used as a soak cleaner or as an electrolytic cleaner, can be prepared according to the following formula:

Trisodium phosphate ($Na_3PO_4.12H_2O$)	4 oz
Sodium carbonate ($Na_2CO_3.10H_2O$)	4 oz
Soap	0.1 oz
Water	to make 1 gal

After alkaline cleaning, rinsing must be very thorough to avoid contamination of subsequent chemical baths.

Acid Pickling. Cleaning by pickling is an important step in the fabrication and surface finishing of magnesium alloys either as an intermediate treatment or as a final operation before application of protective coatings. Oxide layers, drawing compounds, mill scale and foreign metallic impurities that cannot be removed by common solvent and alkaline cleaning, may be removed readily in various acid solutions; no single acid pickle can remove every type of surface contamination satisfactorily. Pickling is sometimes used for producing decorative effects but applications are limited.

Sulfuric Acid Pickle. After blasting operations in foundry casting cleanup, general oxide coatings and surface impurities such as iron and silica, may be removed from castings by treatment in a solution of 3 to 5% sulfuric acid. The solution is operated at room temperature and the duration of pickling varies from 10 to 30 sec. The parts are rinsed in cold running water and are then dipped in not water to facilitate drying. Satisfactory containers for this solution are earthenware crocks, rubber-lined tanks or lead-lined tanks.

Chromic Acid Pickle. An aqueous solution containing 15 to 20% chromium trioxide is used extensively in the surface cleaning of magnesium. The solution may be operated at room temperature, but is most effective when used at or near the boiling point. Chromic acid does not attack magnesium seriously, but readily removes oxide and hydroxide coatings. Consequently, chromic acid is employed to remove oxides as well as various chemical coatings before retreatment. Chromic acid is also satisfactory for removing the standard graphite-base lubricants from drawings and forgings. The usual duration of treatment is 2 to 15 min, depending on the temperature and freshness of the bath, and the type of material to be removed. After the chromic acid treatment, the work material is rinsed in cold running water and then dipped in hot water if drying is required.

Hydrofluoric Acid. Magnesium is not attacked appreciably by this acid. A solution containing 10 to 15% hydrofluoric acid removes surface impurities—silica, iron and the like—without causing a dimensional change. In the past this pickling treatment has been used primarily for processing finished machined parts as a pretreatment before chemical treatment and painting, in certain standard procedures for chemical treatment. The hydrofluoric acid bath is operated at room temperature and the duration of treatment is usually 5 min. Subsequently the work material is thoroughly rinsed in cold water and, if further processing is not immediately anticipated, the material is given a final dip in hot water. Steel tanks, lead-lined or rubber-lined, and also magnesium tanks are satisfactory for holding this solution.

Nitric-Sulfuric Acid Pickle. In certain instances a solution that contains 8% nitric acid plus 2% sulfuric acid, is used instead of the 3 to 5% sulfuric acid solution, for pickling alloys of higher aluminum content. This solution of mixed acids reduces the tendency for smut to form on the surface during pickling and usually produces a clean surface from matte to bright. The pickling procedure is similar to that for sulfuric acid pickling. Satisfactory containers for the nitric-sulfuric acid pickle are made of crockery, glass, ceramic, or steel lined with synthetic rubber.

Acetic Acid Pickle. Acetic acid is used primarily for the removal of mill scale from sheet after hot rolling. The scale is removed very effectively and the loss of metal is lower than when inorganic acids are employed. An aqueous solution that contains 15 to 20% glacial acetic acid, is used at room temperature. The pickling time is 30 sec to 1 min or longer. Dilute acetic acid (0.1 to 0.25%) is sometimes used for producing a decorative light gray to white hydroxide coating on magnesium. Since this coating has very little protective value, wax or clear lacquer is ordinarily applied subsequently. Pickling in acetic acid is followed by rinsing in cold running water and then dipping in hot water to facilitate drying. Containers for these solutions may be of crockery, glass, pure aluminum, or steel lined with synthetic rubber.

Vapor Degreasing. Vapor degreasing may be accomplished in either trichlorethylene or perchlorethylene solvents. These materials do not attack magnesium while they are dry, but contamination with water may cause corrosion. Commercially inhibited solvents of this type will prevent attack on magnesium.

Emulsion cleaners have been widely used, consisting of a low-cost mineral distillate and an emulsifying agent. Ordinarily the bath may be operated at room temperature, but penetration is more rapid if the solution is between 140 and 160 F. Three to five minutes is usually sufficient to permit penetration of the solvent; then the work material is rinsed in hot water or sprayed with it.

Finishing

Although magnesium and magnesium alloys show good resistance to corrosion in most atmospheres, the protective film that is formed does not remain metallic in appearance, but changes gradually to dark gray. The resistance of magnesium to tarnish can be improved greatly by building up supplementary coatings on the surface with either chemical or electrochemical treatment and in either acid or alkaline solutions.

The acid baths used in chemical treatment are normally solutions that contain a dichromate with or without additions of sulfates, phosphates, fluorides or nitrates. The films that are formed are usually amorphous mixtures composed largely of hydrated chromium and magnesium oxides. When alloying elements, such as aluminum, zinc or manganese, are present in the alloy that is being treated, they are also found in the film that is formed; when sulfates, phosphates, fluorides or nitrates are added to the chromate solution, they too are found in the coating. In strongly alkaline solutions, the film that is formed is normally $Mg(OH)_2$, although it may contain traces of other agents that were added to the bath.

Chemical Treatments. *Bright Pickle.* Although magnesium is bright after pickling in an aqueous solution of any one of many acids or a mixture of acids (such as 10% HNO_3 or a mixture of 8% HNO_3 plus 2% H_2SO_4) the film that is formed does not resist tarnish. An acid bath that produces good resistance to tarnish in all commercial magnesium alloys is composed of 18% chromic acid, 4% calcium nitrate and 0.25% magnesium fluoride. After normal degreasing operations, the work metal is immersed for ½ to 5 min in this solution maintained at 20 to 30 C. The duration of the treatment depends on the surface condition of the metal. The bath should be agitated for cooling and stirring. When the parts have been removed from this solution, they should be rinsed quickly in ■ bath containing 5% sodium metasilicate or sodium carbonate. Iridescent coatings may form if parts are not quickly rinsed in this alkaline solution or if they are rinsed in water, if the temperature of the solution is allowed to rise, or if thorough agitation is neglected. When die castings of AZ91 or similar alloys are to be processed, they should first be pickled in a strong phosphoric acid solution (about 75%) for 30 to 60 sec to remove the nonhomogeneous layer normally found on the surface.

This bright-pickle treatment provides a thin, clear film that is quite resistant to atmospheric change. The resistance to interior atmospheres varies with alloy content; pure magnesium or M1 alloy will maintain a bright surface for at least a year after receiving this treatment; without the treatment a gray coating will form in a few weeks.

This bright-pickle coating is also resistant when applied to commercial alloys that contain aluminum and zinc, but the coating will tarnish more rapidly than when applied to the M1 alloy. During exterior exposure exactly opposite effects are produced; the alloys that contain aluminum are more resistant than M1 alloy. Parts given this treatment may be handled extensively without tarnishing. Clear or pigmented organic coatings may be applied.

Chrome Pickle (Type I). Of all chemical treatments for magnesium, the chrome-pickle treatment is the most widely used. It is applied by dipping the work material for ½ to 2 min in a bath consisting of 180 g per liter $Na_2Cr_2O_7 \cdot 2H_2O$ and 187 ml per liter concentrated HNO_3. This bath is maintained at room temperature. Parts are held in the air for 5 sec after removal from the bath, before being rinsed in cold and hot water. This treatment is described extensively in technical publications.

Sealed Chrome Pickle (Type II). This treatment consists of two steps; that is, the chrome-pickle finish described above is subsequently sealed when the metal is held for 30 min in a boiling solution that contains 100 to 150 ■ per liter $Na_2Cr_2O_7 \cdot 2H_2O$.

Dichromate (Type III). Of all the chemical treatments, this one affords the best resistance to corrosion and the best adhesion of paint. This treatment also is applied in two steps, as follows:

Step 1. Dip parts for 5 min in a cold aqueous solution containing 15 to 20% by wt of hydrofluoric acid. Rinse in cold water.

Step 2. Boil parts 30 min in an aqueous solution containing 100 to 150 ■ per liter $Na_2Cr_2O_7.2H_2O$, saturated with either MgF_2 or CaF_2. Rinse and dry.

All three of these treatments may be applied to any of the commercial alloys, although the dichromate treatment does not produce a dark coating on M1 alloy. Exposures of alloys at Kure Beach, North Carolina, have shown that the coatings produced by these treatments maintain surface appearance somewhat better than bare magnesium. However, after 2 years of exposure at a station located 800 ft from the ocean, no effect of the chemical treatment on the losses in mechanical properties can be determined. In aqueous chloride solutions, the dichromate treatment produces considerably superior resistance to corrosion whether the metal is painted or unpainted. When properly applied, all three coatings are excellent bases for paint. The dichromate treatment is generally superior, since it is less subject to variations. The chrome-pickle treatment, when applied from a freshly made solution, is equal to the dichromate treatment as a base for paint; but in normal operations where the solution must be revivified to maintain its coating ability, the adhesion of paint decreases as the age of the solution increases.

Electrochemical Treatments. *Acid Anodizing.* Protective coatings may be applied to magnesium electrochemically, by making it the anode in certain acid or alkaline solutions. All acid solutions employed in commercial treatments involve the use of dichromates with additions of sulfates, fluorides or phosphates. The baths are similar to those used normally for direct chemical treatment. The main advantages gained by the application of current are that the duration of the treatment is greatly reduced and that lower temperatures are required. The main disadvantages are that the throwing power of these baths is often insufficient to coat complicated parts completely and that such baths are often more expensive because of the labor involved. A typical acid anodic treatment is commonly known as the "galvanic anodize" (Type IV). This again is a two-step treatment, as follows:

Step 1. Dip parts for 5 min in an aqueous solution containing 15 to 20% by wt of hydrofluoric acid maintained at room temperature.

Step 2. Anodize the magnesium at 10 amp per sq ft for 10 min in a bath operated at 50 to 60 C and consisting of 30 g per liter $Na_2Cr_2O_7.2H_2O$, 30 g per liter $(NH_4)_2SO_4$ and 2.5 ml per liter NH_4OH (sp gr = 0.88).

The magnesium is connected electrically to the steel tank that contains the solution to generate the current. The resistance to corrosion and value as a paint base are similar to those developed in the dichromate treatment (Type III).

Caustic Anodizing. Some coatings that are produced by anodic oxidation in strongly alkaline solutions, are more resistant to corrosion in aqueous solutions than are coatings formed either chemically or electrochemically in chromate baths. A typical anodizing solution contains 25% NaOH, 7% diethylene glycol and 0.2% sodium oxalate. Several variations of this type composition have been proposed but all produce coatings that are essentially $Mg(OH)_2$ formed in a hard, compact manner.

The anodic oxidation is performed by applying either direct or alternating current to the magnesium for 15 to 25 min at a current density of 10 to 25 amp per sq ft in a bath operated at 75 to 80 C.

The coating formed is normally of a neutral light gray shade. The method of preparing the surface of the magnesium parts before they are anodized, is important in the production of attractive coatings. Surfaces that are buffed or bright-acid-pickled develop a relatively clear coating. Die castings that contain a nonhomogeneous phase on the surface are more difficult to coat than wrought or cast materials; the pickling of die castings in a strong phosphoric acid solution will produce a bright and more homogeneous surface to which the coating can be applied more evenly. The coating process is applicable to all commercial magnesium alloys.

This anodic coating is more resistant to corrosion in aqueous mediums than are coatings formed in chromates, and it shows good resistance to atmospheric change. Maximum resistance may be obtained by waxing or painting the anodized surface. The coating is relatively porous and can be dyed subsequently in organic baths. The coated article is immersed in the dye bath for 5 to 30 min at 90 to 100 C. Concentration of dye and duration of treatment will affect the shade of color obtained and must be closely controlled. A typical dye bath for obtaining ■ red coating contains 0.4% neolin Bordeaux, 0.7% boric acid and 1% sodium chromate. The pH of the dye bath must be maintained at 6 to 8 by the addition of boric acid.

Because of the alkaline nature of the film formed, the coating produced by this electrochemical treatment is not receptive to paint. Modifying treatments, which are essentially controlled neutralizers, provide a surface to which paint adheres well. After being anodized and rinsed in water, the parts are immersed for 15 min at room temperature in an aqueous solution containing 0.5% sodium fluosilicate and 0.1% sodium dichromate. The coating as applied has fair resistance to abrasion; for maximum resistance to abrasion or wear, the parts should be waxed. The abrasion resistance increases with alloy content of the metal; M1 alloy gives the softest coatings.

Electroplating. No commercially acceptable electroplating process has been developed for magnesium, but results of recent research indicate that satisfactory methods will be available shortly for applying various metallic deposits to magnesium.

Painting. In general, the painting of magnesium follows the rather well-established procedure for other metals. As in all metal finishing, the preparation of the surface is important. This includes proper choice of chemical treatment and adequate cleaning before painting. Where suitable chemical treatments cannot be employed, the surface must be finished freshly by mechanical means and cleaned with solvent just before painting.

The chemical treatments discussed previously ensure a satisfactory surface, which should be painted immediately after treatment when practicable. If this cannot be done, the surface usually becomes contaminated and a final cleanup is necessary before painting. Vapor degreasing has proved satisfactory in commercial practice. An alternative method employs a solvent wipe or wash. The solvent chosen should be similar to that used as a diluent for the finish to be applied. Hot alkaline cleaners are not recommended, since they impair the chemical coating.

The finishing schedule can employ either air-dry or baked materials; the selection of paint coatings for magnesium depends on the intended service.

For interior use, organic finishes are chosen ordinarily, because of their decorative value. These finishes may be high-gloss japan or enamel or may consist of the popular novelty finishes—wrinkle, crackle, crystal and the like. Both air-dry and baked finishes may be used. Systems can be employed that comprise one or two coats, depending

Table I. Finishing Schedules for Magnesium Alloys

Service Conditions	Mechanical Finish	Chemical Treatment	Organic Finish: Primer	Organic Finish: Finish
Interior	Buffed	None	None	1 to 3 coats of special clear coatings
	None	Chrome-pickle	One coat of baked	1 or more coats of air-dry, baked or novelty finish
	None	Chrome-pickle	One coat of air-dry	1 or more coats of air-dry enamel or novelty finish
	None	Chrome-pickle	None	1 or more coats of baked japan or novelty finish
	Aloxiting	None	One coat of special baked	1 or more coats of baked japan or novelty finish
	Aloxiting	None	One coat of special air-dry	1 or more coats of compatible enamel or novelty finish
Ordinary exterior	None	Chrome-pickle	One coat of baked	2 or more coats of air-dry or baked enamel, or lacquer
	None	Chrome-pickle	One coat of air-dry	2 or more coats of air-dry enamel or lacquer
	Aloxiting	None	One coat of special baked	2 or more coats of baked enamel
	Aloxiting	None	One coat of special air-dry	2 or more coats of air-dry enamel or lacquer
Severe	None	Hydrofluoric acid-dichromate	Two coats of baked inhibitive	2 or more coats of baked enamel
	None	Sealed chrome-pickle	Two coats of air-dry inhibitive (P-27)	2 coats of air-dry enamel, aluminized lacquer or spar varnish

on such variables as surface treatment, choice of finishing materials, and conditions of service.

Ordinary exterior use of magnesium usually requires a protective finishing system. Decorative considerations are secondary; in fact, the usual decorative finishes are not intended for exterior exposure. Normally, three-coat systems should be used, and the finishing system should be chosen for ability to withstand the conditions to be encountered in the intended service.

Severe exterior exposure will include aircraft applications, marine exposure and similar applications. For this type of service, two coats of inhibitive primers, such as AN-TT-P-656b, are recommended; these should be followed by two finish coats, which should possess maximum impermeability and be no less than 0.002 in. thick.

Baking schedules that employ either convection or infrared heat are widely used. The heating schedule recommended by the manufacturer should be followed. Baking greatly decreases the drying time and improves the adhesion and the resistance to abrasion.

Air-dry primers are usually applied over a chemically treated surface. However, primers have been developed that give satisfactory performance when applied to bare metal. Finish coats must be compatible with primers to ensure satisfaction.

Clear lacquers may be applied over either freshly polished or bright-pickled magnesium. The protection thus afforded varies widely, depending on the formulation of the clear lacquer, the method of finishing mechanically or chemically, and the mediums to which the magnesium is exposed. Special formulations must be employed to give good adhesion and protection.

Details of baking time, temperature and materials are not included because such information is best furnished by the manufacturer. Table I is a summary of the finishing schedules normally recommended.

Corrosion of Magnesium

By W. S. Loose*

THIS article describes the corrosion of magnesium in various atmospheres, aqueous mediums, nonaqueous mediums, and soils. Galvanic corrosion and corrosion at high temperatures are also discussed. The stress corrosion of magnesium is discussed in the article on page 228 of this Handbook. Protective coatings are described on page 991.

Atmospheric Corrosion. *Exposure.* Magnesium shows inherently different rates of tarnishing, depending on the alloy content, the alloying elements present, indoor or outdoor location, and humidity. During interior exposure M1 alloy (1% Mn) is more resistant than the alloys that contain aluminum, but during exterior exposure the reverse is true. The alloys containing aluminum show a decreased tendency to tarnish during exterior exposure as the aluminum content increases to about 9%. With higher aluminum content, the films formed are much thinner and have a metallic appearance after long periods of exposure to rural atmosphere or to an interior atmosphere. Zinc, especially if more than 5% is present, greatly increases the rate of tarnishing. Small amounts of silver also increase this rate. The increase in resistance to tarnishing with increase in aluminum content correlates with electron diffraction observations that a different type of hydroxide film is formed in which the distance between the molecular magnesium hydroxide sheets has been increased to accommodate amorphous hydrated aluminum oxide.

Humidity plays a major role in the corrosion or tarnishing of magnesium alloys. At 9.5% humidity neither magnesium nor magnesium alloys showed tarnish after 18 months. At 30% humidity a small amount of an amorphous phase and slight tarnish were seen. At 80% humidity, crystalline magnesium with 30% of an amorphous phase was seen, but the surface showed tarnish. Only at 93% relative humidity was crystalline magnesium hydroxide formed.

Atmospheric Pollution. At Midland, Mich., the atmosphere is industrial and contains varying but detectable amounts of chlorine, bromine, caustic soda, hydrochloric acid and magnesium chloride, as well as other inorganic and organic compounds. The slow rate of corrosion on outdoor test racks indicates that these substances do not cause rapid breakdown of the protective film on magnesium. Extensive atmospheric tests on machined test bars were started in 1933 to determine how the cast and wrought alloys of uncontrolled purity that were then commercial, compared with various aluminum-base alloys as well as with certain ferrous materials. With the advent of magnesium alloys of controlled purity, bars of these alloys too were added. The results from sheet alloys are shown in Fig. 1.

The tensile strength of the uncontrolled-purity alloys (commercial, 1933) shows a straight-line loss of approximately 1000 psi per year. The controlled-purity alloys (commercial, 1940) have been under test only four years but they show a somewhat lower rate of corrosion. Longer exposures will be required to show the exact effect of exposure time. The corrosion losses shown are considerably higher than they would have been had panels rather than test bars been exposed, for edge corrosion reduces the strength of the bars abnormally, and especially the elongation.

As shown by Fig. 2, the loss in strength on the machined round test bars of extrusion and casting alloys was only about 500 psi per year. Alloys with controlled purity and those with uncontrolled purity have shown the same rate of loss after four years.

These data, when considered in relation to the results

* The Dow Chemical Company, Midland, Mich.
Prepared for the Magnesium Committee

obtained for aluminum and steel, indicate that magnesium compares favorably with aluminum alloys and is superior to low-carbon steel in this industrial atmosphere.

Marine Exposure. At an extensive marine corrosion station located at Kure Beach, N. C., many thousands of panels of magnesium and other nonferrous as well as ferrous metals are being exposed. Besides immersion racks, stations are being operated 80 ft and 800 ft from the ocean.

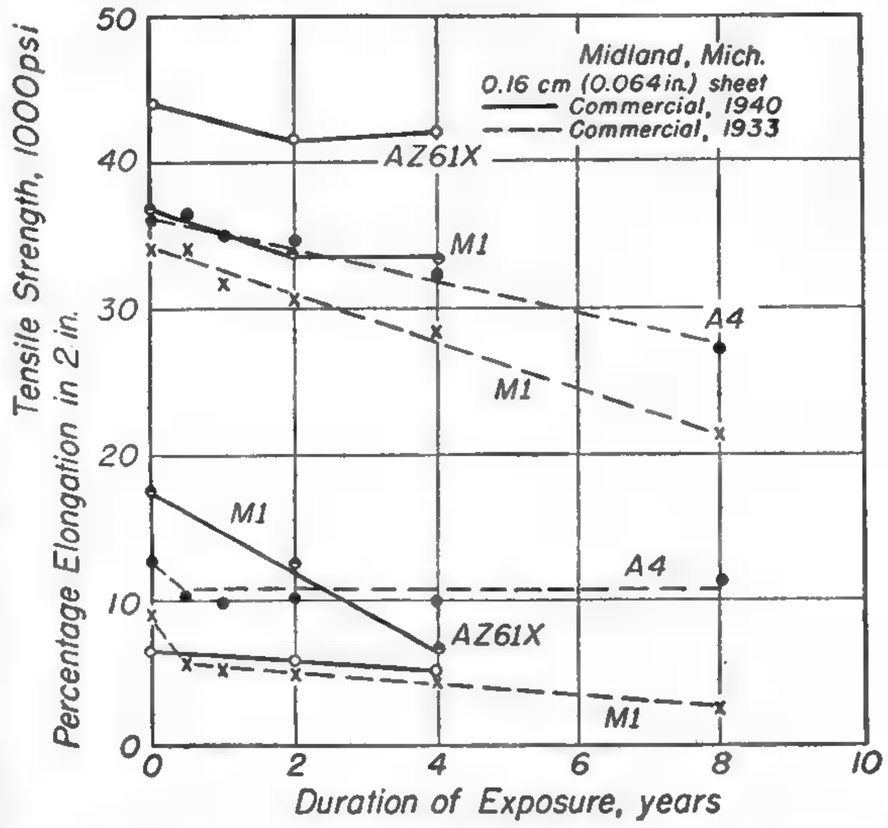

Fig. 1 Decrease of tensile properties during corrosion of sheet-alloy test bars exposed to industrial (Midland) atmosphere

Specimen size. **1933, 1.2 cm (0.5 in.) reduced section test bars, 0.16 cm (0.062 in.) thick. 1940, 0.16 cm (0.062 in.) by 2.5 cm (1 in.) by 17.5 cm (7 in.) sheets.**

Surface preparation. **Commercial 1933, as-rolled. Commercial 1940, chrome-pickled**

Temperature. **Winter, 6 C (21 F); summer, 22 C (71 F)**

The effect of the severe 80-ft marine exposure on the corrosion of sheet alloys that have controlled purity and those that have uncontrolled purity is shown in Fig. 3. The uncontrolled-purity A4 alloy (4% Al) was completely corroded away in one year, but the A6X alloy, similar but with controlled purity, (6% Al, high purity) had suffered little loss in tensile strength after four years. The lesser susceptibility of alloy AZ31X (3% Al, 1% Zn, high purity) to notches, and the fact that this alloy is least sensitive in the annealed state are conditions believed to account for the loss in elongation being significantly lower than that of the other controlled-purity alloys.

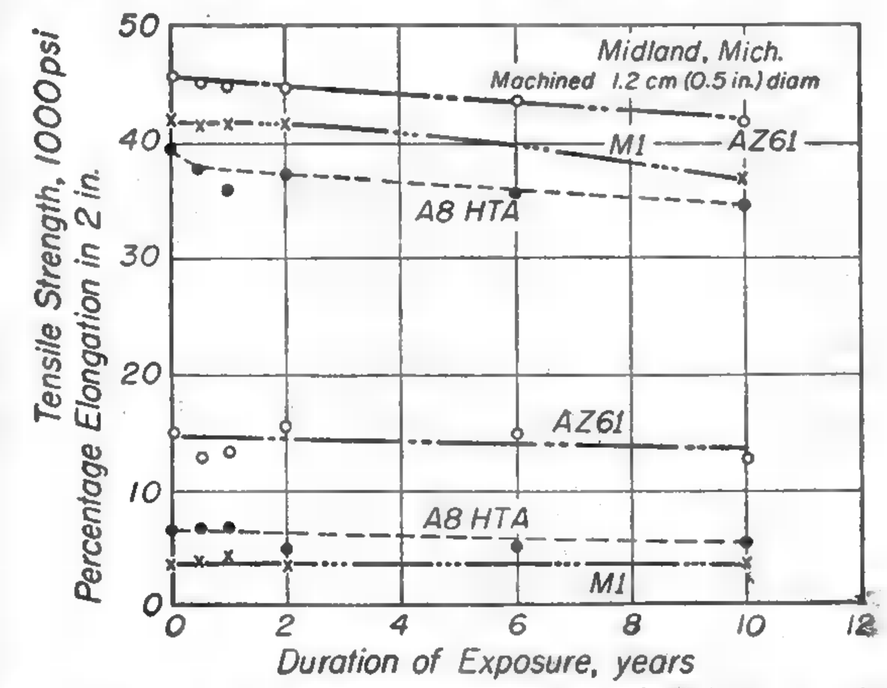

Fig. 2 Decrease of tensile properties during corrosion of extruded and cast magnesium alloy test bars in industrial (Midland) atmosphere.

Temperature. **Winter, 6 C (21 F); summer, 22 C (71 F)**

Similar data have been obtained at this location, for aluminum-base alloy 24 S-T and sheet panels of mild steel, as well as for machined test bars. As at the industrial location, the mechanical-property losses of magnesium and aluminum were similar; however, the steel suffered severe attack in a few months.*

The losses in mechanical properties sustained by round extruded and cast magnesium test bars—some with controlled, others with uncontrolled purity—at this 80-ft station are shown by Fig. 4. Controlled-purity extruded and cast alloys showed no significant loss after four years. Uncontrolled-purity extruded and cast alloys showed considerably higher losses than controlled-purity alloys, but did not exhibit such a severe decrease in mechanical properties as the sheet alloys shown in Fig. 3.

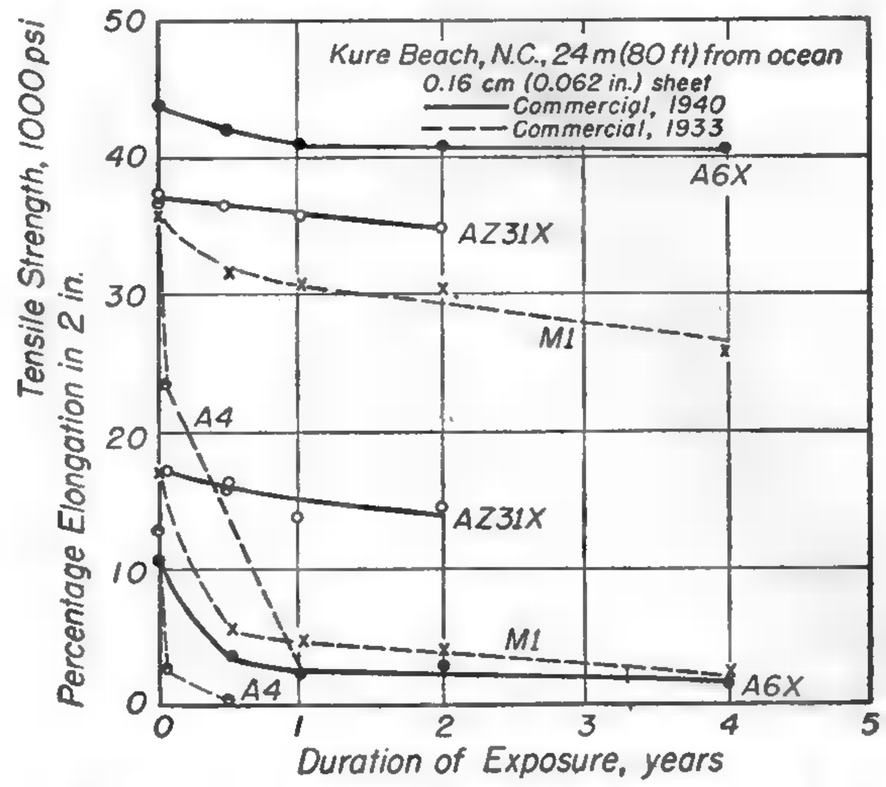

Fig. 3 Effect of controlling purity on the decrease in tensile properties of sheet exposed to corrosion under marine conditions.

Specimen size. **1933, 1.2 cm (0.5 in.) tensile test bars, 0.16 cm (0.062 in.) thick. 1940, 0.16 cm (0.062 in.) by 2.5 cm (1 in.) by 17.5 cm (7 in.) sheets**

Surface preparation. **A4, as-rolled A6X, AZ31X and M1, acetic pickle plus chrome pickle**

Controlled-purity cast alloys show no effect of heat treatment at the marine location. Uncontrolled-purity cast alloys, in the heat treated state, show a somewhat greater loss than as-cast or aged alloys at the coastal site; but after both types of alloy had been exposed ten years at Midland, no effect of heat treatment could be observed.

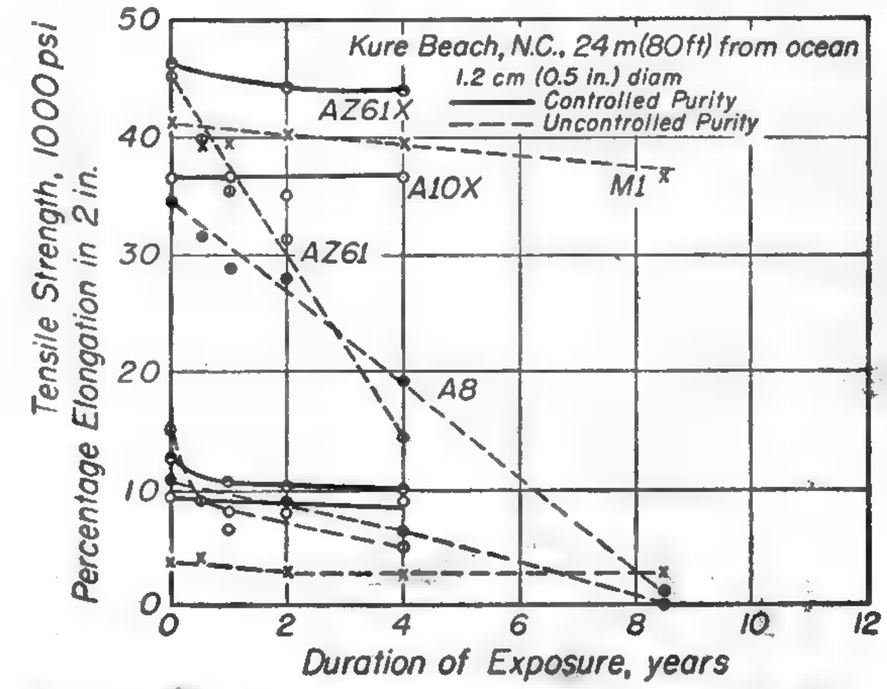

Fig. 4 Effect of controlling purity on the decrease in tensile properties of magnesium alloy test bars exposed to corrosion under marine conditions.

Surface preparation. **A8 pickled in acid. All others machined.**

At the more recently installed 800-ft station, data concerning mechanical properties have been obtained over a two-year period only. With cast alloys A10 (10% Al), AZ92 (9% Al, 2% Zn) or AZ63 (6% Al, 3% Zn) no effect of purity has been noted.

* The copper content of this steel is unknown. It is well known that 0.05% Cu additions will improve considerably the stability of steel in coastal atmospheres.

Aqueous Mediums. Certain fundamental factors control the corrosion of magnesium in aqueous mediums. Tests on controlled-purity magnesium or magnesium alloys indicate that dissolved oxygen does not play a major role in the corrosion process in solutions containing salt. Carbon dioxide, however, probably because of the acidic tendency, increases the rate of corrosion.

The effect of temperature depends largely on the purity of the metal. With increases from room temperature to the boiling point, the corrosion rate of controlled-purity magnesium and magnesium alloys in 3% sodium chloride solution, approximately doubled. However, when cathodic impurities such as iron and nickel are present in amounts greater than the tolerance limit, the rate of corrosion, and especially the tendency to pit severely, increases rapidly with temperature. In tap water containing approximately 70 parts chloride per million, the rate of corrosion is low but tends to increase just lower than the boiling point, as shown in Fig. 5. Because of localized impurities, M1 alloy shows a greater tendency toward severe pitting with increasing temperature than do the alloys of controlled purity.

The corrosion of magnesium is strongly influenced by the hydrogen ion concentration (pH). Magnesium is resistant to alkalies but is ordinarily attacked by acids. With increasing pH above the point at which magnesium hydroxide is formed (pH 10.2), the effect of cathodic impurities in the metal, and salts in the mediums, is overshadowed by the greater tendency for formation of film.

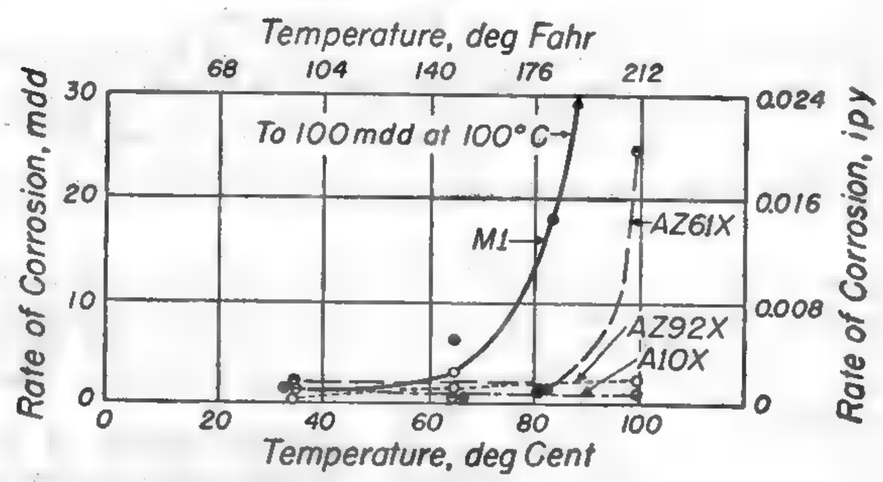

Fig. 5 Corrosion of magnesium alloys in tap water.
Specimen size, 5 cm (2 in.) by 2.3 cm (0.9 in.) by 1 cm (0.4 in.); surface preparation, Aloxite ground; aeration, natural convection; volume of testing solution, 200 ml; velocity, natural convection; duration of test, 14 days; test, continuous immersion.

Salts. Table I shows the effect of representative oxidizing and nonoxidizing salt solutions on the corrosion of a commercial magnesium alloy of controlled purity. Chloride solutions are normally more corrosive, since the only formation of film on the magnesium is of a porous magnesium hydroxide type. Neutral or alkaline fluorides form insoluble magnesium fluoride and are not appreciably corrosive. Ammonium salts usually show more attack than salts of alkali metals. Oxidizing salts, especially some containing chlorine or sulfur atoms, are more corrosive than nonoxidizing salts; but chromates, vanadates, phosphates and many others form a film and tend to retard corrosion, except at elevated temperatures.

Acids. Magnesium is attacked rapidly by all mineral acids except hydrofluoric and chromic acids. Hydrofluoric acid, because of the formation of an insoluble magnesium fluoride film, does not attack magnesium to an appreciable extent; but at low concentrations of acid, pitting develops. With increasing temperature, the rate of attack at the waterline increases, but below the surface the increase in rate of attack is negligible. Magnesium has been used commercially for float-control units, tanks, and piping for closed units handling concentrated hydrofluoric acid.

Chromic acid, when pure, attacks magnesium and magnesium alloys at a very low rate, but traces of chloride or sulfate ions increase this rate. A boiling solution of 20% chromic acid is widely used to remove products of corrosion from magnesium alloys.

Most organic acids attack magnesium and magnesium alloys. The stronger acids, such as acetic and tartaric, are often used at about 10% concentration to pickle cast and wrought products.

Alkalies. Magnesium is resistant to dilute alkalies at temperatures as high as the boiling point, and is resistant to 50% caustic liquors as high as about 60 C; but at higher temperatures the corrosion rate increases rapidly.

Aqueous Solutions of Organic Compounds. In aqueous solutions of organic compounds, magnesium is normally resistant. With the exception of methanol, alcohols attack magnesium at a slow or moderate rate. In acid organics, such as fruit or tomato juices, a slow but definite attack occurs. Milk will cause attack, particularly while souring.

At room temperature, ethylene glycol solutions produce negligible corrosion on magnesium used alone or connected galvanically with steel; but at elevated temperatures, such as 115 C, the normal rate increases to some extent and galvanic corrosion will occur unless inhibitors, like those used for aircraft engines, are added.

The M1 alloy has been used extensively for oil and gasoline tanks on aircraft, since there is no tendency for attack. The addition of tetraethyl lead and ethylene dibromide, in order to raise the antiknock rating of gasoline, may cause pitting at the waterline in gasoline-water mixtures, unless slushing compounds, or special capsules that contain slightly soluble chromates, or other inhibitors are used.

Metallurgical Factors. Impurities such as iron, nickel and copper have definite tolerance limits.[1] The quantity and state of these impurities in magnesium alloys determines the resistance of the metal to corrosion in aqueous salt solutions. Commercially pure magnesium exhibits corrosion rates that vary from 500 to 10,000 mdd* in 3% sodium chloride solution. Figure 6 gives a broad view of the corrosion of magnesium-base binary alloys. Some elements are not harmful in large proportions, but others are detrimental even when present in minute amounts. The present commercial alloy compositions come from a combination of elements that are not harmful. The effect of impurities on these alloys is of maximum importance.

The M1 alloy shows a marked tolerance for both iron and nickel. The limit of tolerance for iron is 0.017%, the same as for pure magnesium; but greater amounts of iron are much less deleterious when manganese is present than with

* mdd = milligrams per square decimeter per day

Table I. Corrosion of Magnesium Alloy AZ61X in Salt Solutions

Specimen size, 7.5 cm (3 in.) by 2.5 cm (1 in.) by 0.15 cm (0.06 in.)
Surface preparation, HNO_3 pickled
Temperature, 35 C (95 F)
Volume of testing solution, 100 ml
Duration of test, 7 days
Test, alternate immersion, 30 sec in solution, 2 min in air
Concentration of solution, 3% by weight

Acid Salt	Corrosion Rate, mdd	Neutral Salt	Corrosion Rate, mdd	Alkaline Salt	Corrosion Rate, mdd
		Nonoxidizing			
Aluminum sulfate	112	Sodium chloride	14	Sodium silicate meta	0.7

Ferric sulfate	297	Sodium chlorate	59	Sodium iodate	40
		Sodium pyrophosphate	51		

magnesium alone. Manganese also greatly increases the tolerance limit for nickel.

With the magnesium-aluminum binary alloys, the tolerance limit for iron is strikingly changed. With even as little as a few hundredths per cent aluminum, the tolerance limit for iron decreases from 0.017% to a few thousandths per cent. With 7.0% Al, the limit is about 0.0005% Fe; while with 10.0% Al, the limit is too low to be determined. An explanation of this may lie in the formation of an iron-aluminum phase, which is even more active than discrete iron particles alone.

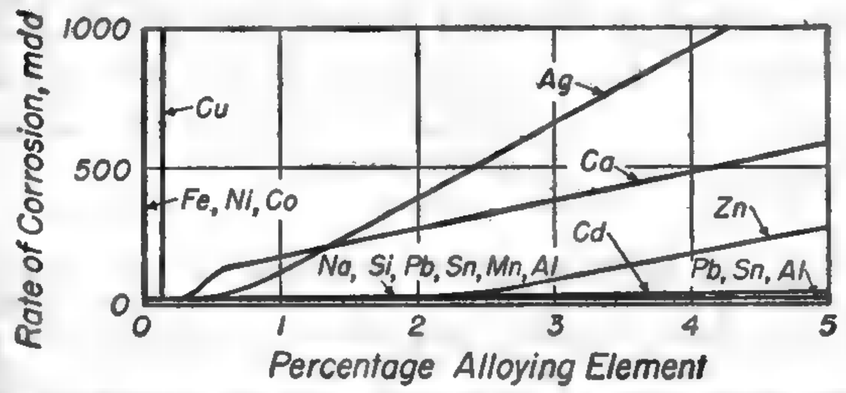

Fig. 6 Corrosion rate of binary alloys in 3% sodium chloride solution.
Corrosive medium, 3% sodium chloride solution; size of specimen, 3.8 cm (1.5 in.) by 2.5 cm (1 in.) by 0.6 cm (0.25 in.); surface preparation, Aloxite ground; temperature, room; aeration, natural convection; volume of testing solution, 100 ml; velocity, quiescent; duration of test, 16 weeks; type of test, alternate immersion, 30 sec in medium, 2 min in air.

The addition of even a few hundredths per cent of manganese to the magnesium-aluminum binary alloys is sufficient to raise the tolerance limit for iron to 0.002%.

Of maximum practical importance is the effect of iron, nickel and copper on the Mg-Al-Mn and Mg-Al-Zn-Mn alloys. Figure 7 shows the results of adding 0.5% and 3% Zn to alloys containing 6% Al, 0.2% Mn. The presence of 0.5% Zn does not shift the position of the tolerance limit at 0.002% Fe, but somewhat reduces the magnitude of the corrosion rates for higher percentages of iron. The addition of 3% Zn raises the tolerance limit to 0.003% Fe and greatly reduces the rate for higher concentrations of iron. Zinc additions show somewhat similar effects in raising the tolerance limit for nickel and copper, and in reducing the corrosion rates at higher concentrations of zinc.

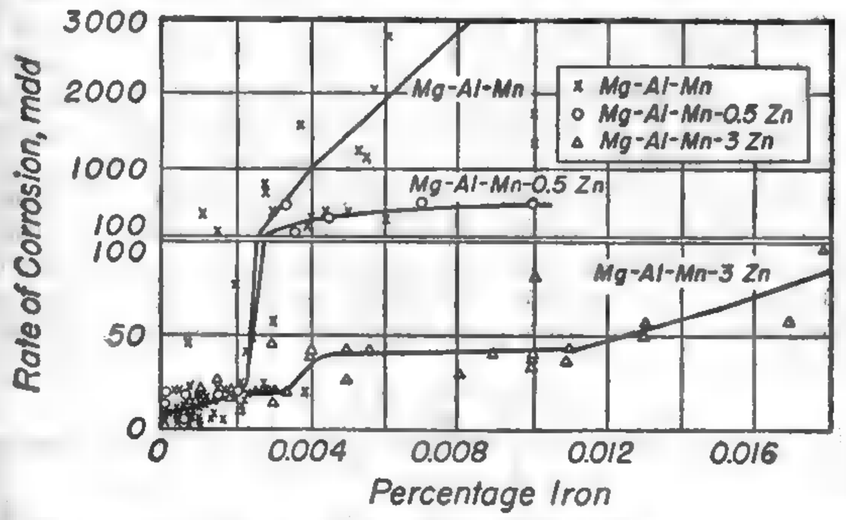

Fig. 7 Effect of iron on the corrosion rate of three magnesium alloys in 3% sodium chloride solution.
Corrosive medium, 3% sodium chloride solution; specimen size, 3.8 cm (1.5 in.) by 2.5 cm (1 in.) by 0.6 cm (0.25 in.); surface preparation, Aloxite ground; temperature, room; aeration, by convection; volume of testing solution, 100 ml; velocity, quiescent; duration of test, 16 weeks; type of test, alternate immersion, 30 sec in solution, 2 min in air.

Heat Treatment and Cold Work. The effect of heat treatment on the corrosion rate of magnesium alloys in aqueous electrolytes, varies with the heat treating temperature, rate of cooling, the alloying elements, and the impurity content of the alloys. With M1 alloy, heat treatment of sheet in the range of 260 C (500 F) to about 485 C (900 F) usually at least doubles the corrosion rate and greatly increases the tendency to pit. Heat treatment at 540 C (1000 F) to 620 C (1165 F), followed by rapid cooling, completely eliminates pitting and provides increased resistance to corrosion. These effects of heat treatment on M1 account for the pitting tendency adjacent to welds corroding in a salt solution.

With controlled-purity Mg-Al-Mn alloys, containing 0 to 1% Zn, slight if any difference in corrosion rate is noted between the as-fabricated, solution heat treated, or solution heat treated and aged states, if cooled in air from the solution heat treating temperature. With similar cooling, controlled-purity alloys containing ▪ to 3% Zn show a slight increase in the corrosion rate in the solution heat treated state or solution heat treated and aged state when compared with the rate in the as-cast state. In alloys that contain iron in amounts greater than the tolerance limit, solution heat treatment will increase the corrosion rate by a factor of two to five, and solution heat treating and aging will usually increase the rate to a somewhat slighter extent.

The heat treatment, and especially the cooling rate from the solution heat treating temperature, appear to affect the tendency toward pitting. However, with increasing zinc content as high as 3%, the pitting caused by quenching appears to decrease. This effect of heat treatment and quenching on the corrosion rate is particularly noticeable adjacent to welds in alloys containing aluminum and zinc, corroded in a 3% sodium chloride solution. Severe attack may take place in the rapidly cooled heat-affected zone.

Comparison of Atmospheric and Salt-Water Tests. It is extremely difficult to evaluate the way a material will withstand varying atmospheric conditions, by the use of an accelerated test in salt water. Extensive data have been compiled attempting to correlate results from the 3% sodium chloride, alternate-immersion test with the results obtained in atmospheric tests. The distinct lack of correlation is

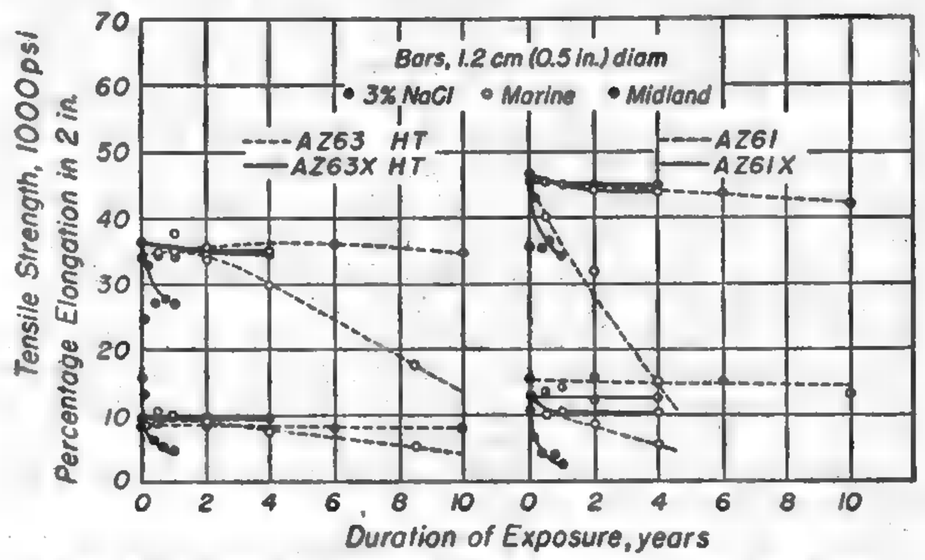

Fig. 8 Comparative behavior of magnesium alloy test bars, in accelerated and atmospheric mediums.

shown in Fig. 8 where the mechanical properties are given that were obtained on AZ61, AZ61X, AZ63, and AZ63X alloys after exposure to various mediums. The amount and distribution of impurities present in magnesium alloys strongly affect the results obtained in 3% salt solutions. In an industrial atmosphere, however, the influence of these impurities is apparently negligible. Although the effect of impurities in the alloys is more evident both in 3% salt solutions and in the marine atmosphere, the difference in results in these two mediums is so great that it would be extremely difficult to predict the life of a magnesium structure, basing the estimate on the tests in 3% salt solution.

Soil Corrosion. Extensive data in a wide variety of soils are not available, but the information which has been obtained indicates that magnesium is quite resistant to soil corrosion. Bare M1 and AZ31X extrusions and an AZ63 casting were buried in a vertical position in loam soil on the bank of a river for a year. The bottom of each section was immersed approximately 6 in. below the lowest river level. During examination after this exposure, a heavy calcareous-like deposit was found on the sections. No corrosion was evident. Parts coated with a bitumastic type of paint and buried at the same time showed no evidence of failure.

Similar results were obtained on extruded telephone poles used in the Panama Canal Zone. After several months of use, their condition was reported as very satisfactory.

Nonaqueous Corrosion. *Liquids.* Magnesium exhibits good resistance to corrosion in a wide variety of organic compounds. Aliphatics and their halide derivatives, as well as aromatics, cause little or no corrosion. A welded drum has been used for intraplant shipment of phenol for five

years. Methyl bromide storage containers are similarly unattacked. A storage tank for phenyl-ethyl alcohol has been in use for ten years. Alcohols, with the exception of methanol, cause little or no corrosion. Anhydrous methanol attacks magnesium vigorously with the formation of magnesium methylate. The attack may be partially inhibited by the addition of a little water; however 1% ammonium sulfide and beet-pulp distillate will inhibit the solution completely. Aliphatic acids and many of the compounds containing nitrogen cause appreciable corrosion.

Gases. Dry chlorine, iodine, bromine, and fluorine cause little or no attack on magnesium at room temperature. Dry bromine, containing 0.02% water, causes no more attack at the boiling point (58 C) than at room temperature. The presence of a small amount of water causes pronounced attack by chlorine, some attack by iodine and negligible attack by bromine or fluorine. Sulfur dioxide, ammonia and Freon cause no attack in either the liquid or vapor phase. Water vapor may cause some corrosion.

Galvanic Corrosion. Although the strongly electronegative potential has prevented the use of magnesium in some instances where otherwise the chemical and physical properties would make it an ideal material, in actual practice the widest usage of magnesium is under conditions of atmospheric exposure where, because of the poor conductivity of the mediums encountered, very small galvanic corroding currents are usually obtained.

Aqueous Systems. In completely aqueous systems, inhibitors may decrease galvanic corrosion radically. Alkaline chromates, fluorides and sulfides have proved effective in many instances. The addition of magnesium or calcium nitrate to solutions containing chloride, provides inhibition, apparently because of the precipitation of a magnesium or calcium hydroxide on the cathode. In aircraft systems that use ethylene glycol and water as a coolant, corrosion at 240 F, resulting from contact with iron, was inhibited by the addition of small amounts of phosphoric acid and triethanolamine. The type of inhibitor that is most effective is normally specific for a given medium.

Since magnesium is not ordinarily used in highly conducting mediums, the galvanic effects that may be produced under various atmospheric conditions are of more practical significance. Because of the strong effect on the conductivity, the type of atmosphere largely controls the galvanic corrosion that may be produced.

Inland Atmospheres. For an inland atmosphere, even under severe industrial conditions, the possibility of galvanic corrosion is relatively remote, and the extent is usually slight if such corrosion does occur. Under severe inland conditions, painting is normally sufficient to protect magnesium during long periods of exposure. Canoes were constructed using 2S aluminum rivets with steel bolts to fasten air chambers. After 10 years service they showed no galvanic attack. Die-cast generator parts, having steel inserts and bolted connections, showed little galvanic attack after 5½ years exposure on the roof of the Midland laboratory. During the same exposure, the steel parts had become badly corroded. Automobile wheels in use for more than a year have shown no galvanic corrosion at contacts with cadmium-plated steel bolts or between wheel and hub.

Where exposure is severe (as, for example, where contact with weak electrolytes may be expected) proper choice of alloy combinations or other protective measures may be required. The Germans have used plastic washers under steel bolts to protect both magnesium and aluminum from corrosion on artillery wheel applications. Aluminum alloy 52 S washers will give equal protection to magnesium and are superior where bearing loads are high.

Coastal Exposure. In coastal exposure, galvanic corrosion may occur, but the extent may be reduced or entirely eliminated by proper choice of the dissimilar metals, by application of protective treatments and paints, or by use of insulating plastics.

At the 80 and 800-ft coastal stations, the effect of a wide variety of metals on the promotion of galvanic corrosion was determined by fastening sheets of dissimilar metals directly to AZ61X alloy sheet by means of cadmium-plated steel bolts. The relative galvanic corrosion effects of the different metals are shown in Table II. Aluminum alloy 52 S and zinc caused less galvanic attack than lead and the other aluminum alloys. Copper, brass, monel, 18-8 stainless steel and mild steel caused appreciable galvanic corrosion. At the 80-ft station the severe exposure caused perforation of the magnesium panels at contacts with the more noble metals after six months to one year. At contacts with zinc or 52S aluminum, the galvanic corrosion was relatively much less severe.

Table II

Qualitative Evaluation of Effect of Equal Areas of Dissimilar Metals on the Galvanic Corrosion of AZ61X Magnesium Sheet at the 800-ft Station, Kure Beach, N. C.

Most galvanic attack	Copper, brass, monel, 18-8, mild steel, 17 S-T
Intermediate	3 S, 24 S-T, and clad 24 S-T, lead, galvanized iron, zinc
Least galvanic attack	52 S

Rivets. In ordinary inland atmospheres the choice of rivet alloy would have little or no effect on the corrosion resistance of an assembly, but in coastal atmospheres galvanic corrosion both of the magnesium rivet alloy and of an aluminum rivet alloy may occur unless proper selection is made. The alkaline nature of the corrosion product of magnesium causes pronounced attack on the rivet when aluminum rivets that contain copper are used, but none when the more alkali-resistant type, such as 56 S, is used. Painting riveted structures will normally delay somewhat the galvanic attack adjacent to A17 S-T (aluminum alloy) rivets; but because of the porosity usually found at section changes, painting may be insufficient for prolonged exposure to a coastal atmosphere.

Bolted Connections. When galvanic corrosion may be expected adjacent to bolts, proper choice of washer alloy may eliminate it. The effect of washer-alloy composition under cadmium-plated steel bolts was determined at the 800-ft station. Plain steel, cadmium-plated steel, zinc-plated steel, and 52 S aluminum alloy washers were used. After exposure during 19 months, severe corrosion had taken place adjacent to the plain steel, and some at the juncture with the cadmium-plated washer; but the zinc-plated steel washer had caused almost no galvanic corrosion, and no attack adjacent to the 52 S washers.

Paint will greatly reduce the galvanic corrosion that may occur at dissimilar metal connections, particularly when the faying surfaces are painted. If only one metal may be painted, it should preferably be the cathode, because this greatly reduces the cathodic area involved and consequently reduces the generated currents. At contacts between magnesium surfaces, negligible corrosion has been found after two years exposure at the 800-ft location. Zinc chromate primers on the faying surfaces are usually sufficient for dissimilar metal connections; however, very severe service may require more impervious paint system or plastic insulators.

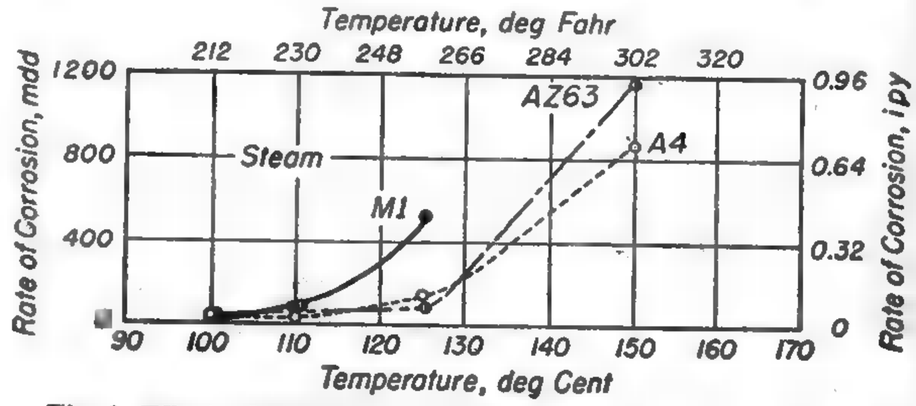

Fig. 9 Effect of steam temperature on the rate of corrosion of magnesium alloys.

Corrosion at High Temperatures. At elevated temperatures the rate of oxidation of magnesium in oxygen is a linear function of time; with increasing temperatures the rate also increases markedly. In general, the rate of oxidation is higher in air than in oxygen. Most alloying elements, such as aluminum and zinc, increase the rate of oxidation at a given temperature. Cerium, lanthanum and beryllium have been shown to reduce the rate of oxidation lower than that of pure magnesium. Beryllium additions have the most striking effect, giving protection to some alloys up to the

melting point, over extended periods of time. It has been observed that in the molten state, 0.010% Be will protect aluminum-containing magnesium alloys from burning at a temperature of 870 C (1600 F); however, the presence of dust and acid fumes in the atmosphere will reduce the protection afforded.

Water vapor in air or in oxygen increases markedly the rate of oxidation at temperatures greater than 100 C (212 F), but carbon dioxide and sulfur dioxide are effective in reducing it. Fluorides are also effective at temperatures lower than about 375 C (707 F) but at higher temperatures the film breaks down to form magnesium oxide.

The corrosion of typical magnesium alloys in steam is shown in Fig. 9. At 100 C (212 F) the rate of corrosion in the steam phase is distinctly greater than in the liquid phase. At temperatures higher than this, M1 exhibits a more rapid rate of corrosion than alloys that contain aluminum or aluminum and zinc. None of the magnesium alloys appear to be resistant to steam at temperatures higher than approximately 120 C (248 F), since magnesium hydroxide is formed rapidly.

Designing for Magnesium

By A. M. Lennie*

ALTHOUGH principles of good design apply to all structural metals, every material possesses distinct characteristics, each warranting separate consideration. The rules of design established for magnesium are based on principles of good design modified according to the inherent properties of the metal. The basic qualities responsible for the widespread acceptance of magnesium may be summarized as follows: (1) extreme lightness in conjunction with good mechanical properties, resulting in a material with a high ratio of strength to weight; (2) adaptability to modern processes of fabrication, such as casting, extrusion, rolling, forging, welding, riveting, and forming; (3) excellent machinability.

In addition to these basic characteristics, magnesium possesses other properties useful in specific applications. It is nonmagnetic and nonsparking. Further, it has electrical resistivity useful in certain applications, good corrosion stability under normal atmospheric conditions, high capacity for absorbing elastic energy, excellent hot drawability, and etching qualities that make it desirable as a photoengraving material.

The combination of properties of magnesium offers to the engineer possibilities for saving weight, reducing cost, and improving quality and performance of products.

Weight can be reduced by substituting magnesium directly in some designs, but reduction can be obtained best by designing efficiently for magnesium. Many structural sections are heavier than necessary because of manufacturing limitations; for example, in castings where, for successful pouring, wall thicknesses must not be less than a given minimum. When such sections are made of magnesium rather than other structural metals, they can be used more efficiently with greater saving in weight than a comparison of the mechanical properties would seem to indicate. The lightness of magnesium is an advantage also in forgings and extrusions, which must sometimes be made heavier than is required.

Since the strength and stiffness in bending of many structural members increase approximately as the square and cube of the depth respectively, it is possible to obtain large increases in strength with some enlargement of section that involves little increase in weight. When such changes in section are permissible it is usually possible to redesign a part more efficiently for magnesium than for other metals. The greater bulk of magnesium also eliminates the problem of local instability. Even where redesign, using increased sections, does not result in maximum saving of weight, the design can usually be simplified and manufacturing costs can be lowered.

Incorporating magnesium into the design of a product may achieve one or more of the following effects: reduced operating costs, because of the higher operating speeds of machines, particularly those with intermittent or reciprocating motions; reduced wear and consumption of power; greater payloads; easier handling; improved efficiency of workers through reduction of fatigue; decreased shipping costs.

Fabricating costs may be reduced by taking advantage of the machining characteristics, the methods of fabrication and the design possibilities of magnesium. Magnesium may be machined so as to produce excellent surface finish at higher feeds and speeds than are suitable for other structural metals, and with consequent possible reduction in machining costs. Magnesium die castings offer the possibility of low-cost units that require much less machining than cast-iron parts. The extrusion process makes available an almost unlimited variety of special cross sections that can usually be produced more cheaply than shapes fabricated from other metals, which may require welding or riveting. The light weight of magnesium makes it possible to utilize heavy-gage monocoque sheet structures which, because of their simple design, are usually cheaper to fabricate than structures requiring ribs and stiffeners.

The combination of lightness and strength may improve machine operation by removing vibration and increasing speed; thus, imperfections in quality of the product can be minimized and production can be increased. Portable consumer goods may be made lightweight and easy to handle. In some applications such as aircraft engines, improvements in performance have been made to an extent impossible with other metals.

Prepared for the Magnesium Committee

Mechanical Properties

Values for all mechanical and physical properties of magnesium are given in the data sheets for each alloy, pages 1013 to 1024. The mechanical properties given are typical values. The properties of castings are determined from separately cast test specimens; the properties of wrought products are determined from specimens machined from extrusions, sheet or forgings. A summary of the typical mechanical properties of several magnesium alloys in various forms is given in Table I.

The following designations, suffixed to the alloy number, are used to indicate the condition of heat treatment or temper.

- a, Annealed sheet
- h, Hard rolled sheet
- AC, As cast
- ACS, As cast plus a stabilizing heat treatment
- HT, Heat treated
- HTA, Heat treated and aged
- HTS, Heat treated and stabilized
- A, Aged

Typical stress-strain curves in tension and in compression have been reported but are not included in this discussion. The mechanical properties of wrought magnesium alloys may vary somewhat, depending on the amount of working and the direction of metal flow. The lowest properties will usually be found in the heaviest

or least worked sections and in a direction perpendicular to the direction of metal flow. In sheet, however, the properties in the transverse direction may be somewhat higher than those in the longitudinal direction—that is, the direction of rolling.

Tensile Properties. On the basis of equal weight, most of the magnesium alloys have properties comparable with those of other structural metals.

The yield strength of magnesium alloys is defined as the stress required to produce a deviation or offset of 0.2% from the modulus line. Minimum tensile properties normally used for purposes of specifications and as a ready means for determining the acceptance or rejection of material are given in Table II.

Compressive Strength. The compressive yield strength is defined as the stress required to produce a deviation or offset of 0.2% from the modulus line. Castings have a compressive yield strength approximately equal to the tensile yield strength. In wrought alloys, however, the yield strength in compression may be considerably less than the yield strength in tension. The ratio of the yield strength in compression to the yield strength in tension varies from about 0.4 for M1 alloy to about 1.0 for AZ80X HTA with an average value of about 0.7 for the other alloys.

Columns. The strength of magnesium columns loaded axially and sufficiently stable to prevent local failure may be represented by the following general equation:

$$\frac{P}{A} = \frac{M}{1 + \frac{M(KL/r)^2}{64{,}600{,}000}}$$

where

P = ultimate column load, lb
A = cross-sectional area, sq in.
M = a constant that depends on the compressive yield strength (F_{cy})
K = a constant depending on end conditions, 0.5 for fixed end and 1.0 for pin ends
L/r = slenderness ratio

The values of M corresponding to various values of F_{cy} are as follows:

Table I. Typical Mechanical Properties of Magnesium Alloys

(a) Properties determined on separately cast test bars.

F_{cy}	M	F_{cy}	M	F_{cy}	M
6,000	13,100	14,000	21,100	22,000	47,000
8,000	14,100	16,000	25,500	26,000	68,800
10,000	15,700	18,000	31,200	30,000	97,000
12,000	17,900	20,000	38,500	34,000	129,000

Typical values for F_{cy} of various magnesium alloys, to be used in the above formula are:

Alloy	F_{cy} Shapes	F_{cy} Tubing
M1	9,000	7,000
AZ31	15,000	12,000
AZ51	18,000	14,000
AZ80	20,000	.....
AZ80 HTA	30,000	.....

The values for the column loads, as determined in the foregoing equation, are ultimate. As with steel it is recommended that ½ the value obtained be used for the working stress. Column curves are given in Fig. 1.

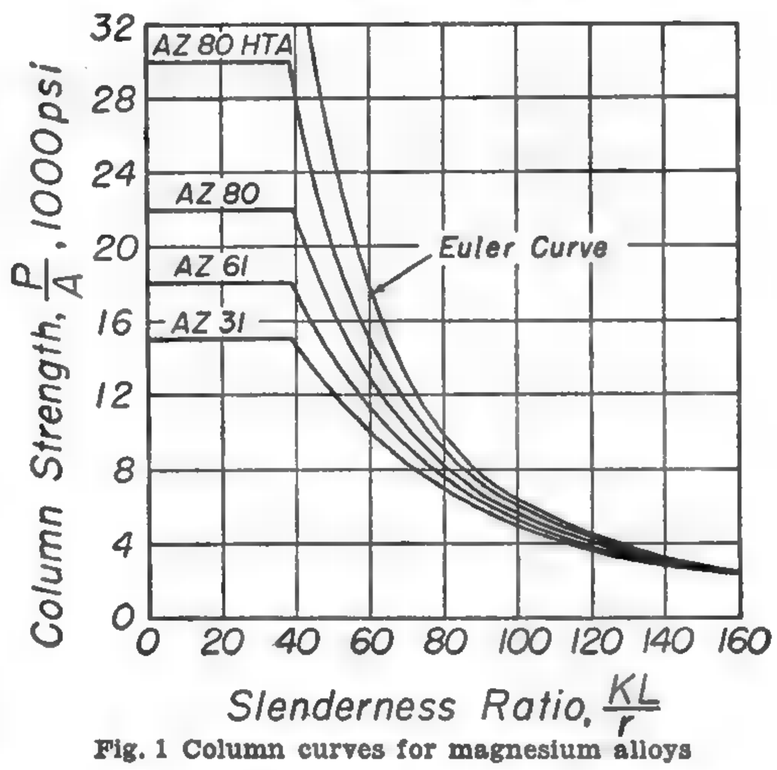

Fig. 1 Column curves for magnesium alloys

Bearing Strength. Bearing strength is particularly important in the design of bolted and riveted joints. The bearing yield strength is defined as the stress required to produce an offset of 2% from the initial curve of bearing stress versus hole elongation. Bearing-strength values listed in Table I were determined on specimens having an edge distance of 2½ times the pin diameter and a width of 8 times the pin diameter. It has been shown that increasing the edge distance to more than approximately 2 times the pin diameter has little effect on the bearing values.[1] Sheet thicknesses within a wide range have been tested and no effect of the ratio of pin diameter to sheet thickness was observed.

Moduli. The modulus of elasticity is approximately 6,500,000 psi in both tension and compression[2] and the modulus of rigidity is approximately 2,400,000 psi. These values give a Poisson's ratio of 0.35. The modulus of elasticity must be considered in any design involving stiffness or rigidity. When stiffness is a factor, the modulus can be compensated by increasing the section size, preferably the depth or thickness, since stiffness increases with the cube of the depth, and relatively small increases in depth will result in large increases in stiffness.

Bending Strength. Since magnesium alloys are ductile, no values for the modulus of rupture can be given. In the design of beams, the bending strength may be defined as the moment developed when the outer fibers are stressed to the yield strength of the material. Since the tensile and compressive yield strengths of most wrought magnesium alloys are not equal, the maximum stress to use in the standard formula $f = \frac{Mc}{I}$ has been determined as the average of the tensile and compressive yield strengths.[4] This applies to solid sections, such as rounds, squares, and rectangles, as well as to tubes that have a D/t ratio of less than 20. In standard I-beams, channels and such, the yield strength in bending will be slightly less than the average yield strengths in tension and in compression.

Shear Strength. This property is important in the design of connections in magnesium such as threaded joints and spot welds. The values for castings and extrusions were obtained by the conventional double shear method using solid rods. The values for sheet and AZ80X HTA structural shapes were obtained by the punch method, using a flat specimen.

Hardness and Wear Resistance. Magnesium alloys have sufficient hardness for all structural uses, except where subjected to severe abrasion. Rockwell and Brinell hardness numbers are given in the data sheets and summarized in Table I. Although rather wide variations in hardness are observed, the resistance of the alloys to abrasion varies by only about 15 to 20%. When subjected to wear by rubbing, by frequent removal of studs, or by heavy bearing loads, magnesium may be protected by inserts of steel, bronze, or nonmetallic materials, attached as sleeves, liners, plates or bushings. Such inserts may be attached mechanically by pressing, shrinking, riveting, bolting or bonding; in castings, inserts may be cast in place. Recommended types of inserts are discussed under General Considerations of Design, page 1004.

Magnesium alloys perform very satisfactorily as a bearing material where the following conditions are met: loads not to exceed 2000 psi; hardened shafts (350 to 600 Bhn); ample lubrication; low speeds, 1000 fpm max; and operating temperatures not to exceed 220 F.

Table III. Effects of Surface Condition on the Bending-Fatigue Properties of Sand-Cast Magnesium Alloy Plate

Alloy	Surface Condition	Fatigue strength in psi for given number of cycles[c] 10^5	10^6	10^7
All commercial[a] Sand-casting Alloys	As-cast	16,000 to 10,000	15,500 to 8,500	9,500 to 6,000
	Machined	19,500 to 14,000	16,000 to 10,000	14,500 to 8,500
	Ground[b]	15,500 to 11,000	13,000 to 9,000	11,500 to 9,000
AZ92 HT	Machined & polished	15,000	12,500	10,000
AZ63 HT	Machined & polished	15,500	12,500	10,000

(a) Applies to all commercial sand-casting alloys whether heat treated or not.
(b) Ground surfaces are typical of foundry cleanup.
(c) The limits define the upper and lower boundary of the scatter band.

Fatigue Strength. Magnesium alloys have good resistance to fatigue. Like other metals, magnesium alloys are sensitive in fatigue to the effects of stress raisers, such as notches or abrupt changes in section; therefore consideration should be given to stress raisers when a part is subject to fluctuating stresses.

The values for the endurance limit given in Table I were determined by the R. R. Moore rotating-beam method and are based on 500,000,000 complete reversals of stress. Although the endurance limits of polished bars are of little quantitative use in design, they do have value in a comparative way.

Since the surface condition, type of load application, and design are important in determining the fatigue properties of actual parts, these factors must be considered. In evaluating these variables for magnesium castings, the data given in Table III can be used quantitatively. The limits given in the data are the upper and lower boundary of the scatter band. Any effect shown by alloy composition or heat treatment is inconsequential, since the results were all dispersed at random in one scatter band. There is a significant difference, however, in the endurance limit for the several types of surface finish.

AZ63 HTA	77	21.5	38.9	4.5	1.6	75
	−110	24.4	35.4	2.5	1.5	85

(a) Tensile properties are average of 2 tests.
(b) Impact properties are average of 4 tests.
(c) Hardness is average of 5 tests.

Resilience. This property is the ability to absorb energy without permanent deformation. Resilience or elastic potential energy is inversely proportional to the modulus of elasticity and directly proportional to the square of the stress applied. Since resilience concerns only the elastic range, the yield strength of the metal must be considered in evaluating this property. Since magnesium alloys have a relatively low modulus of elasticity, they have a high unit resilience.

Toughness. This property is a function of the strength and ductility of a material. Toughness is measured by the area under the stress-strain curve but can be approximated by multiplying the tensile strength by the elongation in the tensile test. Calculations made according to the latter method show that, on the basis of equal weight, magnesium alloys have toughness equivalent to that of other structural metals.

The single-blow impact test was devised as a method of determining toughness, but since this test normally employs a notched bar, it is in reality a test of the effect of a notch. Values for both Izod and Charpy impact strength are given in Table I. Because the impact test is really a test of notch effect, the test values should be used with caution.

Effect of Temperature. *Low Temperature.* The mechanical properties of magnesium alloys at minus 110 F are given in Table IV.[4] The tensile strength, yield strength and hardness increase slightly with decreased temperature, while the elongation and notch-impact strength show a slight decrease.

Table V

Properties at Elevated Temperature. The properties of metals at elevated temperature are usually determined by three different methods: short-time tests, stress to rupture tests and creep tests. Each method gives data of value for particular service conditions.

Short-Time Tests. The short-time test data (*see* Table V) are useful in the various hot working operations.

Stress to Rupture. This test gives the length of time at temperature during which a material will withstand a constant stress before rupture. The data in Table VI give the stress necessary to produce rupture of various magnesium alloys in 1000 hr at elevated temperature. More complete stress-rupture information is available.[5]

Creep. When a design calls for a limiting amount of deformation, creep properties become important. Creep, which may be defined as the continuous deformation of a material under stress, takes place in three distinct stages commonly known as the first, second and third stages. In the first stage, extension starts at a rapid rate, which

is decreased until a constant value is reached during the second stage. Finally, in the third stage, the rate increases until eventually rupture may take place. The extent of deformation in any material depends on the stress level, temperature and time. The results given in Table VI are stresses required for producing rates of extension of 0.1 and 0.5% in 1000 hr. These rates are determined in the constant-rate or second stage of the creep curves between the 750th and 1000th hr. It is not recommended that creep rates be extrapolated over a wide period of time unless substantiated by tests.

Creep results may also be reported as the total extension by creep at a specified stress and temperature.[5] This total extension does not include the initial extension produced in loading the specimen. The service conditions determine the type of high-temperature data to be used.

Properties at Room Temperature After Heating Magnesium to an Elevated Temperature. In operations such as forming and drawing, it is sometimes necessary to work magnesium at elevated temperatures. Since temperature has a deleterious effect on the properties of hard rolled sheet, maximum working temperatures have been established. The maximum temperatures used in forming, in order to retain the hard rolled properties, are 300 F (135 C) for AZ31Xh, 400 F (204 C) for AZ51Xh, and 500 F (260 C) for M1. Table VII gives the properties of hard rolled sheet at room temperature after the sheet has been heated to various temperatures. Annealed sheet will show no change in properties, since the annealing temperature is higher than the processing temperatures.

Physical Properties

All available information on the physical properties of magnesium alloys is given in the data sheets (pages 1013 to 1024). For convenience, tables summarizing a few properties are given in this section.

Specific Gravity. Specific gravities and weights per cubic inch are given in Table VIII.

Table VIII. Physical Properties of Magnesium Alloys

Alloy	Form	Specific Gravity, 75 F	Weight per cu in.	Thermal Conductivity between 100 and 300 C, cgs units
AZ92	As Cast	1.82	0.066	0.16
A10	As Cast	1.81	0.066	0.17
AZ63	As Cast	1.84	0.066	0.18
AZ91	Die Cast	1.81	0.066	0.17
AZ31X	Extruded	1.78	0.064	0.23
AZ61X	Extruded	1.80	0.065	0.19
M1	Extruded	1.76	0.064	0.30
AZ80X	Extruded	1.80	0.066	0.18

Thermal Conductivity. The thermal conductivity of magnesium is important where rapid dissipation of heat is required. Pure magnesium has a conductivity of 0.376 units, while the alloys have conductivities ranging down to 0.17. Table VIII gives the values of thermal conductivity for the various alloys.

Specific Heat. All the magnesium alloys have virtually the same specific heat, which is 0.25 cal per g per °C.

Coefficient of Thermal Expansion. The mean coefficient of thermal expansion for magnesium alloys is 0.0000143 in the temperature range from 68 to 212 F. The coefficient of expansion increases slowly with temperature; the value for the temperature range from 68 to 752 F is about 0.000016 per degree. Allowance must be made for this expansion of magnesium in structures subjected to variations in temperature, especially where the structures are rigidly connected to dissimilar metals and restrained from expanding and contracting freely. In pressed or shrunk-in inserts, the differential in expansion must be considered so that sufficient grip will be retained on the insert when the assembly is heated.

Table VII. Properties of Hard Rolled Magnesium Sheet at Room Temperature After Heating for 15 Minutes at Various Temperatures

Dimensional Stability. Magnesium alloys generally exhibit good dimensional stability in service, with permanent dimensional changes seldom observed in properly designed parts. Such changes may occur as a result of one or more of the following causes: (1) growth produced by long exposure at elevated temperatures and by the resulting metallurgical change—for example, precipitation of magnesium compounds from solid solution; (2) distortion caused by the relief of residual stresses; (3) creep caused by the gradual yielding of the metal under the influence of stress, temperature and time.

AZ80X	Forged	0.00092	0.00084	.....	.....

Permanent Growth. Some magnesium alloys are subject to small amounts of permanent growth if used at temperatures exceeding 200 F for extended periods of time. For all practical purposes, magnesium alloys are free from growth, but where close tolerances must be maintained, the designer should refer to Table IX, which gives the maximum permanent growth that can be expected from typical magnesium alloys. Under normal operating conditions, however, the growth taking place is only a fraction of the maximum values listed. Growth results from a metallurgical transformation, possible to any appreciable extent only in alloys that can be heat treated; therefore most wrought magnesium forms will exhibit no growth in service.

Table X. Electrical Properties of Magnesium Alloys

Alloy	Volume Conductivity, % IACS[a]	Resistivity at 20 C, microhm-cm

(a) International Annealed Copper Standard, percentage of the conductivity of standard copper

Residual Stresses. Residual stresses set up during fabrication or straightening operations may result in warpage or permanent distortion of magnesium parts. The low modulus of elasticity of magnesium, absence of skin effect in castings, wide range of solidification, and use of heat in forming operations mean that stresses will be induced less frequently in magnesium than in other metals. Heating castings to approximately 500 F for 2 hr and cooling slowly will remove residual stresses effectively. Relief of welding stresses is discussed in the article entitled "Joining Magnesium Alloys", page 983.

Creep. See Effect of Temperature, page 1002.

Electrical Properties. The electrical conductivity of magnesium is relatively high. Table X gives the values of conductivity as well as of resistivity in various magnesium alloys. Pure magnesium, on a basis of equal weight, has a conductivity of 198% IACS, that is, 98% greater than standard copper.

The conductivity of the various alloys is influenced by the alloying elements present and by the metallurgical condition. Heat treatment reduces the conductivity; aging increases it.

Magnesium is weakly paramagnetic, but for all practical purposes it may be considered nonmagnetic.

General Considerations of Design

Safety. Magnesium alloys must be heated to and held at their lower melting point (800 to 1200 F) for an appreciable time before ignition occurs. The degree of fineness of the magnesium will also determine to some extent the ease of ignition. Fine particles will ignite more readily; therefore, in grinding and polishing operations, adequate precautions must be taken to prevent accidental ignition of magnesium dust. Ordinary machining scrap presents no unusual hazards if precautions advised by the industry are followed. The great majority of structural parts are thick enough for the burning characteristics to be of no importance to the design engineer. The high thermal conductivity of magnesium dissipates heat rapidly, making it difficult to raise the temperature to the ignition point. If magnesium sections, including thin sheet, are not preheated, local ignition will be restricted and any burning that occurs will cease.

Since the designer is limited to service temperatures below 400 F by the mechanical properties of magnesium, the problem of combustibility need not be considered in normal applications. Even where magnesium might be exposed to accidental fires, tests have shown that structural failures will occur in other metals as well as in magnesium before magnesium ignites. As an additional precaution, however, special paints that greatly inhibit burning may be used on magnesium.

The safety of magnesium was demonstrated strikingly by an experiment in which an aircraft gasoline tank made of magnesium was exposed to a blowtorch. A hole was burned in the tank and the gasoline was burned with no damage to the tank except the hole burned by the torch. Examples of the safety of magnesium are the many applications in aircraft engines, cooking utensils, cigarette lighters and industrial equipment, all of which have been serving successfully for years.

Machining. Although the technique of machining magnesium is not of direct interest to the designer, the good machinability of magnesium creates several factors that influence design. The high speeds and heavy feeds that can be used, as well as the general ease of machining, mean that magnesium can be machined more cheaply than most other metals. The machining cost for magnesium may be 50 or 60% lower than that for iron and steel. Such economies in the cost of processing must be kept in mind by the designer, since it may be cheaper to machine a casting rather than to use some other method for producing the part, or it may be cheaper to specify magnesium rather than some other metal.

When spot faces are specified, or other similar machined surfaces, generous radii should be used in order to eliminate stress concentration. For like reasons, part numbers should not be stamped on stressed sections but should be placed on raised pads.

Inserts. As discussed under Hardness, it is necessary to protect magnesium surfaces where they are subjected to heavy bearing loads or severe wear. Inserts to provide this protection can be of a wide variety and attached in numerous ways.

Cast-In Inserts. Inserts in magnesium may be cast in place in the same manner as in other metals. Cast-in inserts may be made of steel, brass, bronze or other metals. Nonferrous inserts should be plated with cadmium or chromium to prevent alloying with magnesium, and ferrous inserts should be plated with cadmium to decrease the possibility of galvanic effects.

Inserts are made secure when the cast metal shrinks

around them and provides a bond. This anchorage may be obtained more easily by knurling, grooving or shaping the insert suitably. For severe service, some type of nose or hook should be used, but care should be taken to ensure that sharp corners or insufficient metal around the insert do not set up concentrations of stress. In highly stressed castings it may be desirable to cast in a pilot to which the insert may be attached, thus avoiding high shrink stresses around the insert. Cast-in inserts may also be used for providing details not otherwise feasible, such as lubrication lines of steel or copper, or appendages that could not be attached conveniently otherwise. Generally, cast-in inserts complicate the manufacture of castings; hence such inserts should be specified only when other methods of attaching are not feasible.

Press-Fit and Shrink-Fit Inserts. The low modulus of elasticity of magnesium requires that greater interference be used for pressed or shrunk inserts in magnesium than is used for inserts in other metals, in order to obtain sufficient gripping force. An interference of 0.0005 to 0.001 in. per in. is usually satisfactory, but may be increased appreciably where high torque loads are likely to be encountered. Table XI presents recommended interferences for normal service at various temperatures when steel and bronze inserts are to be used. The values given in the table serve only as a guide, since service temperature, type of insert material, severity of service and thickness of insert, all influence the necessary amount of interference. Differences in thermal expansion, yield strength and modulus of elasticity must also be considered for service at elevated temperatures. Inserts are more easily assembled by shrinking, since it is relatively easy to heat the magnesium part and expand the hole sufficiently to receive the insert. Where necessary, the insert may be cooled to facilitate insertion. Assembly by pressing requires careful machining of both insert and hole, and proper lubrication. When large interferences are required, it is generally best to specify shrunk-in inserts, since press-fits may score the magnesium.

Screw Inserts. Various types of screwed-in and mechanically attached inserts may also be used successfully in magnesium parts. When inserts of this type are used, care must be taken to avoid stress concentrations in locating threaded holes and to provide sufficient engagement for the thread.

Assembly Protection. Good design for an assembly of any metal demands that suitable surface protection be provided, especially in enclosed structures and where metal surfaces are in contact. Although magnesium alloys have good general stability at the surface, requiring only normal protection, the possibility of galvanic corrosion, discussed fully in the article entitled "Corrosion of Magnesium", requires that added precautions be taken where magnesium comes in contact with dissimilar surfaces under corrosive conditions.

Enclosed surfaces, when neither tightly sealed from external exposure nor concealed in a structure so as to be inaccessible, should be protected with zinc chromate primer or painted, if service conditions are likely to be severe. Wherever possible, parts that have enclosed surfaces of this sort should be designed to provide drainage and ventilation, thus avoiding entrapped moisture and condensation that provide the corroding mediums.

Faying surfaces on magnesium parts should be primed with zinc chromate primer before assembly, and the entire structure should be painted after assembly.

When magnesium is assembled in contact with dissimilar metals or wood, sealing compounds or gaskets should be used at faying surfaces in addition to priming, in order to provide extra protection. Also the entire structure should be protected with an adequate paint.

Anodized rivets of 56 S aluminum are preferred for use on magnesium structures, since they minimize the possibility of galvanic corrosion; however, other types may be used if the exposure conditions are not severe. Steel bolts, screws, studs or rivets should be plated with zinc or cadmium.

The extent to which these protective precautions should be used depends entirely on the corrosive conditions.

Product Design

Castings. Magnesium alloys may be cast in sand molds, permanent molds or dies. The choice of casting process depends on (1) the number of parts to be produced, (2) the size and intricacy of the part, (3) service requirements, and (4) limitations imposed on the process, such as allowable section size and tolerances. Differences in strength, as well as in cost, exist among the various types of magnesium castings; hence in the following sections the design requirements will be discussed from the standpoint of producing castings that have adequate strength and can be manufactured economically.

Sand and Permanent Mold Castings. Data for the design of sand castings and permanent mold castings are very similar and may usually be applied equally well to both types. Permanent mold castings, made in metal molds, are restricted to smaller and less intricate designs than those made in sand. Properties of both types of casting are very similar, though permanent molds have better finish and closer tolerances. When parts can be made by either method, the choice depends mainly on the number of castings to be produced. If only a few are required, the lower cost of pattern equipment and molding makes sand casting cheaper, but if a relatively large number of castings is required, the cost per piece in a metal mold is minimized and the simpler casting procedure results in cheaper castings by the permanent mold process.

The mechanical properties of cast magnesium alloys are determined from tests made on separately cast specimens poured from the same melt as the castings and in accordance with ASTM specifications. Specimens cut from actual castings will have somewhat lower mechanical properties than separately cast specimens poured from the same melt. Magnesium castings and separately cast specimens are more similar in properties than are castings and specimens of other metals. Average values for coupons from castings will be from 75 to 85% of the value for typical test specimens. However, good design and good foundry practice can minimize factors such as microshrinkage, grain size and foreign inclusions, which cause the variations in properties.

Alloys AZ63 and AZ92 are the most widely used sand-casting alloys; A8 and M1 are used to a limited extent. AZ63 combines good yield strength with maximum toughness and resistance to corrosion, but AZ92 has better castability and combines maximum yield strength and hardness with good soundness and toughness. Since AZ92 is less subject to microporosity, it is preferred to AZ63 for applications where pressure tightness is a factor. Alloy A8 should be used for applications that require maximum toughness, soundness and weldability; however,

Table XI. Approximate Interferences Suggested for Press-Fit and Shrink-Fit Inserts in Magnesium

Inserts		Interference, inch							
		Steel Inserts				Bronze Inserts

6	1/4	0.0036	0.0053	0.0098	0.0147	0.0036	0.0043	0.0070	0.0098

if resistance to corrosion is a determining factor, the purity of A8 must be controlled. Alloy M1 has relatively low strength but is used to a limited extent for castings such as tank fittings to be welded to sheet assemblies.

Magnesium alloys A8, A10, and AZ92 are used for permanent mold castings; AZ92 has been more widely adopted because of its superior mechanical properties and resistance to corrosion. As in sand castings, A8 is used where maximum toughness, soundness and weldability are desired. Alloy A10 is preferred for more complicated castings because of its superior foundry characteristics, but it has slightly lower mechanical properties and resistance to corrosion than AZ92.

With the exception of M1, all the alloys used for casting in sand and permanent molds, can be heat treated to improve their mechanical properties. Reference to Table I shows the improvement that can be effected in mechanical properties by the various heat treatments.

Co-operation between the designer and foundryman is desirable in all metal casting, and since magnesium requires larger risers and different techniques in chilling and gating, such co-operation means that castings of higher quality will be obtained. The foundryman with an appreciation of the design problem can place risers and chills more efficiently to produce the soundest metal

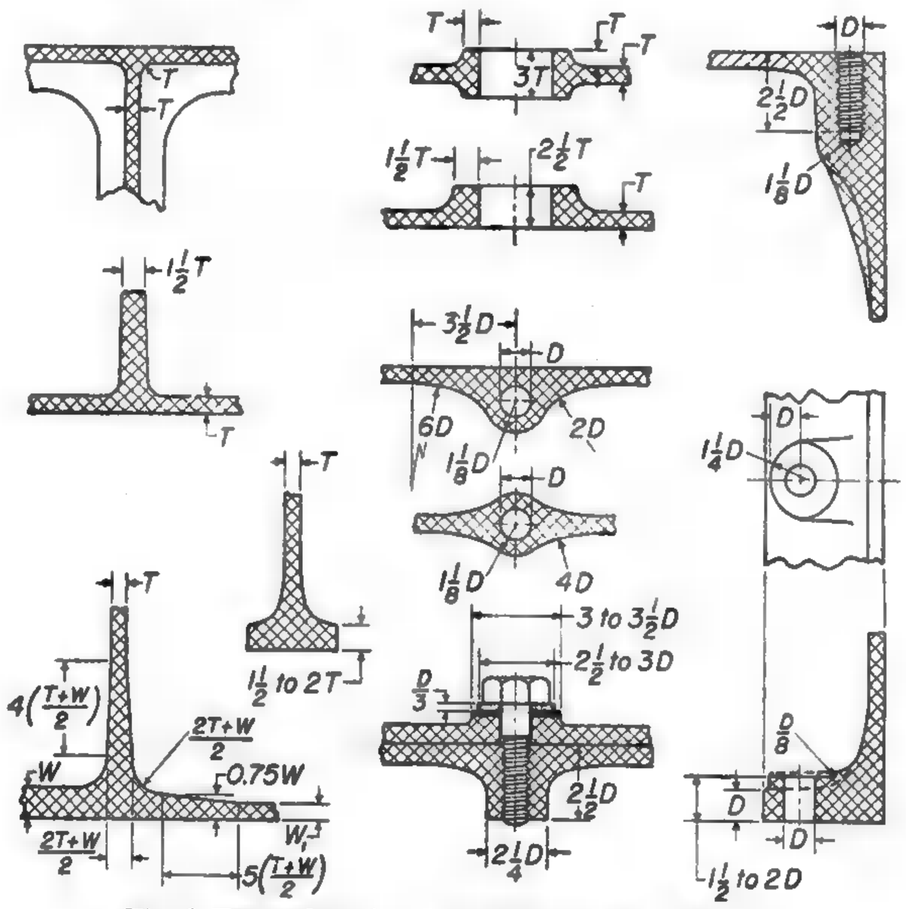

Fig. 2 Examples of recommended casting design

at the most highly stressed locations, and can sometimes recommend changes in design that will result in simplified production and lower cost.

As in all cast metals, magnesium parts designed for strength may fail prematurely as a result of stress concentrations caused by abrupt changes in section, small radii and fillets, and similar factors. In magnesium design, larger radii and more gradual changes in section should be used than are common in designing for other metals. Examples of good magnesium casting design are illustrated in Fig. 2. Particular attention should be given to section changes in order to ensure that thin walls are gradually blended into heavy sections. Fillets should be ample but not excessive, since excess metal in such places might cause shrinkage cracks. Ribs should have broad flat tops rather than pointed or round ones, in order to reduce the intensity of the stress at these points, and should be blended into the supporting members. The low specific gravity of magnesium permits the use of additional metal for providing these features, with very little added weight. Pattern numbers, symbols recording heat treatment and such marks of identification should be placed on raised pads and located in relatively nonstressed areas.

Typical changes in the redesign of a crankcase bearing wall from cast iron to magnesium are shown in Fig. 3.

Limitations of section thickness for magnesium are approximately the same as for other nonferrous metals. The normal minimum wall thickness of a magnesium sand casting is 5/32 in., but thinner walls can be cast, provided they are relatively small in area and favorably located with respect to gates and risers. Low ribs may be cast as thin as 1/10 in. at the top but a 1/8-in. minimum is preferred. Wide variations in thickness of section are permissible in sand castings and permanent mold castings made of magnesium, but the thin sections must

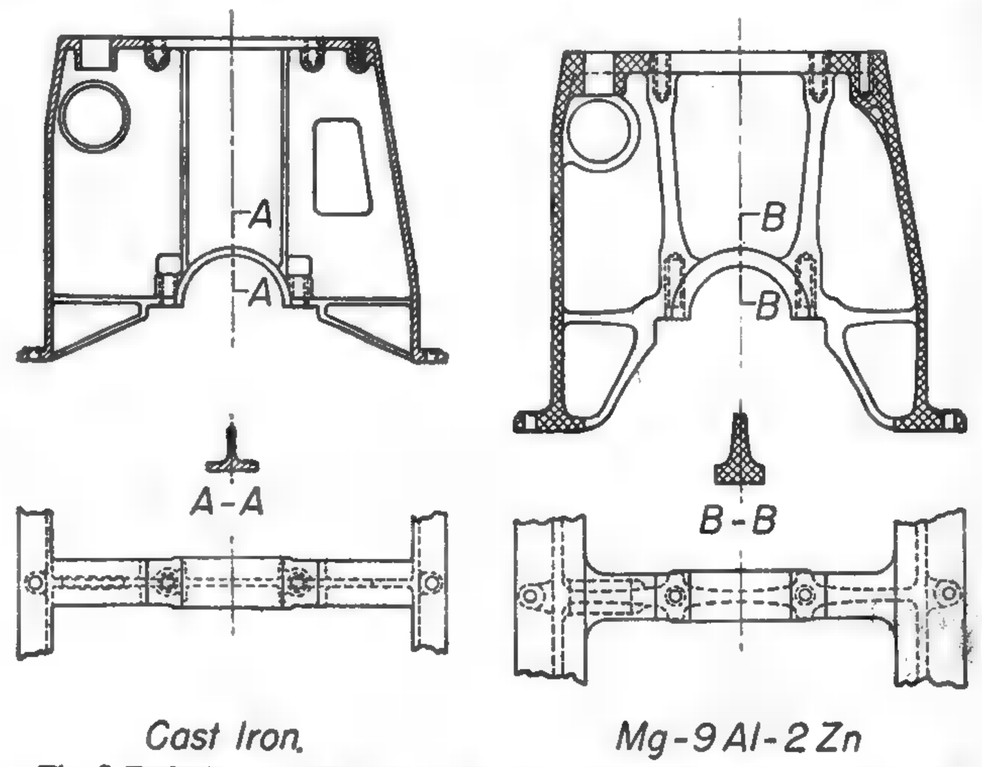

Fig. 3 Redesign of crankcase bearing wall from cast iron to a heat treated magnesium alloy of the AZ92 type. Rigidity and resistance to fatigue of the magnesium crankcase wall at least equal to that of the cast-iron wall.

be blended gradually into heavy walls. Heavy sections (more than 2 in.) may be cast in magnesium with good mechanical properties.

A nominal tolerance of plus or minus 1/32 in. is maintained on dimensions for sand castings—wall thickness, core shift and the like. Tolerances will vary with the casting; occasionally it is possible to hold tolerances to less than 1/32 in.

Magnesium castings made in permanent molds can be held to closer dimensional limits; walls and such can be held within plus or minus 1/64 in. Dimensions greater than 12 in. will have slightly larger tolerances.

The shrinkage of sand castings made of magnesium depends on the size and complexity of the part, number and location of cores and the presence of inserts. The normal unrestrained shrinkage of small magnesium castings is approximately 11/64 in. per ft. In large or complicated castings where shrinkage is restricted by cores, this value may decrease to between 1/10 and 1/8 in. per ft. Inserts will tend to reduce shrinkage further, to the extent that around large inserts no allowance for shrinkage is required.

In permanent mold castings the allowance must be determined on the basis of foundry experience, since shrinkage is greatly restricted by the metal molds.

In both sand mold and permanent mold castings, cores, holes and undercuts should be designed to facilitate production in the foundry. Sand cores should be large enough for easy handling, and projecting parts should be minimized, since they are easily broken. Cores for permanent mold casting should be relatively simple to facilitate removal, and undercuts should be avoided because they necessitate the use of collapsible cores, thus increasing the cost of casting. Sand cores may be used in metal molds (the semipermanent mold process) and they eliminate the necessity for collapsible or complex metal cores.

Inserts may be cast in place in magnesium castings, to provide bearing or wearing surfaces, to attach accessory parts, or to obtain details not otherwise possible, such as oil lines. The section on Inserts provides more detailed information.

Die Castings. Magnesium die castings offer many ad-

vantages, including strength and soundness, low cost in quantity production, reduction in machining, excellent surface finish, dimensional accuracy, and additional saving of weight because thinner sections can be cast. Size is limited by available equipment to approximately 10 lb in weight and to a maximum projected area of 250 sq in.

Magnesium alloy AZ91 is the most widely used die-casting alloy because it combines good mechanical properties, casting characteristics and resistance to corrosion. Magnesium die castings are supplied only in the as-cast condition. Just as with sand castings, the mechanical properties listed in the data sheets for die castings are obtained on separately cast specimens. The mechanical properties of test bars may deviate from actual section properties more than for sand castings. With good conditions of production and casting technique, die castings can be made for use in stressed parts where sand castings would normally be employed.

Generally, good sand-casting design is good die-casting design, using ample fillets, rounded corners, blended sections and similar factors. The use of heavy sections should be avoided in die castings, because such sections tend to be porous and to give areas of low strength. Strength may be secured in thin sections by the use of I-sections and ribbed construction. Section thicknesses within the range from 1/16 to 3/16 in. are preferred, since maximum mechanical properties are secured in that range. Walls as thin as 0.035 to 0.050 in. can be cast, provided the projected area of such thickness does not exceed 30 to 50 sq in. Dimensional tolerances for magnesium die castings are summarized in Table XII.

Table XII. Dimensional Tolerances and Design Limits for Magnesium Die Castings

Dimension	Tolerance[a]
Dimensional Tolerances	
Dimension within solid die block	± 0.0015 in. per linear in.
Minimum tolerance	± 0.0025 in.
Dimensions across and perpendicular to parting line	± 0.010 in. additional [b]
Dimension across and parallel to parting line	± 0.015 in. additional [b]
Dimensions affected by moving cores	± 0.015 in.
Flatness	Bow not to exceed 0.005 in. in any 1 in. or 0.015 in. in 8 in.
Trimming tolerance	To within 0.010 in. of edge
Finishing tolerance	1/32 in.
Design Limits	
Maximum depth of cored holes	3 times the diameter
Draft in cored holes	0.010 in. per in. depth per side
Draft on side walls	0.010 in. per in. depth
External screw threads	Can be cast if coarser than 24 threads per in.[c]
Engraved lettering	
Minimum size of letters	1/16 in.
Minimum face of letters	0.010 in.
Maximum depth of letters engraved in die	0.010 in.

(a) In special instances the tolerances can be reduced. When lower tolerances are required, the die caster should be consulted.
(b) This tolerance is to be added to the total tolerance allowed within solid dies.
(c) If located so as to make the casting of threads practical.

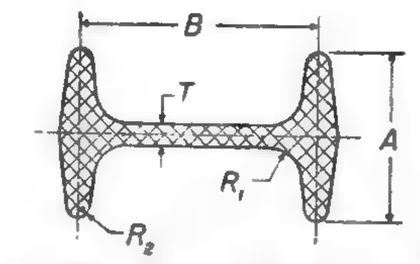
Proper allowance for draft must be made in the design of magnesium die castings so that high production can be maintained. Outside surfaces should have a minimum draft of 0.010 in. per in. of length to prevent galling, but this may be increased for improved surface finish. Allowances for draft of cored holes, side walls, and the like are given in Table XII. Undercuts should be used sparingly since they require loose pieces in the die and reduce rates of production.

External threads can be cast in magnesium die castings, provided they are 24 per in. or coarser and the axis is in the parting plane. If a free fit is permissible, cast threads can be used; otherwise 0.005 to 0.010 in. oversize on the diameter should be allowed for chasing.

Inserts can be used for wear on bearing loads in die castings the same as in sand castings.

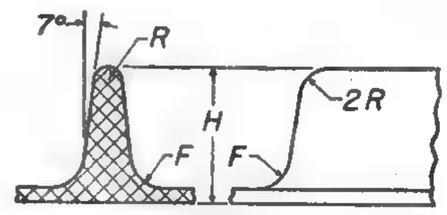
As in other types of casting, close co-operation should be maintained between design engineer and die caster, especially if thick sections or close tolerances are required; in addition, routine factors, such as location of ejector pins, should be discussed in order to produce the best possible casting at the lowest possible cost.

Forgings. Magnesium alloys can be forged readily to give high-strength forgings that have uniform properties, pressure tightness and good fatigue strength. Limitations concerning complexity of shape are the same as for other metals, and design should be as simple as possible to facilitate production.



A	B	R_1	T	R_2
1	1 to 1 1/2	1/4	1/8	1/16
1	1 1/2 to 2 1/2	3/8	5/32	1/16
2	1 1/2 to 2 1/2	7/16	3/16	3/32
2 1/2	2 1/2 to 4	5/8	7/32	1/8

Fig. 4



H	R	F
Up to 5/16	1/16	H
More than 5/16 to 1/2	1/16	3/4 H
More than 1/2 to 3/4	1/16	1/4 to 1/2 H (a)
More than 3/4 to 1 1/2	1/8	1/4 to 1/2 H (a)
More than 1 1/2 to 2	3/16	1/4 to 1/2 H (a)
More than 2 to 2 1/2	1/4	1/4 to 1/2 H (a)
More than 2 1/2 to 3	3/16	1/4 to 1/2 H (a)

(a) 1/4 H when metal is not confined; otherwise 1/2 H

Fig. 5

Fig. 4 Proportions of I-beam sections in magnesium forgings
Fig. 5 Proportions of ribs in magnesium forgings

The principal alloys used for magnesium forgings are AZ61X, AZ80X and TA54. AZ80X has the highest strength of the forging alloys, can be heat treated and aged for improved yield strength and endurance limit, and therefore is used for heavy-duty applications. The creep strength of AZ80X is greatly improved by heat treating and aging. AZ61X has somewhat lower strength but greater forgeability. These alloys can be forged on either hydraulic or mechanical presses. TA54 combines good mechanical properties and forging characteristics and can be forged on upsetters, hammers and rolls, as well as on hydraulic or mechanical presses. Directional properties exist in magnesium forgings, as in other forged metals, with highest properties obtained in the most thoroughly worked sections and in the direction of maximum metal flow.

Since magnesium forgings are generally used for highly stressed applications, good principles of design must be adhered to in order to eliminate stress concentrations. Sharp corners and notches should be avoided by the use

Table XIII
Dimensional Tolerances of Magnesium Forgings[a]

Dimension	Forging Size	Tolerance
Length and width (parallel to parting line)	2 in. or less	± 0.010 in.
	Each inch over 2 in.	± 0.003 in. additional
Thickness (across parting line)	1 lb or less	± 1/32 in.
	More than 1 lb to 5 lb	± 3/64 to 1/16 in.
	More than 5 lb	± 1/16 in.
Straightness	18 in. or less	
	More than 18 in. to 30 in.	± 3/64 in.
	More than 30 in. to 45 in.	± 1/16 in.
	More than 45 in. to 60 in.	± 3/32 in.
	More than 60 in. to 80 in.	± 1/8 in.
Shrinkage[b]	.....	± 0 to 0.002 in. per in.
Mismatch[b][c]	1.5 lb or less	0.015 in.
	More than 1.5 lb to 10 lb	0.024 in.
	More than 10 lb	0.032 in.
Punched holes	.....	± 1/16 in.
Fillet radii	Radii 1/4 in. or less	± 1/64 in.
	Radii more than 1/4 in.	± 1/32 in.
Draft	.....	± 1/2 degree
Trimming tolerance (flash)	.....	flush to 1/8 in. extending

(a) In special instances the tolerances can be reduced. When lower tolerances are required, the forger should be consulted.
(b) Shrinkage and mismatch tolerance should be used in conjunction with each other; not as the sum of two, but as the critical of the two.
(c) Mismatch is caused by a shift of the dies in relation to each other. When mismatch is applied to a dimension, it must be used as a plus or minus. When mismatch is applied as a variation in wall thickness of a circular or boxlike flange, the variation in thickness becomes double the mismatch allowance.

Table XIV. Characteristics of Magnesium Alloy Sheet

Alloy	Temper	Relative Properties[a] Tensile Strength	Tensile Yield Strength	Elongation	Compressive Yield Strength	Hardness	Ultimate Shear Strength	Fatigue Strength	Formability	Weldability	Resistance to Salt Water	Cost
AZ31X	Annealed	C	F	A	E	C	B	C	A	C	B	B
	Hard rolled	B	B	E	B	A	A	A	C	C	B	B

	Hard rolled	C	C	G	C	C	D	D	C	A	C	A

Alloy	Temper	Remarks	Working Temperature Range, deg Fahr
AZ31X	Annealed	Best cold formability with limited gas and arc weldability.	400 to 500
	Hard rolled	Best combination of good fatigue and shear strength and toughness with low notch-sensitivity. Gas and arc weldability are limited.	275 to 300
AZ51X	Annealed	Used for parts requiring medium strength and limited formability, but which are to be arc welded.	550 to 650
	Hard rolled	Best combination of strength, hot formability and arc weldability.	400 max
M1	Annealed	Lowest cost, maximum gas weldability and hot formability, moderate strength.	550 to 650
	Hard rolled	Lowest cost, moderate-strength alloy with heat resistance to creep at elevated temperatures. AZ31X hard rolled is preferred from the standpoint of toughness and general serviceability.	400 max

(a) "A" Rating. Highest property value, best formability, weldability and resistance to salt water. Also lowest cost.

of generous radii and fillets. Fillets must be larger than normal to aid in filling the die and to avoid excessive die wear. Some details of forging design are shown in Fig. 4 and 5.

Dies designed for use on aluminum can often be used for magnesium with only a few changes. Large or complex forgings, however, require dies designed for magnesium. The dimensional tolerances for magnesium forgings are summarized in Table XIII.

Structural Assemblies. Magnesium alloys are well adapted for use in structures that can be fabricated from extrusions, sheet, castings and forgings. The light weight of magnesium alloys often permits the design of magnesium structures that are as stiff and strong as structures made of other metals—and with less weight. Other parts may be designed to have minimum weight-saving but greatly simplified construction and consequent lower cost. The low modulus of elasticity of magnesium alloys can usually be compensated for by increasing depths of section with minimum increase in weight.

Magnesium sheet is available in alloys AZ51X, AZ31X and M1, as hard rolled or annealed material. Sheet is available in a wide variety of sizes and gages. Table XIV summarizes the characteristics of magnesium sheet in regard to workability and weldability.

Magnesium sheet and plate can be readily formed and drawn; arc, gas and spot welded; riveted; and spun. Details concerning these operations are available in the preceding articles in this Handbook (pages 980 to 986).

Extrusions are available in magnesium alloys AZ61X, M1, AZ31X, and AZ80X, in the form of bars, rods, tubing and structural and special shapes. These alloys are furnished as extruded, except AZ80X, which can be heat treated and aged for improved mechanical properties. The characteristics of the extrusions are summarized in Table XV.

The extrusion process not only provides a wide variety of bars, rods, tubes and structural shapes as standard items, but also affords an economical way of producing special sections to meet specific requirements. Many intricate shapes that cannot be produced by other methods can be extruded, thereby simplifying problems of design. The extrusion of such shapes frequently eliminates the necessity of fabricating from standard shapes, thereby making possible more efficient structures at lower cost. Table XVI lists some of the dimensional limitations that apply to the extrusion of magnesium alloys.

Forming. The methods employed for forming magnesium alloys are similar to those used for other metals, except that magnesium alloys are usually formed at elevated temperatures, because of their tendency to work harden when formed at room temperature. Forming at

Table XV. Characteristics of Magnesium Alloy Extrusions[a]

Alloy	Tensile Strength	Tensile Yield Strength	Elongation	Compressive Yield Strength	Hardness	Fatigue Strength	Formability	Weldability	Resistance to Salt Water	Cost
AZ31X	D	D	A	D	D	C	A	B	A	B
AZ61X	C	C	B	C	C	B	B	C	A	C
M1	E	E	D	E	E	D	A	A	B	A
AZ80X	B	B	C	B	B	A	C	D	A	D
AZ80X HTA	A	A	E	A	A	A	D	D	A	E

Alloy	Remarks
AZ31X	Best elongation and cold formability
AZ61X	General-purpose extrusion alloy. Moderate cost and improved strength
M1	Moderate strength alloy with best weldability, hot formability, and lowest cost
AZ80X	Alloy with the highest strength in the extruded condition. Heat treatable
AZ80X HTA	Aged after extrusion to improve strength

(a) "A" Rating. Highest property value, best formability, weldability and resistance to salt water. Also lowest cost.

Table XVI. Dimensional Limitations for Extruded Magnesium Shapes

Over-all dimension, maximum	Approx 7 in.; up to 14.75 in., subject to approval of manufacturer Hollow shapes; approx 5 in.; tubing to 12 in.
Length, maximum	Depends on section; limit of 425 lb max total weight
Thickness, minimum	
Shapes M1, AZ31X	4% of width, min 0.040 in.
AZ61X, AZ80X	6% of width, min 0.060 in.
Hollow shapes, M1, AZ31X	Minimum of 0.060 in.
AZ61X, AZ80X	Minimum of 0.125 in., trial basis
Radii, minimum outside corner	$\frac{1}{16}$ in. recommended
minimum fillet	$\frac{1}{8}$ in. recommended
Blending light to heavy sections	Thin legs attached to thick body should not have length greater than 10 times their thickness

elevated temperatures eliminates the necessity for annealing and redrawing, and for having multiple-stage die equipment for deep-drawn parts. Forming may be done on mechanical and hydraulic presses, press brakes, drop hammers or by hand working.

Sheets of magnesium alloys AZ31X, AZ51X, and M1 are used for formed parts. In the annealed condition these alloys can be hot formed up to the following temperatures: AZ31X, 550 F; AZ51X, 600 F; and M1, 650 F. Heating to the temperature recommended for hot forming has almost no effect on the properties of annealed magnesium alloy sheet at room temperature.

Table XVII shows the approximate bend radii that can be formed in magnesium alloys at various temperatures. The values in the table are based on specimens 6 in. wide, formed in a press brake with a female die made of rubber. Wider sheets will require slightly larger radii than those given; slightly smaller radii can be used if bends are made with the grain instead of across it.

Table XVII
Radii for 90-Deg Bends in Magnesium Alloy Sheet[a]

Alloy	Condition	Minimum[b] Radii at 70 F	Typical Radii at Various Temperatures, deg Fahr 70	300	400	600
AZ31	Annealed	5t	4½t	....	1 to 2t	....
	Hard rolled ..	10t	8t	3 to 4½t	....	....
AZ51	Annealed	9t	7t	....	4 to 6t	2 to 3t
	Hard rolled ..	17t	13½t	....	4½ to 6½t	....
M1	Annealed	7t	5½t	....	3 to 4t	1 to 2t
	Hard rolled ..	12t	9t	....	6 to 7t	....

t = Thickness of sheet

(a) Radii formed in specimens 6 in. wide in square rubber retaining dies

(b) Minimum radius is that which can be formed safely in all sheet with almost no scrap.

Annealed magnesium sheet can be formed readily in the temperature range from 400 to 650 F. The drawability varies with the temper, working temperature and type of equipment used. Maximum drawability is obtained at higher working temperatures and slow working speeds. Reductions as great as 50% can be made in annealed sheet by production methods. Percentage reduction is calculated by the formula

$$R = \frac{D - d}{D} \times 100,$$

where D is the diameter of the blank and d the diameter of the punch. Single cold draws as great as 20% can be made in M1 and AZ31X sheet alloys in the annealed condition, but AZ51X can be reduced only 15% under similar conditions.

Hard rolled sheet can be formed moderately at temperatures from 300 to 400 F, depending on the alloy, but cannot be heated to temperatures for maximum drawability without losing the hard rolled properties. The section on Effect of Temperature discusses more completely the working temperatures for hard rolled sheet. The characteristics of the various sheet alloys and the recommended working temperatures for maximum drawability are indicated in Table XIV.

The tools used in forming magnesium are generally of the same type as those used for other metals. These tools are described in the article on forming magnesium, page 980 in this Handbook.

Joining. Most methods commonly used for joining metals can be used, with minor modifications, for magnesium. Magnesium alloys can be joined by riveting, by arc, gas and spot welding, or by screws and bolts.

Riveting. Riveting is the most widely used method of joining magnesium sheet and extrusions. In general the design of riveted joints follows standard practice.

Aluminum alloy rivets are used and although several rivet compositions are allowable, 56 S is preferred because the possibility of contact corrosion is minimized. Other aluminum rivets can be used where conditions of exposure are not severe. All rivets should be anodized or treated chemically.

Edge distance and minimum spacing, as well as rivet diameters, are governed by the requirements of each design, but certain general rules are established. Figure 6 shows the proportions that give a balanced design when 56 S rivets are used in magnesium sheet. If rough sheared edges are used, the edge distance should be increased by approximately 1/8 in.

Magnesium sheet approximately 0.050 in. thick or less may be readily dimpled for flush riveting, using heated dimpling tools. Sheet thicker than this is countersunk by machine. Countersunk-head rivets with any of the standard included-head angles may be used on machine-countersunk sheet.

Further details of procedure used in riveting magnesium alloys are given in the article entitled "Joining Magnesium Alloys", page 983.

The protection of faying or connecting surfaces of riveted joints is described on page 1005.

Screw Fastenings. Satisfactory joints and connections can be made in magnesium with bolts, screws or studs.

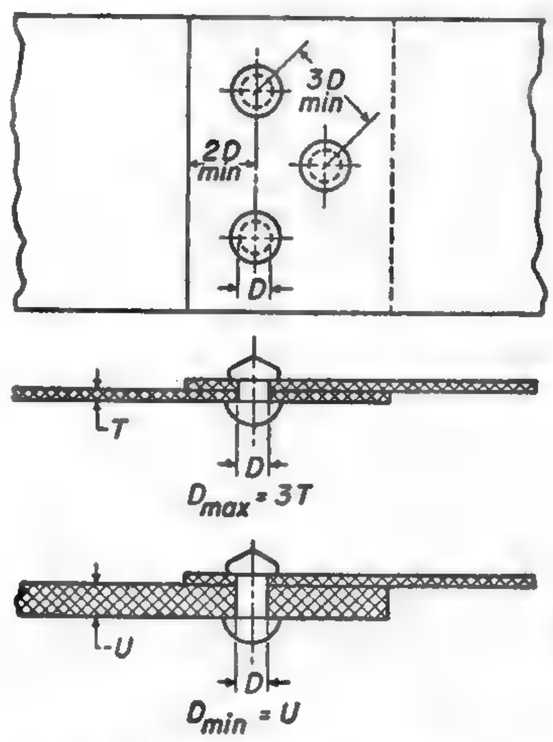

Fig. 6 Proportions of riveted joints in magnesium alloy sheet

In general, a thread length two or three times the diameter of the screw should be provided. When an increase in thread length is not feasible, the diameter of the bolt or stud may be increased or other special features may be utilized to secure adequate shear strength. American Standard coarse threads are preferred and, in addition, they require a smaller engagement. The American Standard fine threads are satisfactory under many conditions, but require the maximum amount of thread engagement. If used as recommended, magnesium threads will sustain a load approximately equal to that which can be held by standard steel bolts. Stress concentrations must be avoided; hence sufficient metal must be left around threaded holes, and a greater number of small screws should be used rather than a few large ones. Examples of properly designed threaded holes are shown in Fig. 2. The use of washers under bolts and nuts is recommended. For heavy service, washers should have an outside diameter two or three times the bolt diameter and a thickness approximately 1/3 the bolt diameter. SAE standard washers will function satisfactorily for moderate service conditions. If parts are to be disassembled frequently, inserts should protect the magnesium threads from wear.

Bolts, studs and washers should be made of anodized aluminum or zinc-plated or cadmium-plated steel. The use of brass or nickel alloys is not recommended because of the possibility of galvanic corrosion.

Arc Welding. Arc welding provides an efficient means of joining wrought magnesium alloys, such as sheet, extrusions and forgings. The molten metal is protected by an inert gas during welding; hence no flux is necessary and there is no danger of flux entrapment. Arc welding can produce welds of high strength at a high rate of production. Table XVIII gives the strengths and joint efficiencies for magnesium arc welds.

Any type of joint commonly used in the arc welding of steel may also be used with magnesium.

Table XVIII. Strength of Arc Welds in Magnesium Alloys

Alloy	Form	Tensile Strength, 1000 psi: Parent Metal	Tensile Strength, 1000 psi: Welded Joint	Average Efficiency of Joint
M1	Annealed sheet	33	20	60
M1	Hard rolled sheet	37	22	60
AZ31X	Annealed sheet	37	32	86
AZ31X	Hard rolled sheet	43	33	77
AZ51X	Annealed sheet	42	41	98
AZ51X	Hard rolled sheet	45	42	93
AZ31X	Extruded	40	34	85
AZ61X	Extruded	45	37	82
AZ80X	Extruded	49	35	71

Heat treatment of arc-welded magnesium structures is recommended in order to relieve the residual stresses set up during welding. The recommended temperatures and times for stress relieving are given in the article entitled "Joining Magnesium Alloys", page 983.

Gas Welding. Magnesium alloys may also be welded by a gas torch. Alloy M1 has superior weldability as compared with AZ31X and AZ51X. The strength of gas welds is somewhat lower than the strength of those made by the arc-welding process.

The molten weld metal must be protected by a suitable flux, which, because of its corrosive nature, must be removed after welding. Cleaning of welds is accomplished by immersing the assembly in hot water and scrubbing, then applying the chrome-pickle treatment, and finally boiling the assembly for 2 hr in a solution of sodium dichromate. Washing followed by immersion in a 1% solution of citric acid will also remove flux effectively. Welded joints must be designed so that they are accessible for the cleaning of the welded seam.

Gas-welded joints are as strong as good cast metal. Efficiencies of welds average 50 to 60% for M1 alloy and 75 to 90% for AZ31X.

Further details concerning welding will be found in the article entitled "Joining Magnesium Alloys", page 983.

Spot Welding. Magnesium alloys can be readily spot welded to produce joints satisfactory for moderately stressed applications.

All wrought magnesium alloys can be joined by this method, but because of limitations of power in welding equipment, 3/16-in. sheet is approximately the maximum thickness that can be spot welded with available equipment. Sections to be welded should be of approximately the same thickness, but if this is impossible, the thicker sheet should be no more than twice the thickness of the thin one. Additional information on the technique of spot welding is given in the article on "Joining Magnesium". Different magnesium alloys may be joined by spot welding, but the differences in electrical conductivity must be taken into consideration and the thicknesses of the sections must be proportioned accordingly. The best welds are secured, however, when alloys of the same composition are welded together.

When spot welds are loaded in direct tension, they should be subjected only to light loads. Shear strengths of spot welds in magnesium alloys are shown in Table XIX. The recommended spacing for spot welds is approximately 16 times the sheet thickness with a minimum of 8 times that thickness. The edge distance should be at least 4 times, preferably 6 times the sheet thickness. Spacing and edge distance should never be less than ¼ in.

After the assembly has been welded, it should be given an appropriate chemical treatment (*see* page 991).

Flash Welding. Wrought magnesium alloys can be flash welded to obtain joints of good strength. Joint efficiencies of approximately 90% have been obtained on alloys AZ31X and AZ61X. Equipment for the flash welding of magnesium is the same as that required for aluminum.

Soldering. Magnesium alloys can be soldered by using special solders developed for the purpose, but soldering is used only for filling surface imperfections.

Adhesive Bonding. Magnesium alloys can be joined by recently developed methods of adhesive bonding. The shear strengths developed depend on the adhesive used, but strengths of approximately 2500 psi can be attained.

Table XIX

Shear Strength of Spot Welds in Magnesium Alloys

Thickness of Single Sheet, inch	Strength, pounds per spot: Alloy M1a	Strength, pounds per spot: Alloy AZ51Xh
0.020	150	200
0.025	175	250
0.032	200	330
0.040	260	415
0.051	350	520
0.064	470	650
0.072	550	730
0.081	650	830
0.091	775	940
0.102	885	1050
0.114	1060	1175

The Metallography of Magnesium and Magnesium Alloys

By A. M. Montgomery*

SPECIMENS for microscopic examination should be chosen with care so as to be representative. Thus, both longitudinal and transverse samples of sheet should be examined, edge and center sections of large ingots should be considered, the mouth of a casting crack should be studied as the point of origin, and so on. The specimen should be removed from its surroundings with the least possible rough handling, since cold work may alter the microstructure and complicate the subsequent examination. Usually a light band saw or hack saw is satisfactory for this purpose.

* Head, Metallographic Department, Cleveland Research Division, Aluminum Research Laboratories, Aluminum Company of America

Prepared for the Magnesium Committee

Polishing. Specimens that are too small to be held conveniently during polishing, or that have some edge characteristic to be studied, may be mounted in one of the common plastics—bakelite, lucite, tenite or the like. Wood-filled bakelite, especially if improperly cured, may cause some staining when the mounted sample is immersed in glycol etch. Clear amber bakelite produces mounts with an excellent bond. If plastic mounting equipment is not available, specimens can be mounted in sulfur. A sample is placed on a steel or glass plate inside a shallow metal ring, preferably of magnesium or aluminum, and molten sulfur is poured over the sample to fill the ring. The ring may be removed after the sulfur has solidified. Sheet samples approximately ¾ in. long by ½ in. wide may be bolted to-

gether to form packs, which can be polished satisfactorily.

The rough preparation of mounted or unmounted specimens consists of filing on a single-cut file of second-cut fineness. It is preferable to clamp the file in a vise and draw the sample over it by hand rather than to clamp the sample and file it. Clamping the sample tightly in a vise may induce cold work and lead to an erroneous interpretation. After being filed flat, the specimen is ground on a series of metallographic polishing papers. Good results are obtained by grinding successively on No. 120 abrasive cloth, No. 1 and No. 000 abrasive papers, all moistened with kerosene. The kerosene prevents clogging of the papers and serves as a coolant. It is preferable to grind the specimen by hand with the papers placed on a piece of plate glass, although some time may be saved by mounting the papers on a wheel that can be rotated at about 500 rpm. If the papers are mounted, care should be taken that the specimen does not become overheated during grinding, because this may affect the microstructure and may cause a plastic mount to retract from the metal insert. The specimen should be turned 90 deg in progressing from one paper to the next, and should be cleaned with a cloth saturated with kerosene or gasoline, so as to prevent coarse abrasive particles from being carried to fine papers.

The specimen is rough polished on a wheel that may be equipped with various cloths (Gamal, velvet, Vel-chamee, duvetyn or broadcloth). A tap-water suspension of 600 alundum powder (about 35 g in 500 ml) is employed as an abrasive. The specimen is slowly revolved counter to the direction of rotation of the wheel, which is rotating at a speed of approximately 500 rpm. This polishing should not be prolonged unnecessarily or marked relief of the manganese constituents will result. When the polishing is completed, mild soap is applied to the wet wheel. The specimen is then retouched on the soapy wheel for a few revolutions. This removes clinging alundum particles and leaves the polished surface bright and clean. The sample and the hands of the polisher should be carefully washed to prevent carrying abrasive to the final wheel.

The final polishing is done on a Vel-chamee or a silk velvet cloth with short pile which has been softened by boiling 30 min in distilled water acidulated with a few drops of hydrochloric acid. Merck's USP heavy grade of magnesium oxide is recommended as an abrasive. This can be used after sifting through a 100-mesh sieve. A small quantity is placed on the wheel and moistened with *distilled* water. This paste is then worked into the cloth. Polishing is begun at about 250 rpm by revolving the sample slowly counter to the direction of rotation of the wheel. The wheel speed is gradually decreased, the pressure on the sample is diminished and the paste is diluted with distilled water as the polishing progresses. Final polishing speed may be as low as 50 rpm. The abrasive should not be entirely washed away during polishing or the sample will stain. The sample is then immersed in hot, flowing distilled water for a moment and blown dry. When not in use, the final polishing cloth should be kept moist and covered to prevent the formation of hard magnesium carbonate particles and the collection of abrasive dust particles.

In all the grinding and polishing operations it is recommended that the time of grinding or polishing be twice as long as that necessary to remove the scratches from the preceding operation that are visible to the naked eye. This insures the removal of sufficient distorted material from the surface before the next operation.

Magnesium and magnesium alloys can be polished electrolytically by Jacquet's method to yield excellent surfaces free from flow. A solution consisting of 375 ml of orthophosphoric acid (H_3PO_4), density 1.71, and 625 ml of ethyl alcohol, 95% by volume, is used as an electrolyte. The magnesium specimen serves as the anode while 18-8 stainless steel or nickel sheet is the cathode. The surface of the sample is ground down as described for mechanical polishing, through at least the 000 abrasive paper. Further mechanical polishing decreases the duration of electrolytic polishing and the amount of relief obtained. Manganese particles, magnesium silicide, and massive Mg_4Al_3 eutectic particles are not appreciably dissolved during electrolysis. A closed-circuit voltage between cathode and anode of 1.5 volts is applied with a current density of 0.5 to 1.0 amp per sq dm. The duration of the electrolysis is from 3 min to 1 hr, depending on the extent of previous mechanical preparation. The sample should be removed from the solution while the current is on, washed immediately in running water and dried. It may be examined as polished or etched.

The preparation of large samples for macroscopic examination is best begun by machining a flat surface of the specimen on a lathe or shaper using a high speed, a fine feed and a sharp tool. The machining marks should be removed by rubbing on No. 1 metallographic paper moistened with kerosene. The specimen is then rotated 90 deg and rubbed on ■ 00 or 000 abrasive paper with kerosene to remove the previous scratches. If possible, it is desirable to continue the polishing operations outlined for microscopic test specimens, at least through the alundum wheel. If not, the macro samples can be polished chemically with good results. First, however, the kerosene should be removed from the sample with gasoline or other suitable solvent. The chemical polishing then consists of swabbing the ground surfaces for 30 to 60 sec with a solution of 15% nitric acid in denatured alcohol. This yields a clean, bright surface for macro-etching.

Etching. The chemical characteristics of magnesium preclude the use of strong mineral acids for etching, except in weak solutions. Organic acids in aqueous solutions, inorganic acids in organic solutions, aqueous salt solutions and combinations of these are used for etching. The etching solutions listed in Table I are recommended.

Table I. Etching Solutions for Microscopic Examination

Composition	Use	Procedure
1 ethylene or diethylene glycol 75 ml, distilled water 24 ml, concentrated nitric acid 1 ml	castings—any condition, all aged alloys, best general etch	Pour solution on sample, blow gently to disengage bubbles, wash in hot water and blow dry. Etch as-cast or aged specimens ■ to 10 sec. Etch solution heat treated specimens no longer than 2 min.
2 ethylene or diethylene glycol 60 ml, glacial acetic acid 20 ml, concentrated nitric acid 1 ml distilled water 19 ml	solution heat treated castings and certain wrought alloys	Pour solution on sample, blow gently to disengage bubbles. Etch for 5 to 30 sec, wash in hot water and blow dry.
3 tartaric acid 10 g, distilled water 90 ml	solution heat treated castings and certain wrought alloys	Swab for 5 to 30 sec, wash in hot water and blow dry.
4 concentrated nitric acid 2 ml, denatured alcohol 98 ml	general etch	Immerse 5 to 30 sec, wash in hot water and blow dry.
5 citric acid 10 g, distilled water 90 ml	solution heat treated castings and certain wrought alloys	Swab for 5 to 30 sec, wash in hot water and blow dry.
6 hydrofluoric acid (48%) 1 ml, distilled water 99 ml	used to distinguish between Mg-Al and Mg-Al-Zn constituents. Darkens Mg-Al	Immerse 20 to 30 sec, wash in hot water and blow dry.
7 glacial acetic acid 3 ml, 5% nickel nitrate Ni $(NO_8)_2$. 6 H_2O in water 5 ml, distilled water 92 ml	grain boundary etch for sheet alloys low in aluminum	Immerse 3 to 5 sec, wash in hot water and blow dry.
8 orthophosphoric acid (sp gr 1.70) 0.7 ml picric acid 4.0 g 95% ethanol 100 ml	to determine the amount of massive compound	Immerse face-up with gentle agitation until specimen darkens; wash in ethanol and dry.

Table II. Etching Solutions for Macroscopic Examination

Composition	Use	Procedure
1 glacial acetic acid 10 ml, distilled water 90 ml	grain size of pure magnesium	Swab for 10 sec to 2 min.
2 glacial acetic acid 10 ml, denatured alcohol 90 ml, picric acid 10 g	grain size of as-cast or heat treated castings	Flow etch on polished surface, etch 15 sec to 1 min after red color is obtained, wash off in hot water and blow dry
3 chromic acid (CrO_3) 12 g, concentrated nitric acid 15 ml, distilled water 85 ml	grain size of some solution heat treated and aged cast alloys that do not respond to solution No. 2	Immerse sample in etch, wash immediately in hot water and blow dry
4 same as 3 for high-aluminum alloys increase water to as much as 150 ml	grain flow of forging alloys	Immerse from 10 to 30 sec, wash immediately but carefully in hot water and blow dry. Do not wash etching products off the surface.
5 tartaric acid 10 g, distilled water 90 ml	grain flow of wrought alloys	Immerse 10 to 20 sec, wash in hot water, blow dry. Do not wash etching products off the surface.
6 concentrated nitric acid 15 ml, distilled water 85 ml	wrought Mg-Mn alloys	Etch 10 to 30 sec, wash in hot water and blow dry.
7 ammonium persulfate 10 g, distilled water 90 ml	Mg-Mn wrought alloy ingots	Etch until brown deposit forms; swab off until desired contrast is obtained.

The macro-etches are generally used to reveal the grain size in casting alloys and the grain flow in wrought products. In castings the presence of porosity, cracks, and entrapped oxide films may also be shown. The presence of a segregated constituent that contains aluminum is difficult to reveal unless the material has been aged. Recommended etching solutions for macroscopic examination are listed in Table II.

Interpretation of Microstructures. *Effect of Alloy Additions.* 1 Aluminum combines with magnesium in magnesium-base alloys to form a phase variously described as Mg_3Al_2, Mg_4Al_3, $Mg_{17}Al_{12}$, and β(Mg-Al). This phase forms a eutectic system with magnesium. Magnesium can retain as much as 12.7% Al in solid solution at the eutectic temperature. However, in commercial solid-solution alloys, some eutectic is usually present in the as-cast condition because of the coring effect. The eutectic does not exhibit the familiar lamellar structure, but is of the divorced type consisting of massive white particles of Mg_4Al_3 in a solid solution matrix. The Mg_4Al_3 particles of the eutectic occur chiefly along grain boundaries and to a lesser extent within the grains. Metallographic polishing causes the particles to stand in slight relief above the matrix. The phase Mg_4Al_3, precipitated from the solid solution by slow cooling from solidification or fabrication temperatures or by commercial precipitation treatment, appears in a lamellar arrangement similar to pearlite in steel. This precipitate forms first along grain boundaries and around undissolved intragranular particles. Precipitate formed at temperatures lower than commercial aging temperatures is considerably finer than the pearlitic precipitate, is globular and is more generally distributed throughout the grains. Precipitate formed at high temperatures is coarse and may assume an obvious crystallographic pattern.

Zinc in commercial magnesium alloys does not occur as a binary phase. Zinc is usually dissolved in the magnesium matrix and in the magnesium-aluminum phase in ternary alloys. Occasionally particles of the ternary phase $Mg_3Al_2Zn_3$ may be present and can be distinguished from Mg_4Al_3 by the 0.5% hydrofluoric acid etch.

3 Manganese in binary alloys occurs in solid solution or as hard gray angular particles of elemental manganese (probably containing some magnesium in solid solution). The particles stand out in pronounced relief and, unless properly polished, appear spheroidal. In magnesium-aluminum-manganese alloys, manganese also occurs as a manganese-aluminum phase. Bulian and Fahrenhorst[2] report that this phase appears as needles. However, such needle-like constituents are rare.

4 Tin is slightly soluble in magnesium. Beyond the limit of solubility, tin forms Mg_2Sn, which appears bluish gray as polished. Etching may produce a color, tan to deep blue, depending on the time of the reaction.

5 Calcium, usually present in very small quantities, is chiefly in solid solution. If present in amounts greater than approximately 0.1%, calcium occurs as Mg_2Ca. However, calcium in this amount combines first with the silicon to change the appearance of the Mg_2Si present. In magnesium-aluminum alloys, besides altering the shape of the Mg_2Si, calcium forms an irregular gray constituent closely associated with the Mg_4Al_3 phase.

6 Silicon is the major impurity in magnesium alloys. Silicon is only slightly soluble in solid magnesium and generally occurs as Mg_2Si, which is easily recognized by the distinctive blue color in the as-polished condition. It is angular in form and shows slight relief after polishing. In alloys containing approximately 0.5% Si or more, the particles form imperfectly, yielding a "Chinese script" structure.

General Microscopic Features. Magnesium alloys deform plastically by slip and twinning. As in other metals, slip lines are visible only when a polished surface is deformed or when a deformed specimen has been given a subsequent heat treatment to cause precipitation along the slip planes. Twins, on the other hand, are not destroyed by polishing and may be recognized by their lenticular shape after etching.

Shrinkage and gas porosity, both singly and combined, may form voids in magnesium castings. If the resulting voids are small and dendritic, they are termed "microporosity". Microporosity is chiefly intergranular but may be interdendritic. If the voids are distinctly spherical, it is an indication that the alloy contained excessive gas.

Eutectic melting or incipient fusion occurs if solution heat treatment is performed at a temperature higher than the eutectic temperature. This phenomenon may be detected microscopically by the formation, along the grain boundary, of angular deposits of eutectic material, varying from coarse single particles to extremely fine unresolved deposits, depending on the temperature and the duration of heating.

The absence of a protective atmosphere (usually 0.5% SO_2) during solution heat treatment causes an effect termed "high-temperature oxidation" or "burning". The eutectic deposits are attacked preferentially and the effect proceeds inward from the surface. This high-temperature oxidation is particularly rapid if eutectic melting is present simultaneously. Fusion voids unaccompanied by oxidation of the eutectic can also result from improper heat treatment of castings. High-temperature oxidation and fusion voids are recognizable under the microscope by small voids, chiefly intergranular, which are similar in appearance to microporosity, though microporosity is generally more irregular in outline.

Voids of doubtful origin in magnesium-aluminum alloys can be identified by a partial solution heat treatment, followed by a precipitation treatment to reveal the distribution of Mg_4Al_3 constituent. If no precipitate is formed in the immediate vicinity of the voids, the voids are definitely attributable to microporosity. However, the presence of precipitate in this location does not prove that the voids are caused by high-temperature oxidation.

Oxide films are occasionally found as thin, dark irregular lines in the microstructure of castings. Films formed in the crucible are usually thick and clustered and may contain entrapped manganese particles. Films are thin and extended when produced by the breaking of the oxide "tube" in pouring or by turbulence in filling the mold.

The grain size of magnesium alloys is most easily deter-

mined by the microscopic comparison of suitably etched metallographic specimens with micrographs of samples of known grain size. Grain size can also be determined by Heyn's intercept method or by Jeffries' planimetric method, in the order of increasing accuracy and time required. The results are expressed as the number of grains per unit area or as the average diameter in inches or millimeters. Occasionally samples may not reveal an obvious grain size because of the presence of confusing subgrain boundaries. Such specimens should be given a precipitation heat treatment and should then be examined microscopically under polarized light or with the sensitive tint attachment of some microscopes. The individual grains will have a distinct shade or color, depending on their orientation, and the size and number can be determined readily.

PROPERTIES OF MAGNESIUM AND MAGNESIUM ALLOYS

Magnesium (99.80 Mg)

COMPILED BY R. A. TOWNSEND*

A *1 Common name.* Pure magnesium
2 Trade name. Mazlo AM2S
3 ASTM number. B 92-45
4 Government number. 46M10 (ingot), 57-21-1 (powder)

B *1 Typical uses.* Alloying agent, deoxidizer, getter in vacuum tube manufacture, dry electric current rectifiers, pyrotechnics
2 Precautions in use. Magnesium powder must be kept dry.

C *1 Density* at 20 C (68 F). 1.74 g per cu cm (0.0628 lb per cu in.)
5 Solidification shrinkage. 3.97 to 4.2%
6 Volume change during cooling from 650 C (solid) to minus 20 C. 2%

D *1 Melting point.* 650 C (1202 F)
4 Boiling point at 760 mm Hg. 1107 C (2025 F)
6 Thermal expansion[3] (polycrystalline) at 40 C (104 F). 0.000026 per °C*

$$L_t = L_0\ [1 + (24.80t + 0.00961t^2) \times 10^{-6}]$$

7 Thermal expansion along *a* axis, 15 to 35 C (59 to 95 F). 0.0000271 per °C
9 Thermal expansion along *c* axis, 15 to 35 C (59 to 95 F). 0.0000243 per °C
11 Specific heat at 25 C (78 F). 0.25 cal per g*
13 Latent heat of fusion. 89 cal per g*
15 Latent heat of vaporization. 1316 cal per g
16 Thermal conductivity at 18 C (64 F). 0.376 cal/sq cm/cm/°C/sec, approx
18 Heat of combustion. 5995 cal per g
19 Recrystallization temperature. 177 C (350 F) for one-hour anneal after 30% cold reduction (99.85% Mg), 93 C (200 F) for one-hour anneal after 30% cold reduction (99.99% Mg).

E *1 Volume conductivity* referred to standard copper. 38.6%
2 Electrical resistivity (polycrystalline) at 20 C (68 F). 4.46 microhm-cm
3 Electrical resistivity along *a* axis, at 18 C (64 F). 4.54 microhm-cm
Electrical resistivity along *c* axis, at 18 C (64 F). 3.77 microhm-cm
5 Temperature coefficient of electrical resistivity at 20 C (68 F). 0.01784 microhm-cm per °C
6 Temperature coefficient of electrical resistivity along a axis at 18 C (64 F). 0.01889 microhm-cm per °C; along *c* axis at 18 C (64 F), 0.01610 microhm-cm per °C

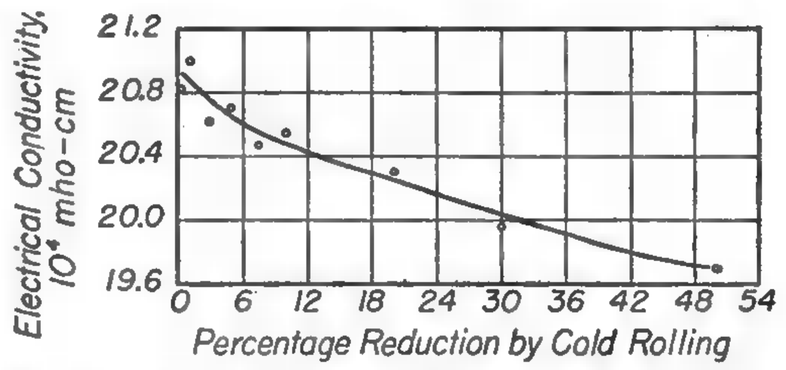

Fig. 1 Effect of cold rolling on the electrical conductivity of cell magnesium

8 Electrical conductivity versus plastic deformation. See Fig. 1.†
10 Electrochemical equivalent. 126 mg per coulomb
11 Electrolytic solution potential versus saturated calomel electrode. 1.63 volts.
Measured in aerated 3% NaCl solution against a saturated calomel electrode at room temperature (20 to 30 C). Surface aloxite ground. Measurements made after 24 hr.
14 Hydrogen overvoltage.[1] 0.30 volts for cast metal

F *1 Reflectivity.*[4] 72%, at $\lambda = 0.500\ \mu$; 74%, at $\lambda = 1.00\ \mu$; 80%, at $\lambda = 3.0\mu$; 93%, at $\lambda = 9.0\mu$

G *2 Magnetic susceptibility* (specific). 0.55×10^{-6} cgs
3 Magnetic permeability 1.000012 cgs

H *1 Velocity of sound.* 15,700 ft per sec

J *1 Crystal structure.* Close-packed hexagonal, $a = 3.2033$ kX; $c = 5.1998$ kX*†
2 Slip plane. Primary (0001) 20 to 225 C (68 to 437 F)*
Secondary $(10\bar{1}1)$ above 225 C (above 437 F)*
3 Twinning plane. $(10\bar{1}2)$*
4 Cleavage plane. (0001)*
5 Minimum interatomic distance. 3.190 kX

K *Mechanical properties.* See Table I.
4 Machinability index[5] (free-cutting brass = 100). 500*
8 Surface tension (liquid).[7]
at 681 C (1258 F). 563 ergs per sq cm
at 894 C (1641 F), 502 ergs per sq cm

* American Magnesium Corporation, Cleveland
* Indicates that values for all magnesium alloys are approximately the same.

† Unpublished data from Dow Chemical Company

Table I. Mechanical Properties of Pure Magnesium

Form	Section	Tensile Strength, psi	Yield Strength, (a) psi	Elongation, percentage	Rockwell Hardness, E scale	Brinell Hardness Number, (b)	Modulus of Elasticity, psi	Modulus of Rigidity, psi	Poisson's Ratio	Shear Strength, psi	Endurance Limit, (c) psi
Sand cast.....	½ in. diam	12,000	3,000	6	minus 16	30	6,500,000	2,400,000	0.35	.....	.....
Annealed	sheet	27,000	14,000	16	36	40	6,500,000	2,400,000	0.35	17,000	9,000
Hard rolled...	sheet	37,000	27,000	9	59	50	6,500,000	2,400,000	0.35	.....	.....

(a) 0.2% offset. (b) 500-kg load, 10-mm ball. (c) Based on 500,000,000 cycles of repeated flexure of a cantilever specimen.

L *2 Radiography.* Type A film with no intensifying screen, 140-kv machine operating at 36-in. focal distance.*

Section, in.	Kilovolts	Milliamperes	Time, min
0.25	50	6.0	1.0
0.50	50	10.0	1.0
0.75	60	10.0	1.0
1.00	70	10.0	1.0
1.25	80	8.7	1.0
1.50	90	7.6	1.0
1.75	100	6.7	1.0
2.00	110	6.0	1.0
2.25	120	5.6	1.0
2.50	130	5.0	1.0
2.75	140	4.65	1.0
3.00	140	5.0	1.1

M *Composition limits* (ASTM B 92-45 for ingot and stick).

Pure magnesium sheet, wire, extrusions, ribbon, and ingot and stick for remelting: 99.80% Mg min; *impurities (max),* 0.02% Cu, 0.001% Ni, 0.20% total of Al, Cu, Fe, Mn, Ni and Si. Powder, Grade C: 96% Mg min; *impurities (max),* metallic Fe 0.05%, insoluble residue 0.25%, Si 0.10%, grease and oil 0.020%, alloyed iron and aluminum as oxides 0.40%.

2 Consequence of exceeding impurity limits. Excessive nickel, copper and iron decrease resistance to corrosion.

N *2 Casting.* (ingot) 650 to 705 C (1200 to 1300 F)

6 Precautions in melting. Molten metal must be kept covered with flux. Crucibles having clay as a bond are attacked by molten magnesium; steel crucibles are not. Low-carbon, welded or cast crucibles are almost always used. Impurities may be picked up from nickel steel crucibles. Moisture should be avoided.

7 Hot working temperature range. 232 to above 482 C (450 to above 900 F)

9 Annealing temperature. 343 C (650 F)

10 Maximum reduction between anneals. 50 to 60%.

17 Joining.

Rivet composition. Aluminum alloy 56 S-H12

Oxyacetylene welding with pure magnesium welding rod, magnesium welding flux and neutral flame.

Resistance welding is satisfactory.

Helium-arc welding is preferred. Use pure magnesium welding rod and no flux.

* Indicates that values for all magnesium alloys are approximately the same.

Mg – 4 Al – 0.2 Mn

COMPILED BY R. A. TOWNSEND*

A *2 Trade name.* Mazlo AM244

B *1 Typical uses.* Low-stressed sand castings that must be leakproof

C *1 Density* at 20 C (68 F). 1.76 g per cu cm (0.064 lb per cu in.)

D *1 Liquidus temperature.*[6] 630 C (1165 F)

2 Solidus temperature.[6] 563 C (1045 F)

3 Minimum "burning" (liquation) temperature.[8] 543 C (1010 F)

6 Thermal expansion[3] at 40 C (104 F). 0.000026 per °C*

11 Specific heat at 25 C (78 F). 0.25 cal per g approx*

13 Latent heat of fusion. 89 cal per g approx*

16 Thermal conductivity 100 to 300 C (212 to 572 F). 0.23 cal/sq cm/cm/°C/sec approx

E *1 Volume conductivity* referred to standard copper. 17.2% for cast metal

2 Electrical resistivity at 20 C (68 F). 10.0 microhm-cm for cast metal

11 Electrolytic solution potential versus saturated calomel electrode. 1.54 volts. Same test conditions as for pure magnesium.

14 Hydrogen overvoltage.[1] 0.04 for cast metal

K *Mechanical properties.* (Sand cast, ½-in. diam specimens): tensile strength 24,000 psi; yield strength 0.2% offset) 9000 psi; elongation 6%; Brinell hardness number 44; Rockwell hardness E 46; modulus of elasticity 6,500,000 psi; impact value, Charpy 2.0 ft-lb; shear strength 14,000 psi; Poisson's ratio 0.35; modulus of rigidity 2,400,000 psi; compressive yield strength 9000 psi.

4 Machinability index[5] (free-cutting brass=100). 500*

L *2 Radiography.* Refer to "Magnesium (99.80 Mg)".*

M *Composition limits.* Sand cast (A4): *components,* 3.5 to 5.0 Al; 0.20% min Mn; *impurities,* 0.3% max Zn; 0.3% max Si; 0.05% max Cu; 0.01% max Ni; others (total) 0.3% max.

2 Consequences of exceeding impurity limits. The resistance to corrosion decreases with increasing amounts of copper and nickel. Increased amounts of zinc affect the pressure tightness and the heat treatment. More than 0.50% Si decreases elongation.

N *1 Melting temperature.* 563 to 630 C (1045 to 1165 F)

2 Casting temperature range. (sand) 735 to 843 C (1350 to 1550 F) (ingot) 649 to 705 C (1200 to 1300 F)

3 Alloying. Add aluminum as Al or Al-Mn. Add manganese as 95 Al-5 Mn.

5 Type of flux. Magnesium melting flux.

6 Precautions in melting. Refer to corresponding section for pure magnesium.

17 Joining.

Oxyacetylene welding with AZ61X welding rod, magnesium welding flux, neutral flame.

Resistance welding is satisfactory.

Helium-arc welding is the preferred method. Use same welding rod as for torch welding. Use no flux.

11 Specific heat at 25 C (78 F). 0.25 cal per g approx*
13 Latent heat of fusion. 89 cal per g approx*
16 Thermal conductivity 100 to 300 C (212 to 572 F). 0.17 cal/sq cm/cm/°C/sec, approx
E *1 Volume conductivity* referred to standard copper. (approximate values) as cast 11.5%; solution treated 9.9%; solution treated and aged 12.3%; wrought 9.7%.
2 Electrical resistivity at 20 C (68 F). (approximate values) as cast 15.0 microhm-cm; cast and solution treated 17.5 microhm-cm; cast, solution treated and aged 14.0 microhm-cm; wrought 18.0 microhm-cm.
11 Electrolytic solution potential versus saturated calomel electrode. 1.57 volts for cast metal. Same test conditions as for pure magnesium.
14 Hydrogen overvoltage. 0.27 for extruded metal; 0.06 for cast metal.
K *Mechanical properties.* See Tables I and II.

All forms. Modulus of elasticity 6,500,000 psi
Modulus of rigidity 2,400,000 psi
Poisson's ratio 0.35

Perm mold or SC HT. Bearing ultimate strength (3/16 in. pin diam) 69,000 psi
Bearing yield strength (3/16 in. pin diam) 45,000 psi

Perm mold or SC HTA. Bearing ultimate strength (3/16 in. pin diam) 81,000 psi
Bearing yield strength (3/16 in. pin diam) 68,000 psi

4 Machinability index[5] (free-cutting brass = 100). 500*
L *2 Radiography.* Refer to "Magnesium (99.80 Mg)".*
M *Composition limits.* (ASTM B 80-47T for sand castings, ASTM B 199-47T for permanent mold castings, American Magnesium Corporation AM-C59 S for extrusions, ASTM B 93-47T for ingot). *See* Table III.
2 Consequences of exceeding impurity limits. The resistance to corrosion decreases with increasing amounts of copper, nickel and iron. Increased amounts of zinc affect the pressure tightness and the heat treatment. More than 0.50% Si decreases elongation.
N *1 Melting temperature.* 464 to 594 C (867 to 1101 F)
2 Casting temperature range.
(sand) 735 to 843 C (1350 to 1550 F)
(chill) 649 to 816 C (1200 to 1500 F)
(ingot) 649 to 705 C (1200 to 1300 F)
3 Alloying. Add aluminum as Al or Al-Mn. Add manganese as 95 Al-5 Mn.
6 Precautions in melting. Refer to corresponding section for pure magnesium.
7 Hot working temperature. 232 to 399 C (450 to 750 F)
8 Shortness range. Above 432 C (above 810 F) (wrought)
9 Annealing temperature. 343 C (650 F) (wrought)
15 Heat treatment (castings).

Purpose	Temperature °C	Temperature °F	Time, hr	Cooling
Solution treatment	421	790	20	strong air blast
Artificial aging (partial)	163	325	12	still air
Artificial aging (complete)	177	350	20	still air or oven
Stabilizing[a]	260	500	4	still air

(a) The stabilizing heat treatment is used on castings in the as-cast or solution heat treated conditions to minimize growth when the castings are used at elevated temperatures.

NOTE. For solution treatment. Alloy A10 requires an atmosphere at least 0.5% SO_2. For other heat treatments air is satisfactory.

17 Joining.
Rivet compositions. Aluminum alloy 56 S-H12 for extrusions
Oxyacetylene welding with AZ101 for extrusions, magnesium welding flux, neutral flame.
Helium-arc welding is suitable for extrusions. Use same welding rod as for torch welding. Use no flux.

Mg – 6 Al – 3 Zn – 0.2 Mn

COMPILED BY H. W. SCHMIDT*

A *2 Trade name.* Dowmetal H, Mazlo AM265
3 ASTM number. Alloy AZ63, specification B 80-47T
4 Government number. AN-M-36, grade A; Army 57-74-1
5 Other designations. SAE 50, AMS 4420, AMS 4422, AMS 4424
6 Foreign equivalents. Elektron AZG, British DTD 59A (as cast), DTD 289 (HT)

B *1 Typical uses.* General sand-casting alloy having good strength properties with best ductility and toughness.

C *1 Density* at 20 C (68 F). 1.84 g per cu cm (0.066 lb per cu in.)

D *1 Liquidus temperature.*[6] 610 C (1130 F)
2 Solidus temperature.[6] 455 C (850 F)
3 Minimum "burning" (liquation) temperature.[6] 363 C (685 F)
6 Thermal expansion[6] 20 to 100 C (68 to 212 F) 0.000026 per °C*

$$L_t = L_0 [1 + (24.80t + 0.0961t^2) \times 10^{-6}]$$

11 Specific heat at 25 C (78 F). 0.25 cal per g approx*
13 Latent heat of fusion. 89 cal per g approx*
16 Thermal conductivity 100 to 300 C (212 to 572 F). 0.18 cal/sq cm/cm/°C/sec

E *1 Volume conductivity* referred to standard copper. As cast 15.0%; heat treated 12.3%; heat treated and aged 13.8%
2 Electrical resistivity at 20 C (68 F). As cast 11.5 microhm-cm; heat treated 14.0 microhm-cm; heat treated and aged 12.5 microhm-cm.
11 Electrolytic solution potential versus saturated calomel electrode. 1.57 volts. Same test conditions as for pure magnesium.
14 Hydrogen overvoltage.[1] 0.34 for cast metal

* Dow Chemical Company, Midland, Mich.
* Approximately the same as for pure magnesium

K *Mechanical properties.* See Tables I and II.
All forms. Modulus of elasticity 6,500,000 psi
Modulus of rigidity 2,400,000 psi
Poisson's ratio 0.35
4 Machinability index[5] (free-cutting brass = 100). 500*

L *2 Radiography.* Refer to "Magnesium (99.80 Mg)".*

M *Composition limits* (ASTM B 80-47T)
Sand castings and welding wire (both AZ63): *components,* 5.3 to 6.7% Al, 2.5 to 3.5% Zn, 0.15% Mn min; *impurities (max),* 0.3% Si, 0.25% Cu, 0.01% Ni, 0.3% total others. Ingot: *components,* 5.5 to 6.5% Al, 2.7 to 3.3% Zn, 0.18% Mn min; *impurities (max),* 0.2% Si, 0.20% Cu, 0.01% Ni, 0.3% total others.
2 Consequences of exceeding impurity limits. Silicon causes brittleness. Excessive copper affects mechanical properties and resistance to corrosion. Nickel affects resistance to corrosion.

N *1 Melting temperature.* 454 to 613 C (850 to 1135 F)
2 Casting temperature range.
(sand) 734 to 842 C (1350 to 1550 F)
(chill) 648 to 815 C (1200 to 1500 F)
(ingot) 648 to 704 C (1200 to 1300 F)
3 Alloying. Add aluminum as Al or Al-Mn. Add zinc as Zn. Add manganese as 95 Al-5 Mn.
5 Type of flux. Magnesium melting flux
6 Precautions in melting. See "Magnesium (99.80 Mg)".

O *15 Heat treatment.*

Purpose	Temperature, °C	Temperature, °F	Time, hr	Cooling
Solution heat treatment	388	730	10	air
Aging	191	375	18	air or furnace
Stabilizing[a]	260	500	4	air

(a) The stabilizing heat treatment is used on castings in the as-cast or solution heat treated conditions to minimize growth when the castings are used at elevated temperatures.

NOTE. For solution heat treatment, Alloy AZ63 requires an atmosphere at least 0.5% SO_2. For other heat treatments air is satisfactory.

References. *See* "Magnesium (99.80 Mg)".

	316	600	8,200	5,600	20.0

Mg–9 Al–2 Zn–0.1 Mn

COMPILED BY R. A. TOWNSEND*

A *2 Trade name.* Mazlo AM260, Dowmetal C
3 ASTM number. Alloy AZ92, specifications B 80-47T and B 199-47T
4 Government number. AN-M-36, alloy C; 57-74-2; 11349.
5 Other designations. AMS 4430, AMS 4434, AMS 4484, SAE 500, SAE 503

B *1 Typical uses.* Pressure-tight sand and permanent mold castings with high tensile strength and good yield strength

C *1 Density* at 20 C (68 F). 1.82 g per cu cm (0.066 lb per cu in.)

D *1 Liquidus temperature.*[6] 593 C (1100 F)
2 Solidus temperature.[6] 443 C (830 F)
3 Minimum "burning" (liquation) temperature.[6] 410 C (770 F)
6 Thermal expansion[3] at 40 C (104 F). 0.000026 per °C*
11 Specific heat at 25 C (78 F). 0.25 cal per g approx*
13 Latent heat of fusion. 89 cal per g approx*
16 Thermal conductivity 100 to 300 C (212 to 572 F). 0.17 cal/sq cm/cm/°C/sec approx

E *1 Volume conductivity* referred to standard copper. (approximate values) As cast 12.3%; solution treated 10.5%; solution treated and aged 12.3%.
2 Electrical resistivity at 20 C (68 F). As cast 14.0 microhm-cm; solution treated 16.5 microhm-cm; solution treated and aged 14.0 microhm-cm.
11 Electrolytic solution potential versus saturated calomel electrode. 1.56 volts. Same test conditions as for pure magnesium.
14 Hydrogen overvoltage.[1] 0.30 for cast metal

* American Magnesium Corporation, Cleveland
* Approximately the same as for pure magnesium

K *Mechanical properties.* See Tables I and II.
All forms. Modulus of elasticity 6,500,000 psi; Modulus of rigidity 2,400,000 psi; Poisson's ratio 0.35
4 Machinability index[5] (free-cutting brass = 100). 500*

L *2 Radiography.* Refer to "Magnesium (99.80 Mg)".*

M *Composition limits* (ASTM AZ92, B 80-47T for sand castings, B 199-47T for permanent mold castings, B 93-47T for ingot). *See* Table III.
2 Consequences of exceeding impurity limits. The resistance to corrosion decreases with increasing amounts of copper and nickel. More than 0.50% Si decreases the elongation.

N *1 Melting temperature.* 443 to 593 C (830 to 1100 F)
2 Casting temperature range. (sand) 735 to 843 C (1350 to 1550 F) (chill) 649 to 816 C (1200 to 1500 F) (ingot) 649 to 705 C (1200 to 1300 F)
3 Alloying. Add aluminum as Al or Al-Mn. Add zinc as Zn. Add manganese as 95 Al–5 Mn.
5 Type of flux. Magnesium melting flux.
6 Precautions in melting. See "Magnesium (99.80 Mg)".
15 Heat treatment.

Purpose	Temperature, °C	Temperature, °F	Time, hr	Cooling
Solution treatment	405	760	20	strong air blast
Artificial aging	215	420	14	air or oven
Stabilizing[a]	260	500	4	air

(a) The stabilizing heat treatment is used on castings in the as-cast or solution heat treated conditions to minimize growth when the castings are used at elevated temperatures.

NOTE. For solution treatment, Alloy AZ92 requires an atmosphere at least 0.5% SO_2. For other heat treatments air is satisfactory.

17 Joining. Resistance welding is satisfactory.

Mg – 1.25 Al – 1 Mn

COMPILED BY R. HAUSER AND N. E. WOLDMAN*

A 2 *Trade name.* Eclipsaloy 130
3 *ASTM number.* AM11
B 1 *Typical uses.* All types of die castings. The alloy is particularly adaptable to parts requiring impact strength and ductility.
2 *Precautions in use.* Requires slightly elevated pouring temperatures, large gates, and high pressure.
C 1 *Density* at 20 C (68 F). 1.705 g per cu cm (0.062 lb per cu in.)
D 1 *Liquidus temperature.*[6] 644 C (1190 F)
2 *Solidus temperature.*[6] 629 C (1165 F)
3 *Minimum "burning" (liquation) temperature.*[6] 626 C (1160 F)
6 *Thermal expansion*[3] 18 to 100 C (65 to 212F). 0.000026 per °C*
11 *Specific heat* 20 to 350 C (68 to 662 F). 0.25 cal per g*
13 *Latent heat of fusion.* 89 cal per g*
E 11 *Electrolytic solution potential* versus saturated calomel electrode. 1.55 volts. Same test conditions as for pure magnesium.
K *Mechanical properties.* (Die cast and aged, section 0.061 sq in.): tensile strength 32,000 psi; yield strength 21,000 psi; elongation 9%; Brinell hardness number 60; Rockwell E 65; modulus of elasticity 6,500,000 psi; impact value, Charpy 10 ft-lb; modulus of rigidity 2,400,000 psi.
4 *Machinability index*[5] (free-cutting brass = 100). 500*
L 2 *Radiography.* Same as for pure magnesium*
M *Composition limits.* Die cast: *components,* 1.0 to 1.5% Al; 0.5 to 1.5% Mn; *impurities,* 0.005% max Fe; 0.005% max Ni; 0.05% Cu; 0.30% max Si.
2 *Consequences of exceeding impurity limits.* Lower ductility and resistance to corrosion.
N 1 *Melting temperature.* 629 to 643 C (1165 to 1190 F)
2 *Die-casting temperature range.* 677 to 732 C (1250 to 1350 F)
3 *Alloying.* Add aluminum as Al. Add manganese as 95 Al – 5 Mn, or as $MnCl_2$.
5 *Type of flux.* Magnesium die-casting flux.
6 *Precautions in melting.* Protect metal with flux or sulfur dioxide atmosphere. Avoid moisture.
15 *Heat treatment.* For aging, hold at 246 C (475 F) for 4 hr in air, then cool in air.

13 Latent heat of fusion. 89 cal per g approx*
16 Thermal conductivity 100 to 300 C (212 to 572 F). 0.30 cal/sq cm/cm/°C/sec approx
19 Recrystallization temperature. 260 C (500 F) for one-hour anneal after 20% reduction

E *1 Volume conductivity* referred to standard copper. 25.7% cast, 34.5% wrought
2 Electrical resistivity at 20 C (68 F). Cast 6.7 microhm-cm; wrought 5.0 microhm-cm
11 Electrolytic solution potential versus saturated calomel electrode. 1.65 volts for cast, 1.64 volts for hard rolled. Same test conditions as for pure magnesium.
14 Hydrogen overvoltage.[1] 0.51 for cast, 0.42 for hard rolled metal

K *Mechanical properties.* See Tables I, II and III.
All forms. Modulus of elasticity 6,500,000 psi
Modulus of rigidity 2,400,000 psi
Poisson's ratio 0.35

Table I. Directional Properties of Alloy M1 Sheet

Property	Annealed	Hard Rolled
Parallel to rolling direction		
Tensile strength, psi	33,000	25,000
Yield strength, psi	18,000	26,000
Elongation, percentage	17	7
Perpendicular to rolling direction		
Tensile strength, psi	32,000	37,000
Yield strength, psi	17,000	27,000
Elongation, percentage	17	13

4 Machinability index[5] (free-cutting brass = 100). 500*

* Dow Chemical Company, Midland, Mich.
* Approximately the same as for pure magnesium

Table II. Strength and Elongation of Alloy M1 at Elevated Temperatures (Short-Time Tests)

Testing Temperature °C	Testing Temperature °F	Tensile Strength, psi	Yield Strength, psi	Elongation, in 2 in., percentage
		Forgings		
35	95	33,600	18,800	11.6
93	200	23,100	13,800	25.7
121	250	22,400	16,000	25.5
149	300	19,900	12,000	30.7
204	400	17,200	9,100	34.2
260	500	10,100	5,900	87.5
316	600	6,000	3,800	140.0
		Extrusions		
35	95	39,600	30,900	7.6
93	200	27,000	21,300	15.0
121	250	24,400	18,800	20.2
149	300	21,300	15,700	18.7
204	400	18,800	11,700	25.0
260	500	13,000	7,500	60.0
316	600	9,000	5,400	93.0
		Annealed Sheet		
35	95	33,000	20,200	17.7
93	200	24,200	16,200	31.0
121	250	21,600	14,700	40.5
149	300	19,300	12,700	44.0
		Hard Rolled Sheet		
35	95	36,000	27,000	10.0
93	200	29,700	26,700	7.7
121	250	27,300	24,500	11.7
149	300	25,000	21,200	16.0

L *2 Radiography.* Refer to "Magnesium (99.80 Mg)".*

M *Composition limits* (AN-M-26 for wrought, and AN-M-36 for cast alloys). Sand castings: 1.20% Mn min. Ingot: 1.30% Mn min. Sheet, welding wire, extrusions, forgings: 1.20% Mn min, 0.3% Ca max. For all these forms, *impurities (max):* 0.3% Si, 0.05% Cu, 0.01% Ni, 0.3% total others.
2 Consequences of exceeding impurity limits. Silicon tends to precipitate manganese. Copper and nickel affect the resistance to corrosion in salt water.

N *1 Melting temperature.* 649 C (1200 F)
2 Casting temperature range.
(sand) 732 to 843 C (1350 to 1550 F)
(ingot) 677 to 732 C (1250 to 1350 F)
3 Alloying. Add manganese as $MnCl_2$.
5 Type of flux. Magnesium melting flux.
6 Precautions in melting. See "Magnesium (99.80 Mg)".
7 Hot working. 293 to 538 C (560 to 1000 F)
9 Annealing temperature. 371 C (700 F)
10 Maximum reduction between anneals. 20 to 50%
15 Heat treatment. M1 annealed sheet may be stress relieved at 500 F in 15 min, the hard rolled sheet, at 400 F in 60 min, and extrusions, at 500 F in 15 min.
17 Joining.
Rivet compositions. Aluminum alloy 56 S-H12
Oxyacetylene welding with M1 welding rod, magnesium welding flux, and neutral flame.
Resistance welding is in general use.
Helium-arc welding is in general use. Use same filler rod as for torch welding. Use no flux.

References. *See* "Magnesium (99.80 Mg)".

The Nickel Industry

BY T. H. WICKENDEN*

NICKEL was used by ancient man in swords and implements fashioned from nickel-bearing meteorites and in coins made from paktong, a nickel-copper alloy first developed in China. It was extracted as an element in 1751 by Axel F. Cronstedt and named nickel from the ore "kupfernickel", so-called by superstitious miners who believed that the ore was bedeviled. The modern nickel industry dates from the opening of the New Caledonia mines in 1875 and those of Sudbury, Ontario, in 1886.

Occurrence. Commercial nickel ores fall into three major classes: (1) Sulfide ores are represented chiefly by the pyrrhotite-pentlandite-chalcopyrite ores of Canada and Norway. Pentlandite, a complex nickel-iron sulfide, is the nickel carrier. Small quantities of ores of this type have been mined in Connecticut, Pennsylvania, California, Missouri, and in Sweden, Finland, Italy, China, Tasmania, South Africa, and Great Britain. (2) Oxidized ores of the garnierite (silicate) type, occur in New Caledonia and, in small quantities, on the border of North Carolina and Tennessee. Similar ores occur in Borneo, Madagascar, Brazil, Spain, Greece, Russia, the West Indies and Oregon. (3) Arsenical ores are found in Ontario, Colorado, New Mexico, Saxony, Bohemia, France and eastern India. Small percentages of nickel are also present in many of the copper ores, in manganese ores of the early class known as "wad", and in nickeliferous ores such as those of Cuba.

*Manager, Development and Research Division, The International Nickel Company, Inc., New York

Smelting and Refining. In the Orford process, the ore is ground fine, classified, roasted in Nichols-Herreschoff roasters, and smelted in reverberatory furnaces to remove a large part of the sulfur. The molten matte is charged into converters with siliceous flux to produce a fluid slag that carries off the iron. The resulting nickel-copper Bessemer matte is smelted in a blast furnace with an alkaline sulfide flux and is cast subsequently into large pots. The product solidifies in two layers. The top layer contains copper sulfide; the bottom layer contains nickel sulfide. Resmelting with nitre cake and excess coke purifies the product progressively. The copper is blown to blister in basic-lined converters and refined electrolytically. The nickel sulfide bottoms are crushed, leached and sintered, melted in reverberatory furnaces and cast into anodes. By electrolytic refining in a continuously purified nickel sulfate electrolyte, cathode nickel is obtained that has a purity of 99.95% Ni plus Co. The range of the cobalt content is 0.30 to 0.50%. Impurities may be copper, iron, carbon, sulfur and silicon.

In the Mond process, crushed nickel sulfide bottoms are calcined to drive off sulfur, are reduced to metal and are then treated with carbon monoxide gas, which forms a volatile nickel compound (nickel carbonyl) at 60 C. The nickel-laden gas is passed over pure nickel pellets at a higher temperature (about 180 C). Metallic nickel is deposited on the pellets and the regenerated carbon monoxide is returned for use again as a nickel carrier.

The New Caledonian silicate ore is smelted to matte.

Sulfur is supplied by adding gypsum or any alkaline sulfide to the furnace. The matte is blown to a high grade in Bessemer converters and the iron is eliminated in the slag. After roasting to drive off the sulfur, the oxide is made into a plastic with reducing materials and produced in the shape of cubes or rondelles.

In the Falconbridge process for recovering nickel, the ore containing nickel and copper is smelted to obtain a high-metal matte. The matte is crushed and ground to pass through a 20-mesh screen and is then roasted in Herreschoff roasters to remove most of the sulfur.

The roasted ground matte is charged into a Pachuca tank, is agitated with an acid solution to remove copper, and is then filtered. The filtrate goes to electrolytic tanks with insoluble anodes where copper is plated out. The filter cake containing the nickel is washed, dried, melted with coke, and then cast into crude anodes that are electrolyzed to produce electrolytic nickel cathodes.

The Nicaro nickel recovery process was developed particularly for low-grade nickel ore. It involves crushing and drying, then grinding to a very fine mesh in hammer and ball mills. The dry dust obtained in this way is reduced by producer gas in oil-heated Herreschoff furnaces that have multiple hearths, and the resulting reduced ore is leached in an ammonia solution from which nickel is precipitated

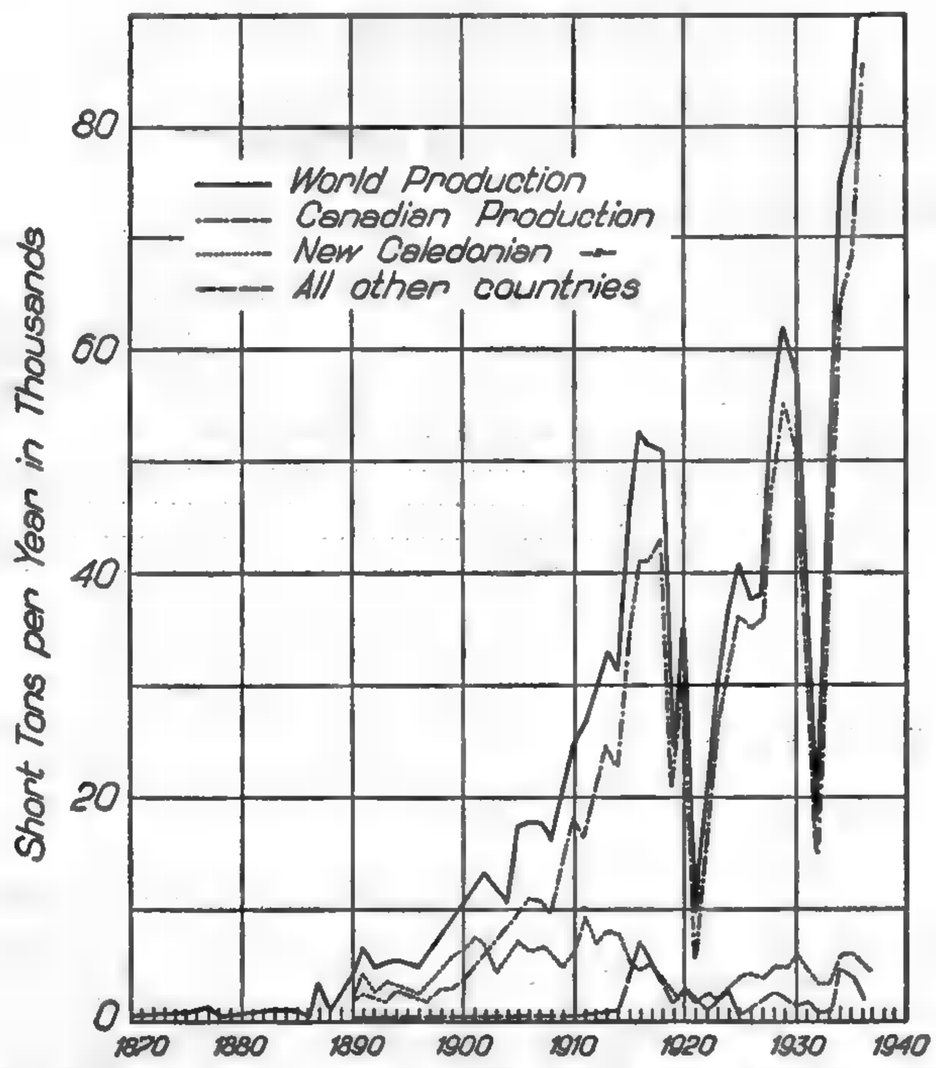

Fig. 1 World production of nickel from 1870 to 1936. Average annual production from 1937 to 1944 was approximately 150,000 tons.

in the form of nickel carbonate. This, in turn, is calcined to nickel oxide, in which form it is marketed.

Products. Nickel is marketed in various forms, as follows: (1) nickel pellets, produced by decomposition of nickel carbonyl gas without fusion; (2) electrolytic cathode sheets cut into various sizes; (3) blocks or shot, obtained by remelting electrolytic nickel, then casting it into pig molds or pouring it into water without deoxidation; (4) malleable nickel, produced by pouring into ingot molds after deoxidation; (5) nickel cubes or rondelles, reduced from the oxide without fusion; (6) nickel salts; (7) nickel oxide; (8) nickel powder; and (9) special alloys for addition to cast irons.

Uses. Nickel is used in the food-processing, radio and chemical industries, in coinage, in the Edison storage battery, and as a catalyst in the hydrogenation of unsaturated organic compounds. Nickel plating is extensively employed and regularly forms a base layer for chromium plating. Heavy nickel plating has been developed for building up the worn parts of machinery, and a hard plate (up to 400 Brinell) is utilized for applications requiring unusual resistance to abrasive wear. Nickel-clad steel has been developed for the construction of heavy tanks and kettles.

Nickel is used most extensively as an alloying element in ferrous and nonferrous alloys. Table I serves to indicate the percentage distribution of nickel in the various metal markets and Fig. 1 shows the world production.

Table I
Approximate World Consumption of Nickel, 1939[a]

Constructional steels, stainless steels and other corrosion-resisting and heat-resisting steels, and steel castings	60%
Nickel cast iron	3%
Nickel-iron alloys	1%
Nickel-copper alloys and nickel silvers	14%
Nickel brass, bronze, and aluminum alloy castings	2%
Heat-resistant and electrical resistance alloys	3%
Malleable nickel, nickel cladding	9%
Electrodeposition	6%
Nickel salts, ceramic materials, storage battery materials and catalysts	1%
Miscellaneous and unclassified	1%

(a) Detailed figures for the war years are not available.

Nickel is one of the chief alloying elements of the alloy steel industry. The most outstanding characteristic of nickel is the ability to impart to steel increased hardness, strength, and toughness without sacrifice of ductility. Nickel steels are applied extensively in the transportation field, in the oil and power industries, and in the production of machine tools and of machinery for agricultural and general purposes. In cast iron, nickel refines the grain, homogeneity and density, and reduces the tendency to chill. Special nickel cast irons have been developed for resistance to abrasion and for applications that require resistance to heat and corrosion.

Nickel-chromium steels, carrying high percentages of the alloying elements, form a series of alloys that resist both corrosion and heat. The most popular of these, 18-8, contains 18% Cr and 8 to 10% Ni. A ferrous alloy containing 60% Ni and 15% Cr is used in electrical resistance heating elements. An 80% Ni, 14% Cr, 6% Fe alloy that has good strength, toughness, and resistance to corrosion and oxidation, is employed in chemical and food-processing equipment.

A variety of nickel-iron alloys have special thermal, magnetic, electrical and elastic properties. Invar, containing 36% Ni and possessing a coefficient of thermal expansion of approximately zero, is one of this series. A 20% Ni alloy, containing aluminum and cobalt, has been developed for permanent magnets.

Monel is a nickel-copper alloy that contains 67% Ni, 30% Cu; the remainder is mostly iron and manganese. Monel is obtained by roasting copper-nickel converter matte and reducing the resulting oxide to metal with charcoal. This is primarily a corrosion-resistant alloy for handling acids, alkalies, brines, water, and food products; it is also resistant to exposure in dry and moist atmospheres.

Nickel-copper alloys containing 20 to 30% Ni are made into condenser tubes for service in contact with sea water. A 25% Ni alloy is used for the five cent coin of the United States. Alloys containing 45 to 55% Ni are marketed for pyrometer and electrical resistance wire, under a variety of trade names.

Table II
Nickel Alloys Used for Nonferrous Melting

	Electrolytic Nickel Cathode	Shot and Ingot from Electrolytic Nickel	Copper-Nickel Shot	High-Nickel-Copper Shot and Blocks
Nickel plus cobalt	99.95%	99.60 %	50.00%	67.00%
Iron	0.01 to 0.04%	0.07 %	0.10%	1.75%
Copper	0.01 to 0.03%	0.026%	49.60%	29.00%
Carbon	trace	0.11 %	0.15%	0.20%
Silicon	trace	0.11 %	0.04%	1.25%
Sulfur	trace	0.01 %	0.02%	0.01%
Manganese	....	....	....	0.75%
Melting point, °F.	2650	2600	2250	2460

The approximate compositions and melting points of the nickel alloys used for melting in the nonferrous industry are listed in Table II.

The effect of nickel as a decolorizer is utilized in the nickel silvers, widely employed for architectural trim and plumbing fixtures, and finds application in the production of white gold. As much as 2% Ni is used in several of the aluminum alloys that are made into sand-cast, permanent mold cast, die-cast, and wrought products.

The Melting and Casting of Nickel and Nickel Alloys

By L. E. Grubb*

THE melting and casting of nickel and nickel alloys closely parallel the practice in casting steel (*see* page 523). The basic equipment and sand mixtures recommended for steel can be used satisfactorily, and no great difficulties should be experienced if certain precautions are taken.

General Information. Electric-arc, induction, oil-heated, and gas-heated furnaces can be used. Coke-heated pit melting is not recommended because of the danger of contamination by sulfur. Natural and basic furnace linings are preferred to the acid type of lining.

Extreme care should be taken in the selection and preparation of the furnace charge. Only materials of known composition should be used.

Some minor elements, such as sulfur and lead, have well-known harmful effects on the mechanical properties and welding characteristics of the nickel materials, and the importance of holding such elements at minimum levels cannot be overemphasized. This factor should be considered in selecting the alloying and degasifying agents, slag materials and fluxing compounds.

Care should be taken to avoid contamination in the furnace from preceding melts, because nickel and nickel alloys are usually specified for the corrosion resistance that is inherent in their chemical composition.

Furnace linings, ladles and all materials to be charged should be dried thoroughly to avoid gassy heats. This is particularly important in the production of nickel and the nickel-chromium alloys.

Pattern equipment should provide for a linear shrinkage of ¼ in. per ft.

Gates and risers should be proportionately larger than those used for steel, because of the large volumetric shrinkage and small liquidus range characteristic of nickel and nickel alloys.

Recommended Melting Practice. *Nickel.* After charging, the nickel is melted down under a thin protective limestone slag. During or immediately after the melt-down period, the heat is oxidized by additions of nickel oxide. Sufficient carbon should be added next to cause a "boil", and the boil should be maintained long enough to remove any dissolved gases. A practical test to determine the effectiveness of the boil consists of pouring a small sample into a dry sand mold. If the top of the sample shrinks normally, the melt is relatively free from gas. If the metal shrinks and then expands, the boil has not been entirely effective. After a satisfactory sample has been secured, the boil is "killed" by a small addition of silicon, and the heat is finished as quickly as possible. The carbon content is then raised to the desired level by an addition of charcoal. Manganese is added approximately 10 min before tapping. The 10-min period is essential to allow any entrapped oxides that have been fluxed by the addition to rise and clear the bath. When the desired tapping temperature is reached, the melt is poured and deoxidized in the ladle by finishing additions of metallic silicon and approximately 0.10% Mg. The pouring temperature is between 2750 and 2900 F, depending on the size of the casting and the type of mold used.

Nickel-Copper Alloys. When using a charge of Monel block or "revert scrap" of known origin, a straight melt-down is employed under a light protective slag of limestone. A small, adjusting addition of manganese, in the form of a silicon-manganese alloy, is made to the furnace bath approximately 10 min before tapping. After reaching the desired tapping temperature (2700 to 2900 F, depending on the silicon content, which is from 1.6 to 4.0%, and the size and section of the castings to be poured) the metal is deoxidized in the ladle by tapping on top of the silicon addition and with 0.10% Mg. An addition of 0.05% Ti may be added at this time to fix any nitrogen present.

In the production of Monel castings from electrolytic nickel and electrolytic copper, the copper is first charged on the bottom of the furnace along with sufficient charcoal to secure the desired carbon content. The nickel is then placed on top and the charge is melted under a thin protective limestone slag. When the carbon content has reached the desired level, any charcoal remaining on the surface of the bath is removed. The practice for the remainder of the melting cycle is the same as outlined above for charges of Monel block or revert scrap; the silicon and manganese additions are proportionately larger. The pouring temperature is 2650 to 2850 F.

Nickel-Chromium Alloys. Approximately half the nickel is charged on the bottom of the furnace and all the chromium is placed on top of the nickel. If weldability is desired in the finished alloy, a columbium addition is included and the silicon content is maintained at 1% max. The remainder of the nickel is then charged, along with a sufficient amount of iron oxide or nickel oxide to ensure a well-oxidized bath. The melt-down should be accomplished as quickly as possible under a protective limestone slag, and a small amount of cryolite should be added to keep the slag fluid. When the bath temperature reaches 2900 F, a gentle boiling will be observed. If high-carbon ferrochromium is used, sufficient carbon is present in the alloy to cause the boil without the addition of charcoal.

Test samples are taken in the same manner as that described for nickel to verify that the bath is free from gas. When the sample is satisfactory, the boil is "killed" by a small addition of metallic silicon. Small amounts of powdered calcium-silicon are dusted on the surface of the slag to maintain it in a reducing condition. When the tapping temperature has been reached (2850 to 3100 F) the surface of the bath is cleaned and deoxidation is accomplished by a furnace addition of 0.10% Mg. Magnesium additions should not be made in the ladle because of the violent reaction that takes place. The necessary additions of silicon and manganese are made in the ladle while the heat is being tapped. An addition of 0.05% Ti may be added at this time to fix any nitrogen present. The pouring temperature is 2800 to 2950 F.

The Melting and Hot Rolling of Nickel and Nickel Alloys

By Clarence Bieber*

THIS discussion describes the methods used for melting, refining, teeming and rolling commercially pure nickel, and some nickel alloys containing copper or chromium with small amounts of manganese and iron.

Melting Furnaces. These materials are melted in three types of furnaces, each of which is adapted especially to the particular function to be performed or to the requirements of the alloy to be melted. Nickel is usually melted in acid-lined open hearth furnaces of the reverberatory type, heated with natural gas. Monel (70 Ni, 30 Cu) is melted first in the same type of furnace and then duplexed into basic-lined, electric-arc furnaces for refining. Inconel (80 Ni, 14 Cr, ▮ Fe) is melted either in high-frequency induction furnaces or in basic-lined, electric-arc furnaces.

Raw Materials. Commercially pure nickel is produced from electrolytic nickel cathodes. Monel is produced from a nickel-copper sulfide matte. Inconel is produced from electrolytic nickel and low-carbon ferrochromium, containing approximately 70% Cr.

Melting of Nickel. Since electrolytic nickel has been refined by the method of production, only melting and the addition of small amounts of minor constituents precede casting into ingots. The minor constituents control the mechanical properties as well as the forging and rolling qualities of the material. Charges weighing from about 9000 to 23,000 lb and consisting of electrolytic nickel, clean nickel mill scrap and about 1% low-sulfur charcoal, are melted in gas-heated open hearth furnaces. These furnaces are lined with bricks consisting of about 55% silica and 45% alumina. No slag is added intentionally, but some incidental slag is formed by fusion of the refractories.

The nickel heats are usually melted down with about 0.25% C. When the temperature of the bath has reached 2850 F, the carbon content is reduced to about 0.05 to 0.10% by the addition of nickel oxide. The reaction between this nickel oxide and the carbon dissolved in the molten metal produces ▮ vigorous evolution of carbon monoxide gas, carrying with it most of the hydrogen gas that may be dissolved in the molten metal. After the carbon content has been adjusted to the desired level, approximately 0.3% Mn is added and the metal is tapped into bottom-pour ladles where it is "deoxidized" with small amounts of titanium, boron and magnesium. The metal is then teemed into cast-iron molds provided with cast-copper bases or "stools". The standard molds are 18 in. square and 40 in. long, with a tile "head" about 5 in. high. The weight of these standard ingots is about 4600 lb. Larger ingots, weighing up to about 14,000 lb, are cast for large forgings or heavy plates.

Electric-Arc "Hot Top". The metal in the heads of the nickel ingots is maintained in the molten condition by the use of an electric-arc "hot top".[1] This eliminates the shrinkage cavities or "pipes" normally found in the heads of fully deoxidized or "killed" ingots. It also results in the production of ingots freer from center sponginess than those cast by the conventional methods. The ingots are allowed to solidify and are then processed according to methods that will be described later.

The deoxidizing elements mentioned earlier perform several specific functions in addition to the reduction of oxides.[2, 3] Magnesium is the principal reducing agent for reactions with oxides that have been dissolved by the molten metal. Magnesium also combines with minute traces of sulfur, forming magnesium sulfide. This compound is relatively harmless since it is insoluble in both liquid and solid nickel and therefore occurs as minute particles in random distribution within the grains. Titanium fixes nitrogen gas and also helps to increase the forgeability of nickel. Boron acts as a fluxing agent and improves the fluidity of the molten metal. Boron also combines with the last traces of gases not "fixed" by the other deoxidizers.

The deoxidation practice just described is the standard practice for producing the regular grade of commercially pure nickel. Special grades of nickel are produced for specific applications. For example, the nickel strip supplied to the radio industry is deoxidized only by manganese and magnesium, since the other elements are believed to impair the performance of some types of vacuum tubes.

Melting of Nickel for Rolled Anodes for Electroplating. Two principal types of rolled nickel anodes are produced for use in the electroplating industry: one is an oxidized type containing about 0.15% O as nickel oxide; the other is a carbon-bearing type containing about 0.20% C and 0.25% Si. Both types of anodes contain also traces of sulfur and copper, which are added to improve the smoothness of corrosion in the plating solutions.

The nickel charges for the oxidized anodes are melted in the same acid-lined, gas-heated, open hearth furnaces described above. Electrolytically refined nickel is used as the base material for the charges, which are melted under mildly oxidizing conditions. When the temperature of the molten metal has reached about 2850 F and the oxygen content of the melts has reached the desired level of about 0.15%, small amounts of sulfur and copper are added and the melts are tapped into bottom-pour ladles and teemed into 3300-lb ingots, 14 by 14 by 60 in.

The nickel charges for the carbon-bearing nickel anodes are melted in the same gas-heated furnaces, which are operated under reducing conditions. About 1% of charcoal is added with the charges. When the temperature of the metal has reached about 2800 F, the carbon content of the melts is adjusted to about 0.20% by the addition of nickel oxide if the carbon content has to be lowered, or by charcoal if the carbon content has to be raised. About 0.25% Si and small amounts of copper, sulfur and magnesium are added, and the melts are tapped into bottom-pour ladles and teemed into 3300-lb ingots, 14 by 14 by 60 in.

Melting of Inconel. Inconel is melted usually in a 960-cycle, coreless induction furnace having a maximum capacity of approximately 6200 lb. The furnace is lined with "Normagal" (Lamagal), which consists of 40% alumina and 60% magnesia.

The charges weigh about 4650 lb and consist of electrolytic nickel, low-carbon ferrochromium and clean Inconel mill scrap. The scrap and electrolytic nickel are melted first, followed by the ferrochromium. No slag is added to the material in the furnace. When the temperature of the bath has reached 2925 F, small amounts of aluminum, titanium, boron and magnesium are added. The metal is tapped into bottom-pour ladles and teemed into cast-iron molds with cast-copper bases or stools to produce 4600-lb ingots, 18 by 18 by 40 in., which are treated with the electric-arc hot top as described previously.

Inconel may also be melted in electric-arc furnaces on a basic magnesite "bottom". The charges weigh about 9200 lb and consist of electrolytic nickel, low-carbon ferrochromium and clean Inconel mill scrap. The scrap and electrolytic nickel are charged first with about 2% nickel oxide. When the melt is fused, a slag consisting of about equal parts of fluorspar and cement clinkers is placed on the surface of the bath and through this slag the ferrochromium is added. The oxides in the slag are then reduced by the addition of aluminum chips and the temperature of the bath is raised to 2925 F. Small amounts of aluminum, titanium, boron and magnesium are added and the melts are tapped into bottom-pour ladles, teemed into 4600-lb ingots, 18 by 18 by 40 in., treated with the electric-arc hot top.

Melting of Monel. Monel matte, containing approximately 52% Ni, 25% Cu, 22% S and 1% Fe, is crushed, ground, roasted in an oxidizing atmosphere in mechanically rabbled Edwards-type "calcining" furnaces, and is thus converted to sulfur-free oxide. The hot oxide is mixed with low-sulfur charcoal as it leaves the calciners. Later it is mixed with more carbon, in the form of tar coke, and for melting is charged into acid-lined, open hearth furnaces, heated with natural gas. After melting, the Monel is duplexed for final refining into basic-lined, electric-arc furnaces of 20-ton capacity. The sulfur content of the Monel

*Works Metallurgist, The International Nickel Company, Inc., Huntington, W. Va.

charges is reduced to approximately 0.005% by refining in these electric furnaces under carbide slags, consisting of approximately equal parts of lime and fluorspar with a small amount of carbon being added in the form of ground electrode dust. After the sulfur has been removed, the carbon content of the melts is adjusted to about 0.15% and the manganese content to about 1.00%. The melts are next deoxidized and "malleablized" by the addition of small amounts of silicon, phosphorus, titanium and magnesium. They are then tapped into bottom-pour ladles and teemed into cast-iron molds with cast-copper bases.

The standard molds for Monel are 14 by 14 by 60 in. long with a tile head about 5 in. long. The Monel ingots weigh about 3300 lb each, although larger ingots weighing as much as 14,000 lb can be cast where heavy plates or big forgings are to be produced. As with nickel, the metal in the heads of the Monel ingots is kept in the molten condition for some time by the use of an electric-arc hot top.

Rolling of Nickel Alloys. After they have solidified in the molds, nickel, Monel and Inconel ingots are stripped, cooled under a water spray and overhauled by milling ¼ to ⅜ in. of metal from each of the four surfaces. They are then overhauled further by chipping out any remaining surface defects with mechanical chipping machines or "billeteers". The ingots are next heated in furnaces fired with low-sulfur natural gas, and are then forged. If forgings are to be produced for subsequent machining, forging is the final hot working operation. When rolled or extruded products are to be produced, the ingots are forged to blooms and are again overhauled by chipping on billeteers to remove the last traces of surface defects which may have developed during forging. The blooms are reheated in furnaces fired with low-sulfur natural gas and are then hot rolled to billets or sheet bars on a 3-high, 24-in. reversing mill. The billets and sheet bars are again overhauled by chipping or grinding, and are finally hot rolled to rods, sheets, strip, shapes, or extruded into tubing shells.

Nickel is generally heated to 2300 F, Monel to 2150 F, and Inconel to 2300 F before forging or hot rolling. The finishing temperatures for hot working vary greatly with the size and shape of the product, but Monel and nickel can generally be hot worked at 1200 F or lower. Inconel is generally not hot worked below 1600 F.

For some applications, the nickel alloys may be shipped in the hot rolled condition, or they may be annealed, pickled and cold rolled or cold drawn to produce rods, sheets, strip, wire or tubing.

In addition to the standard grades of nickel, Monel and Inconel described above, a number of modifications of these alloys are produced also, including age hardenable alloys and other special materials. The melting and processing methods for these special alloys are generally similar to those employed for the standard grades of nickel, Monel and Inconel.

The Hot Forging and Hot Bending of Nickel and Nickel Alloys

By W. F. Burchfield*

When correct procedures are followed, common nickel alloys are readily forged, either in dies or by hand methods, into almost any shape that can be forged in steel. However, since these materials are inherently stronger and stiffer than steel at the forging temperature, success in hot working operations depends more on having the proper conditions of heating. These conditions involve not only the temperature and duration of heating, but also the control of furnace atmosphere by correct combustion of suitable fuels.

The nominal compositions of the alloys discussed in this article are listed in Table I.

Table I. Chemical Compositions of Nickel Alloys

Material	Nominal Composition, per cent
Nickel	99+ Ni
Monel	67 Ni, 30 Cu, 1.5 Fe, 1 Mn
"K" Monel	66 Ni, 30 Cu, 3 Al
"Z" Nickel	94 Ni, 4.5 Al
"D" Nickel	95 Ni, 5 Mn
80 Ni—20 Cr	80 Ni, 20 Cr
Inconel	80 Ni, 15 Cr, 5 Fe
60 Ni—15 Cr	60 Ni, 15 Cr, 25 Fe
Hastelloy A	56 Ni, 22 Mo, 22 Fe
Hastelloy B	62 Ni, 32 Mo, 6 Fe
Hastelloy C	53 Ni, 19 Mo, 17 Cr, 6 Fe, 5 W

Fuels. The susceptibility of the nickel alloys to intergranular attack by sulfur at high temperatures necessitates the use of a fuel that contains very little sulfur.

Natural gas, almost free from sulfur and with a high Btu value, is the most desirable gaseous fuel. City gas, usually very low in sulfur, is also satisfactory, particularly for small furnaces where its good qualities justify the relatively higher cost per Btu. Two other excellent fuels are propane and butane, although butane must be preheated to gasify it before combustion. Propane in cylinders is convenient for occasional heating for forging, hot bending or riveting.

*Development and Research Division, The International Nickel Company, Inc., New York

Oil, the fuel most generally used in forge shops, should be purchased on a specification limiting the sulfur content to 0.5% max. The heavier varieties obtained under such a specification seldom exceed 0.2% S and the lighter distillates are virtually free from sulfur. Burners through which low-pressure air is supplied and utilized are superior to both the high-pressure air and the steam-injector types.

Solid fuels such as coal and coke are unsatisfactory because of the difficulty in maintaining proper heating conditions, inflexibility in the control of heat and the presence of sulfur in excessive amounts.

Heating Temperature and Time. Figure 1 shows the recommended temperature ranges for heavy forging, hot bending and "high-tensile" forging.

During the heating of nickel alloys, the furnace should be maintained at a temperature about 50 F higher than that at which the work is to be removed. In no instance should the work be at less than 2000 F when removed for heavy forging or severe bending.

These materials should not be held in the furnace longer than is necessary to heat the piece to the desired temperature, uniformly from surface to core. It is not possible to give a set of inflexible rules to govern the duration of heating, because furnaces and furnace operation may vary widely; however, Fig. 2 shows the approximate total time desirable between charging nickel alloys into a furnace at temperature and removing them for forging.

Furnace Atmosphere. The furnace atmosphere should be free from sulfur and always slightly reducing, with 2% or more of carbon monoxide. Although there is no maximum limit to the amount of carbon monoxide or free carbon that may be tolerated, the closer the atmosphere is to the neutral condition, the easier it is to maintain the required uniform temperature.

A most harmful condition is encountered when the atmosphere fluctuates between reducing and oxidizing. For this reason, the stack dampers should be closed wholly or partially, to force the gases out through any openings in the furnace and thus prevent the entrance of air.

It is important that complete combustion take place be-

fore the mixture of fuel and air comes in contact with the metal. If the furnace design prevents this condition, then steel plates should be placed so as to protect the nickel alloy from direct impingement of the flame.

thoroughly and uniformly heated, the bar is removed, water quenched or air cooled and bent cold through 180 deg. The absence of surface rupture at the bend indicates that the heating conditions are safe. If no surface ruptures occur on

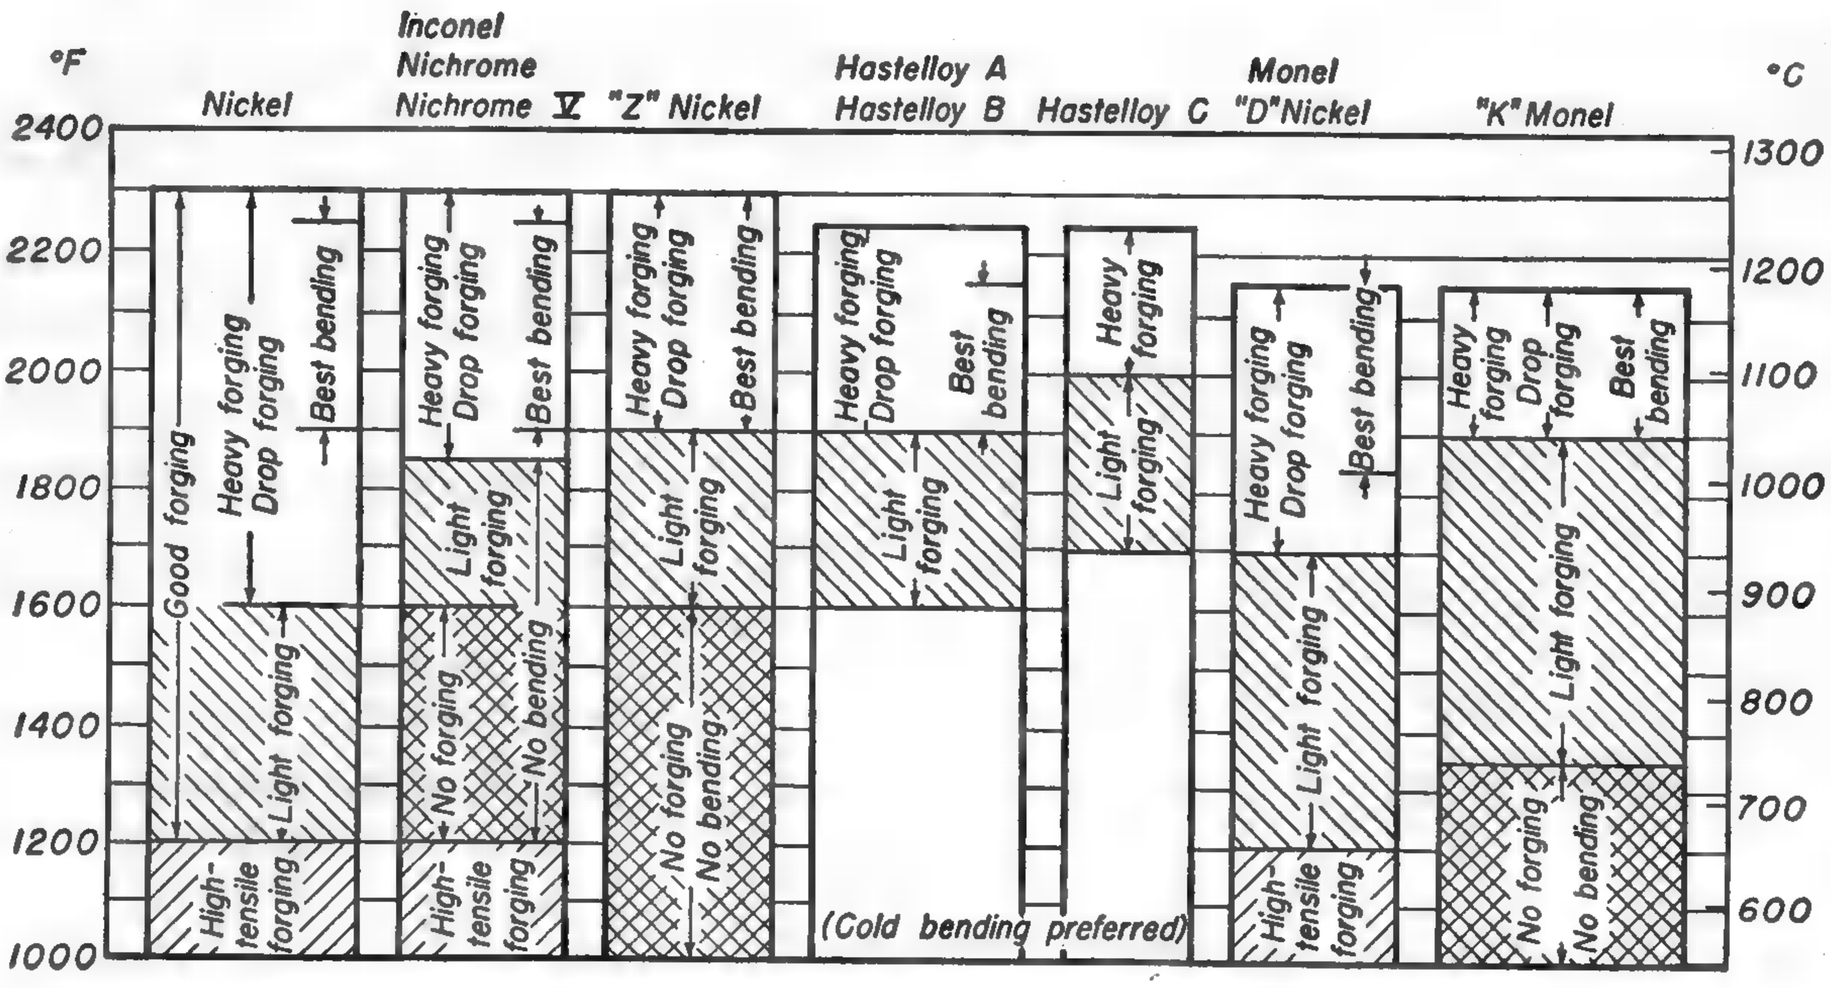

Fig. 1 Recommended temperature ranges for forging and bending nickel and nickel alloys

Quenching. Although it is not essential to cool rapidly or to quench most of the nickel alloys immediately after forging, this procedure is usually desirable when possible. "K" Monel and "Z" Nickel, which are precipitation hardening alloys, must be quenched, because if these alloys are allowed to cool slowly through their precipitation range (1100 to 900 F), they will harden to some extent in the center of the piece and may develop cracks. The Hastelloy alloys are also capable of age hardening, but the process is more sluggish than in "K" Monel and "Z" Nickel, and either quenching or air cooling may be employed. The quenching of alloy forgings that cannot be precipitation hardened, results in the following important advantages: (1) pickling is facilitated, particularly when the quenching bath contains 2% by volume of alcohol; (2) finished pieces can be removed more easily from around the hammer; (3) in forgings of large cross section, slightly higher mechanical properties can be obtained than would result from slow cooling.

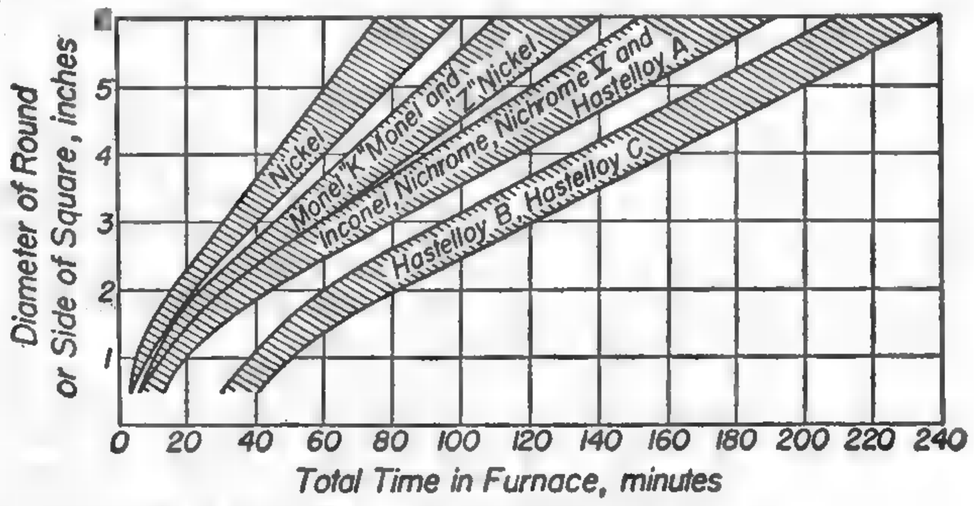

Fig. 2 Approximate duration of heating nickel and nickel alloys for forging

Checking Forging Conditions. After the furnace is at temperature and the furnace atmosphere is adjusted for a production run, it is advisable to make a pilot run for checking the hot forming setup. A small bar of the material to be forged (with oxide removed from the surface) may be placed in the furnace and brought up to temperature. When a second specimen, this time bent hot through 180 deg immediately after pulling, the temperature may be considered satisfactory for forging.

It is extremely important to prevent these nickel alloys from coming in contact with sulfurous atmospheres and with sulfur from other sources during forging or hot forming. Sulfur may be contained not only in the fuel but also in the cinder and slag that accumulate on the hearth. To prevent contact with this accumulation, the work material should be supported above the hearth on rails or other convenient shapes. Before the metals are heated, all sulfate salts, sludge and dirt remaining from a sulfuric acid pickling operation should be removed completely by washing. Marking paints are seldom suspected as sources of sulfur, yet they usually contain sulfide pigments that may lead to local but severe damage. Sand to be used in the bending of pipe should be of the washed variety, high in silica and as free as possible from pyrites and mineral sulfates.

Die Material. Alloy steel is essential to meet modern production requirements for die blocks.

Two widely used die block materials are: (1) Ni-Cr-Mo steel containing 0.40 to 0.60% C, 1.25 to 2% Ni, 0.5 to 0.8% Cr, and 0.25 to 0.35% Mo, and having a hardness ranging from Rockwell C 45 to 55, depending on the depth of the die depression; and (2) Cr-Mo steel containing 0.35 to 1.0% C, 5 to 5.25% Cr, and 1 to 1.75% Mo (sometimes containing also 1 to 1.5% W), and having a hardness ranging from Rockwell C 45 to 50.

In drop forging the nickel alloys, dies will remain serviceable while producing from 3000 to 10,000 pieces, depending on the size, shape and tolerance to be maintained.

Trimming dies for cold or hot trimming may be of 18-4-1 high speed steel containing 0.50 to 0.60% C and hardened to Rockwell C 58 to 60. Clearance for most hot trimming may be about $\frac{1}{16}$ in. *on the side,* and cutting edges are ground with considerable back rake.

Lubricants. The tendency to stick in the die is slightly greater in the nickel alloys than in carbon steel. Swabbing the dies with a mixture of sulfur-free grease and graphite (tallow and bone black) or grease of the type used in roll necks for hot rolling mills, insures proper clearing of the work material from the dies.

Annealing Nickel and Nickel Alloys

By W. A. Mudge*

ANNEALING involves a sequence of heating and cooling operations and usually implies slow cooling. Applied to metals and alloys, it is a process of heating at a predetermined temperature for a definite time, followed by cooling, to produce a change in mechanical properties. For some materials, such as steel, cooling must be slow; for others, such as nickel and copper, it may be either rapid or slow; for a few materials, such as the precipitation hardening alloys, cooling must be rapid.

For the nickel alloys, annealing is usually a complete or partial softening as a result of recrystallization; or, it may be a slight hardening, as a result of equalization of stress. The following are illustrations.

Soft Annealing (Annealing). Nickel and nickel alloys that have been hardened by cold working operations, such as rolling, deep drawing, spinning, severe bending and the like, require softening before cold working can be continued. The thermal treatment that will produce this condition is known as annealing, or soft annealing.

Temper Annealing (Partial Annealing). Work-hardened nickel materials may be heated at a temperature, and for a period, sufficient to accomplish partial softening only. This temper annealing, semi-annealing, or partial annealing is useful only for special processes.

Stress-Equalizing Annealing. Work-hardened nickel materials may be heated at a temperature that is too low to effect any softening, but that will equalize or homogenize stresses in the material and thereby increase mechanical properties. This is known as stress-equalizing annealing. The optimum temperature depends on the manner in which the metal or alloy has been work hardened. Cold worked metals require a lower temperature than hot worked metals. The thermal treatment produces a considerable increase in mechanical properties, especially in the proportional and elastic limits and in proof stress, without appreciable change in elongation and reduction of area. Often this thermal treatment is described incorrectly as normalizing.

The data for Monel (67% Ni, 30% Cu, 1.4% Fe, 1% Mn) in Table I illustrate the effects of these three thermal treatments.[1] Heating at 392 to 572 F produced stress-equalizing annealing with a large increase in proportional limit; heating at 752 to 1112 F gave temper annealing; and heating at 1382 F resulted in soft annealing.

Fuels. Nickel and nickel alloys are sensitive to attack by sulfur at annealing temperatures, and more so in reducing than in oxidizing atmospheres. An ideal fuel contains no sulfur, but such fuel is not available generally. Consequently care must be taken to effect combustion so as to eliminate or minimize the danger of sulfur embrittlement.

Electricity, natural gas and hydrocarbons, such as methane, propane, and butane, are ideal sources of heat. The gaseous fuels can be burned with incomplete combustion, thereby producing a satisfactory reducing atmosphere for bright annealing.

City gas, light distillate oils, and other liquid or gaseous fuels having a maximum sulfur content of 0.5% are suitable fuels when provisions are made in the design and construction of the furnace to effect complete combustion before the hot gases strike the metal.

Fuel oils, coal and coke, which contain more than 0.5% S, are not suitable fuels except when the metal is protected completely from contact with the products of combustion. Therefore such fuels can be used as a source of heat only in box or pot annealing methods, or for annealing baths of molten salts.

Bright Annealing. For soft annealing and for temper annealing nickel and the nickel alloys, the temperatures required are sufficiently high to cause slight surface oxidation unless a reducing atmosphere is provided. If oxidation is not important, the atmosphere need be sulfur-free only—though preferably not strongly oxidizing.

During annealing and subsequent cooling, a reducing atmosphere can be maintained as follows:

1 By regulating the fuel and air supplies so as to secure incomplete combustion and produce an atmosphere containing carbon monoxide or a mixture of carbon monoxide and hydrogen.

2 By introducing into the combustion chamber of the furnace a reducing gas such as hydrogen, with or without carbon monoxide, or a mixture of a reducing gas with an inert gas, such as hydrogen with nitrogen.

3 By burning charcoal in the furnace. Charcoal should always be prebaked for at least 3 hr at temperatures of 1200 to 1500 F to eliminate adsorbed moisture and carbon dioxide.

Bright annealing is more economical than oxidizing annealing, because it eliminates the expense of subsequent pickling[2] or grinding. For that reason, it is generally used for nonferrous materials. Typical bright-annealing atmospheres are described in Table II.[3]

The conditions for bright annealing should be maintained during heating, regardless of the method used for cooling. If facilities are available, nickel and the nickel alloys may be quenched in a 2% (by volume) solution of denatured alcohol. This will reduce the "oxide flash" formed by the oxygen of the air during the transfer from the furnace to the quenching tank.

Table I. The Effect of Annealing Temperature on the Mechanical Properties at Room Temperature of a Cold Drawn Monel Rod 1½ in. in Diam (20% reduction)

Temperature, deg Fahr, (3 hr)	Proportional Limit (0.00% offset), psi	Yield Point (0.5% elongation under load), psi	Tensile Strength, psi	Elongation in 2 in., per cent	Hardness, Rockwell B
None, as cold drawn ...	45,000	99,425	108,500	20.5	[illegible]
392	62,500	103,200	111,200	20.0	100
482	67,500	103,750	113,250	20.0	100
572	69,825	101,150	112,625	20.8	99
662	66,500	97,850	111,575	22.2	98
752	60,000	91,100	110,000	25.2	97
932	58,000	81,000	103,350	27.0	95
1112	52,500	73,125	99,250	30.8	91
1292	22,500	34,000	84,625	44.2	69
1382	20,000	33,750	83,625	43.5	66

The chromium oxide formed on Inconel cannot be reduced by quenching in alcohol. It can be removed best by pickling, according to the appropriate procedures described on page 1040.

Soft-Annealing Methods. The chemical compositions of nickel alloys are given in Table III. Annealing procedures are summarized in Table IV.

The differences in chemical composition among nickel and the nickel alloys require modifications in annealing temperatures as well as in furnace atmospheres. Nickel should be annealed at lower temperatures than Monel, and Nichrome or Hastelloy A requires a higher temperature. The precipitation hardening alloys must be cooled rapidly after annealing if maximum softness is desired.

Usually existing equipment must be used with or without modification, more often the latter. In such instances, control of temperature and atmosphere must be provided. If new equipment is to be added, it can be designed to produce the desired results.

Four soft-annealing methods in general commercial use are described in the following paragraphs.

Open Annealing. This method is used most often. The material to be annealed is heated at the selected temperature and protected from oxidation by the products of combustion in a fuel-heated furnace, or by a reducing gas introduced into an electric furnace. Temperature control is critical since the annealing period is short. During preliminary heating of the furnace, the burners may be adjusted to give optimum combustion; but, before charging, the air supply should be reduced to give the excess of reducing gases required. Also, the top vents or dampers should be closed or partially closed to give a positive gas pressure over the hearth and thereby prevent leakage of air.

Closed (Box) Annealing. Box or pot annealing requires more time than open annealing because of the lower temperatures used. Temperature control is less critical than in open annealing. In most instances, the weight of the container exceeds that of the work material; so the amount of fuel required, the heating time and the cost are greater than in open annealing. Small pressed parts, rivets,

coiled wire and similar work are annealed in boxes because of greater ease in handling.

Bright annealing of nickel and the nickel-copper alloys is accomplished in boxes or pots by introducing an appropriate sulfur-free, reducing gas into the container during cooling. Annealing boxes can be made of a heat-resisting alloy steel or cast iron in a wide variety of shapes and sizes. The alloys that contain chromium or molybdenum cannot be bright annealed in boxes or pots, even if pure hydrogen is used.

After the work has been charged, the boxes should be luted with fire clay or sealed with sand or other suitable refractory material. A small quantity of charcoal, prebaked at 1200 to 1500 F for 3 hr to remove occluded gases, should be packed in the box at points where air could enter. Reducing gas is admitted to the box immediately when the box is withdrawn from the furnace, or when the burners are shut off. Following annealing, the flow of gas should be regulated to maintain a positive pressure within the box; if the gas is combustible, it will burn gently at all outlets.

Salt Bath Annealing. This method is used for special work with small parts. Inorganic salts, such as chlorides and carbonates of sodium, potassium and barium, which are relatively stable at temperatures considerably above their respective melting points, are fused in large metallic or refractory containers by any convenient source of heat. Steel pots are satisfactory containers when used at temperatures up to about 1300 F; at higher temperatures, heat-resisting Fe-Ni-Cr alloy pots or refractory containers should be used. Excessive fuming of the bath is an indication of its maximum usable temperature.

Particular care must be exercised to remove all traces of sulfur from the fused salts in order to prevent embrittlement of the work. This may be accomplished in 2 to 3 hr by adding to the fused salts a small amount (1 lb or more) of a 75 to 25 mixture (by volume) of powdered borax and powdered charcoal. If small test pieces of nickel strip or wire are not embrittled after 3 or 4 hr in the purified salt bath, the desulfurizing treatment has been sufficient.

The material to be annealed is placed in the molten salts and absorbs heat rapidly. After being annealed, the work metal is quenched in water to free it from particles of the salt mixture. The annealed material will not be bright and must be flash pickled.[2]

Electrical-Resistance Annealing. This also is a special method. When an electric current is passed through the material to be annealed, the material acts as a resistor and is heated rapidly.

The method has seldom been satisfactory. Temperature control is difficult unless the work material is uniform in cross section, and it is extremely difficult to provide a suitable reducing atmosphere for bright annealing. The results are generally irregular.

Temper Annealing. Temper or partial annealing is limited to light sections and is usually applied only to strip and wire. It has value for operations where fully annealed material is not required. Any of the aforementioned methods of annealing may be used, although the continuous method is best suited for the purpose. Careful regulation of the time at temperature is essential. The data in Table I illustrate the results obtainable.

Stress-Equalizing Annealing. Cold worked and hot worked nickel and nickel alloys require a low-temperature thermal treatment to develop the optimum combination of strength and ductility for each metal, and to insure against distortion and warping from subsequent machining. The proper temperature to be used depends on the nature of the preliminary fabrication or working.

Table IV. Annealing Conditions for Nickel and Nickel Alloys

Material	Soft Annealing: Open Annealing Temp, deg Fahr	Soft Annealing: Open Annealing Time, min	Soft Annealing: Closed Annealing Temp, deg Fahr	Soft Annealing: Closed Annealing Time, hr	Stress-Relief (Temper) Annealing Temp, deg Fahr	Stress-Relief (Temper) Annealing Time, hr	Stress-Equalizing Annealing Temp, deg Fahr	Stress-Equalizing Annealing Time, hr
Nickel and "L" Nickel	1500-1700	6-1[a, b, c]	1300-1400	3-1[a, b, c]	1000-1100	3-1[a, b, c]	525-600	3-1[a, b, c]

Hastelloy C	2200-2250	180-40[a]	1700-1900	3-1[c]				
Hastelloy D			1700-1900	3-1[a, b]				

(a) Furnace Cool (b) Air Cool (c) Quench

Springs made from heavily cold drawn wire or cold rolled strip should be stress-equalized annealed after coiling. The preferred treatments are 1 hr at 575 F for nickel and nickel-copper alloys, and 1 hr at 850 F for the alloys that contain chromium or molybdenum.

Supplementary Items. *Pyrometry.* Accurate control of annealing temperature cannot be overemphasized. Satisfactory indicating, controlling, recording and controlling-recording pyrometers are available. Iron-constantan and chromel-alumel thermocouples should be changed every three months; noble metal thermocouples may be used as long as their accuracy is not impaired. All thermocouples should be checked daily for accuracy.

The Effect of Cold Work Previous to Annealing. The greater the amount of cold work to which the material has been subjected, the lower is the temperature required to produce the same degree of softness without increasing grain size, and the shorter is the time required at any one temperature. At 1200 F, for example, hard Monel that has been cold worked 40% softens more rapidly than half-hard Monel that has been cold worked 20%.

The amount of any type of previous cold work also has a critical influence on the ductility of nickel and nickel alloys after annealing. If only a small amount of cold work is done (for example, approximately 10% reduction) full ductility for deep drawing and spinning cannot be restored by annealing, even though the hardness is reduced to that of soft material. A minimum of approximately 20% of cold working is required between anneals to insure maximum ductility and softness following annealing.

The Effect of Rate of Cooling. Neither slow cooling, whether in or out of the furnace, nor rapid cooling by quenching, has any specific effect on the softness of the annealed, solid-solution nickel materials. Therefore, rapid cooling is preferable, both to economize time and to minimize the amount of oxidation. The age hardenable alloys must be cooled rapidly by quenching from their annealing temperatures.

Control of Grain Size and the Effect on Fabrication. Coarse-grained material is unsuitable for most cold working operations. A coarse grain in the high-nickel materials cannot be refined by thermal treatment. It can be removed only by cold working in excess of 50%, followed by soft annealing. Maximum workability is obtained with material that has been annealed without allowing appreciable grain growth to occur. The average grain diameter should not exceed 0.0025 in. (0.064 mm). This gives the best combination of ductility to permit extensive deformation, strength to withstand the action of the tools, and surface quality to facilitate polishing.

The Effect of Fluctuating Atmospheres During Annealing. If nickel and the nickel alloys are heated in atmospheres that fluctuate between oxidizing (excess of air) and reducing (excess of carbon monoxide or hydrogen), severe intercrystalline attack will occur with resulting embrittlement, even though the atmosphere is sulfur-free. This type of embrittlement can be prevented by maintaining a constant and sufficient excess of a reducing, gaseous atmosphere during heating and cooling. The alloys containing chromium or molybdenum are affected less than the nickel and nickel-copper alloys.

Dead-Soft Annealing. When the nickel alloys are annealed at higher temperatures and for longer periods, a condition commonly described as "dead-soft" is obtained, and hardness numbers will result that are 10 to 20% lower than those for the "soft" condition. This cannot be accomplished without increasing the grain size of the metal. Therefore, this treatment should be used only for those few purposes in which grain size is of little importance.

Torch Annealing. Some large equipment is hardened locally by the fabricating operations. If the available annealing furnace is too small to hold the work piece, the hardened sections can be annealed with the flames of oil or acetylene torches adjusted so as to be highly reducing. This method is not a good one for general use because it gives irregular and insufficient annealing, with heavily oxidized surfaces. However, if it is the only method available, heating must be gradual and can be facilitated by temporary brick construction to localize the heat and to permit higher temperatures to be attained. The work should be warmed gently at first, with sweeping motions of the torch, and should not be brought to the annealing temperature until sufficient preheating has been done to prevent cracking as a result of sudden release of stresses.

Protection From Contamination by Foreign Material. Many of the lubricants used for deep drawing and spinning contain sulfur or lead. Unless these elements are removed before annealing, they will cause embrittlement. Removal can be accomplished by washing with hot trisodium phosphate solution or with volatile, organic, grease-removing solvents such as carbon tetrachloride or trichlorethylene. Lubricants of any type should be entirely removed from the material before annealing. Paint marks also, and other adherent substances that may contain sulfur, lead or similarly harmful ingredients, should be removed by appropriate methods before annealing.

The Age Hardening of Nickel Alloys

By W. A. Mudge*

THE addition of magnesium, beryllium, aluminum, silicon, titanium, and molybdenum to nickel and the high-nickel materials, separately or in combinations, results in alloys that show appreciable response to age hardening. The commercial alloys available are "K" Monel, "KR" Monel, "S" Monel, "Z" Nickel, Hastelloy A, Hastelloy B and Hastelloy C. The chemical compositions of these age hardening nickel alloys are given in Table I.

The age hardening treatments for these materials differ from those required for steels and for the aluminum-base alloys.[1] The nickel materials are soft when quenched from temperatures ranging from 1450 to 2225 F; however, they may be hardened by holding at temperatures of 1100 to 1600 F and then cooling. Quenching is not a prerequisite to aging; the alloys can be hardened from the hot worked and cold worked conditions, as well as from the soft condition. The temperatures used for the three nickel-molybdenum-base alloys are detrimental to corrosion resistance.

* Development and Research Division, The International Nickel Company, Inc., New York

Age hardening procedures are summarized in Table II.

Table I

Chemical Compositions of Age Hardening Nickel Alloys

	Percentage								
	Ni	Cu	Al	Si	Fe	Mn	Mo	Cr	W
"K" Monel	66	30	3	...	...	...	...	...	...
"KR" Monel	66	30	3	...	...	...	...	...	...
"Z" Nickel	94	...	4.5	...	...	...	...	...	...
"S" Monel	63	30	...	4.0	2.0	0.5	...	...	...
Hastelloy A	56	...	...	...	22	...	22	...	...
Hastelloy B	62	...	...	...	6	...	32	...	...
Hastelloy C	53	...	...	...	6	...	19	17	5

Nickel alloys are usually hardened in sealed boxes placed inside a furnace, although small horizontal or vertical furnaces without boxes may be used. The box or furnace should hold the parts loosely packed, yet afford a minimum of excess space. Electric furnaces provide the optimum

Table II. Age Hardening Treatments for Nickel Alloys

Material	Condition	Temp, deg Fahr	Time at Temp, hr	Cooling
"K" Monel and "KR" Monel	Soft: 140–180 Brinnell, 75–90 Rockwell B Moderate cold work: 175–250 Brinell, 8–23 Rockwell C Full cold work: 260–315 Brinell, 25–32 Rockwell C	1080–1100 1080–1100 980–1100	16 8–16(b) 6–10(b)	Not faster than 15°F per hr, down to 900 F.(a) Furnace cool or air cool below 900 F.
"Z" Nickel	Soft: 140–180 Brinell, 75–90 Rockwell B Moderate cold work: 200–300 Brinell, 15–31 Rockwell C Full cold work: 290–375 Brinell, 30–40 Rockwell C	1080–1100 1080–1100 980–1000	16 8–16(b) 6–8(b)	Not faster than 15°F per hr, down to 900 F.(a) Furnace cool or air cool below 900 F.
"S" Monel	As-cast: 275–350 Brinell Softened: 150–200 Brinell	1080–1100	4–6	Rate not important. Furnace cool or air cool.
Hastelloy A and B	Soft and as-cast: 90–235 Brinell	1375–1400	168	Air cool.
Hastelloy C	Soft: 160–215 Brinell	1575–1600	8–16	Air cool.

(a) The recommendations for slow cooling will apply only when maximum hardness is required. Where hardness slightly lower than the maximum obtainable is satisfactory, the cooling rate may be increased to from 25 to 50°F per hr.

(b) Longer time for softer material; shorter time for harder material.

temperature uniformity of ±10 F and the cleanliness required for this work. Gas-heated furnaces, particularly those of the radiant-tube type, can be made to give satisfactory results. It is difficult to obtain good results from oil heating, even with muffle furnaces. All lubricants should be removed from the work before hardening.

Because of the long time of aging and the difficulty of excluding air from the box or furnace, perfectly bright hardening cannot be accomplished commercially. For semibright hardening, dry hydrogen (dew point minus 50 C) or cracked and dried ammonia (dew point minus 50 C) should be used. When bright or semibright hardening is not required, other atmospheres may be used, such as nitrogen, cracked natural gas free from sulfur, cracked city gas, cracked hydrocarbons, or a generated gas. Freedom from gases that contain sulfur is necessary to avoid embrittlement of the alloy being treated.

Salt baths are used occasionally for small parts. The hardened material is never bright and must be flash pickled to restore the natural color. Inorganic salts are used, such as chlorides and carbonates of sodium and potassium, which are relatively stable at temperatures considerably above their respective melting points. It is extremely important that the salts be free from all traces of sulfur, or the result will be embrittlement of the work. Sulfur can be removed from fused salts by the procedure described on page 1032.

Joining Nickel and Nickel Alloys

By K. M. Spicer*

THE following joining processes used for steel are applicable, with slight modification, to nickel, Monel, "K" Monel, and Inconel:

Widely Used Processes	Less Widely Used Processes
Welding	Welding
Metal arc	Inert-gas-shielded arc
Oxyacetylene (gas)	Submerged melt
Atomic hydrogen arc	Carbon arc
Resistance	Furnace brazing
Silver brazing	Brass brazing
Soft soldering	

Only the first six processes have broad application to the high-nickel materials. Each produces very satisfactory joints. The choice among these processes is determined by the corrosive environment to which the equipment will be exposed, the thickness of material being joined, the design of the piece of equipment and the design of the individual joints in the equipment. The inert-gas-shielded arc and submerged-melt welding processes, furnace brazing, and copper and brass brazing are used for special purposes only. The oxyhydrogen flame is not suitable because of its low temperature. Hammer welding is not possible because union does not occur unless the metal melts. Carbon-arc welding has almost disappeared from the field since the advent of the improved electrodes now in use for metal-arc welding.

Good mechanical properties, strength and ductility are inherent in welded joints in all materials and no treatment, either thermal or chemical (passivation), is needed afterward or recommended to retain or restore resistance to corrosion. The as-welded joints are equal to the parent metal in strength and resistance to corrosion. If thermal treatment is necessary, it can be applied without harm to the welded structure.

Since the coefficients of expansion of the high-nickel materials are almost the same as that of steel, warping and buckling resulting from a welding operation will be essentially the same as with steel in the same construction.

Surface preparation of high-nickel materials before welding, as well as the jigs and clamps used, is also essentially the same as for high-quality steel welding.

Most work is done by metal-arc or oxyacetylene welding. The practice for sheet steel is an acceptable guide in selection of the proper method, not according to the composition of the material but according to the thickness, the design of the piece, and the design of the individual joint. Metal-arc welding, if applicable, will produce less buckling than gas welding.

Surface Preparation for Joining. Electrodes and the oxyacetylene welding wires and fluxes for nickel and nickel alloys were designed for use on clean metal, such as cold rolled sheet, pickled hot rolled plate or cold drawn rod. All oil, grease, paint, marking crayon or oxide must be removed from any area to be joined. To insure satisfactory welding of hot rolled plate, hot rolled bar stock, or material that has been hot worked otherwise in processing or fabrication, it is necessary first to remove the thin, dark-colored oxide film from the immediate vicinity of the area to be welded. This can be done either mechanically by such methods as machining, sandblasting, grinding, or rubbing by hand with abrasive cloth, or chemically by pickling. When hot rolled plate is beveled by machine in preparation for making a butt joint, no further cleaning is needed, because the clean metal surface is exposed on the face of the bevel. However, if an attachment must be made by fillet welding to the surface of a hot rolled plate not cleaned previously, the oxide must be removed, preferably by light grinding either with a disk, a solid grinding wheel of fine grit, or a roll-head wheel; otherwise, difficulty may be encountered.

The sand-cast surfaces of nickel, Monel and Inconel castings need to be removed only from the areas to be welded, either by rough grinding or by machine tools.

Arc Welding. Nickel and Monel can be arc welded in all positions with the same facility as steel. Inconel can be welded in any position, but it is preferable to place the work material in position for downhand or flat welding.

* Development and Research Division, The International Nickel Company, Inc., New York

In general, the lower limit of thickness of sheet for arc welding is set at 0.037 in. but, with modern welding equipment, thicknesses as light as 0.018 in. have been welded.

The shielded-arc, metal-arc electrodes for Monel and nickel have been designed for use with d-c motor generators and will produce satisfactory joints when so used. The electrodes designed for the welding of Inconel are intended to produce satisfactory welds with either alternating or direct current.

The proper diameter of electrode for a specific application is determined by the thickness of the material and the type of joint. Generally, the diameter of the electrode should be as nearly equal as possible to the thicknesses being joined.

Manipulation of the electrodes is similar to that for heavily flux-coated mild steel electrodes; that is, the electrode should be inclined about 20 deg in the direction of welding. This position is best suited for control of the molten flux. The arc should be slightly shorter than would be used for a steel electrode of the same diameter, and a weaving motion should be used to obtain proper width and contour in the weld. Welds should never be wider than three times the diameter of the core wire.

The heat from arc welding has no detrimental effect on the parent metal; only a slight grain enlargement occurs in a narrow band at the edge of the weld. The strength and ductility of the parent metal are not altered noticeably.

Oxyacetylene Welding. Good oxyacetylene welding can be accomplished in flat, vertical or overhead positions. In order to insure uniform resistance to corrosion without galvanic effects, the welding wires are of virtually the same composition as the material being welded. A slightly reducing (carburizing) flame with a small excess of acetylene is recommended for all materials. A soft flame is preferable to the harsh or wild flame that results if too small a tip is used.

The appearance of properly made gas welds is quite similar to that of good welds in steel. Puddling should be avoided and the welding should progress steadily, with the luminous cone of flame just touching the surface of the molten pool.

During welding, the end of the filler wire should always be kept well within the protecting envelope of flame to prevent oxidation of the hot wire.

Fluxes are necessary for all materials except nickel, and usually no detrimental effect on the parent metal would result from leaving on the flux after completion of welding; however, the flux is removed for the sake of appearance. Certain corrosive mediums and applications at high temperature (more than 1000 F) require removal of the flux.

Resistance Welding. When used for nickel alloys, the resistance methods—spot, seam and flash—are much the same as when used for steel. Adjustments in technique must be made to compensate for differences in electrical resistivity and thermal conductivity. Electrode pressure must be great enough to give intimate contact. Recommended conditions for spot and flash welding nickel, Monel and Inconel are given elsewhere.[1]

Silver Brazing. Silver-brazing alloys flowing at temperatures lower than 1400 F are best for joining the high-nickel materials. Appropriate compositions are those that melt and flow in the temperature range from 1140 to 1325 F. A suitable proprietary flux is used with brazing alloys. Borax and boric acid fluxes are not protective for silver brazing, because they are not fluid at the temperatures used. The spent flux that remains after a joint has been silver brazed, is removed by dissolving in hot or cold water.

Since the temperatures required for silver brazing are in the lower end of the range used for annealing nickel alloys, the softening effect is very slight. "Z" Nickel, "K" Monel, "KR" Monel and "S" Monel may be age hardened after silver brazing.

Brazing alloys that contain phosphorus, although excellent for brass and copper, are not recommended for the nickel alloys because of an embrittling effect of the phosphorus.

Soft Soldering. Soft soldering is limited to applications where resistance to corrosion is not an important factor. Soft solder is inherently weak, and usually the strength must depend on mechanical joints—riveted, lock-seamed, or spot-welded—with the soft solder acting only as a sealing medium. The process is ordinarily limited to joints in sheet metal that is not more than 0.062 in. thick, because other processes yield stronger joints in these and heavier gages.

Only those soft soldering fluxes known within the trade as "acid" fluxes are recommended for use with nickel and nickel alloys. Rosin is not suitable, because its cleaning action is too mild. The proprietary or "cut acid" fluxes commonly used for copper are adequate for the soft soldering of nickel and Monel, but a somewhat stronger flux is required with Inconel because of the chromium oxide film that forms during heating.

Strength of Welded Joints. Joints produced by the various arc methods are as strong as the parent metal, or stronger in most instances.[2] Arc welds in nickel, Monel and Inconel will meet all requirements of the ASME Unfired Pressure Vessel Code.

Average Mechanical Properties of Welded Joints

Material	Tensile Strength, psi	Minimum Percentage Elongation in Weld
	Arc Welded	
Nickel	70,000	30
Monel	79,500	30
Inconel	98,500	30
	Gas Welded	
Nickel	60,000	35
Monel	65,000	35
Inconel	75,000	35

Joints Between Dissimilar Metals. Joints between nickel alloys and dissimilar metals or alloys may be made by soft soldering, silver brazing or welding. The process selected depends on the conditions to be encountered in service. If a material can be soft soldered, silver brazed, or welded readily, then, provided other factors are equal, it can be joined to nickel, Monel or Inconel by one or more of these methods.

Metal-arc welding with high-nickel electrodes is used widely for joining nickel and the nickel alloys to other materials. In welding dissimilar joints, it is essential that penetration be kept to a minimum; therefore, excessive current densities and puddling must be avoided. Combinations of materials that have been joined successfully are too numerous for listing here, but complete information about the various combinations is available in publications of the producers of nickel alloys.

Hard Surfacing. A number of alloys that are resistant to abrasion and able to produce a hard surface, can be applied readily to the nickel alloys. The alloys that have acceptable resistance to corrosion are most generally used.[3]

When the facing materials are being applied, the temperature of the base metal should be only slightly higher than the melting point of the hard-surfacing alloy, in order to avoid boiling and the formation of holes in the facing overlay.

Overlaying Nickel Alloys on Ferrous Material. Nickel, Monel and Inconel arc-welding electrodes may be used for the application of facings or overlays of these materials on wrought iron, cast iron, or steel. This application is used generally where openings in lined vessels must be protected or faced with material similar to that used for the lining.

Care should be taken to avoid excessive penetration into the iron or steel, in order to prevent undue dilution of the high-nickel overlay.[3] Apart from this precaution, the use and manipulation of the electrodes is the same as in the arc welding of wrought forms made from nickel materials.

Machining Nickel and Nickel Alloys

By E. L. Fowler*

THE procedures for machining nickel and nickel alloys parallel the practices used conventionally for steel.

Cutting Materials. Tools made from high speed steel, cast cobalt-base alloys, and cemented carbide are recommended for machining wrought and cast nickel and nickel alloys.

Tool Design. To ensure a firm setup, sturdy tools and rigid machines should be used for machining these tough materials. Tools should be designed so as to provide maximum support for the cutting edge and minimum resistance to chip disposal. Front and side relief angles should be just large enough to prohibit drag. When possible the tool should have a lead angle (the side cutting edge angle of a lathe tool). Rake should be sufficient to permit free cutting and disposal of tough chips. Chip breakers are not essential for machining the cast materials.

Suggested designs for tools are shown in Fig. 1 to 20 inclusive. Lathe tools should be set up on the center line of the work with a minimum overhang from the tool holder.

Cutting Compounds. Tool life is lengthened and the finish of the work material is improved by the use of a cutting lubricant. Sulfurized mineral oil of the proper consistency is the lubricant generally recommended for machining nickel and nickel alloys with high speed steel and cast cobalt-base tools. Turpentine or gasoline is recommended for drilling holes smaller than $\frac{3}{32}$ in. in diam. Soluble oil in water is recommended as the lubricant when cemented carbide tools are being used.

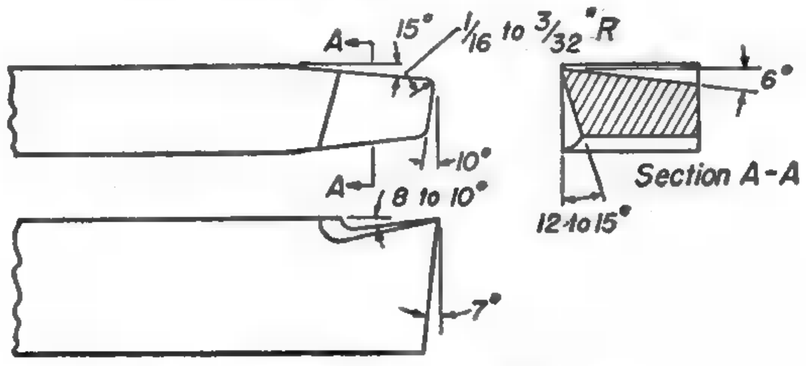

Fig. 1 Turning tool for medium work

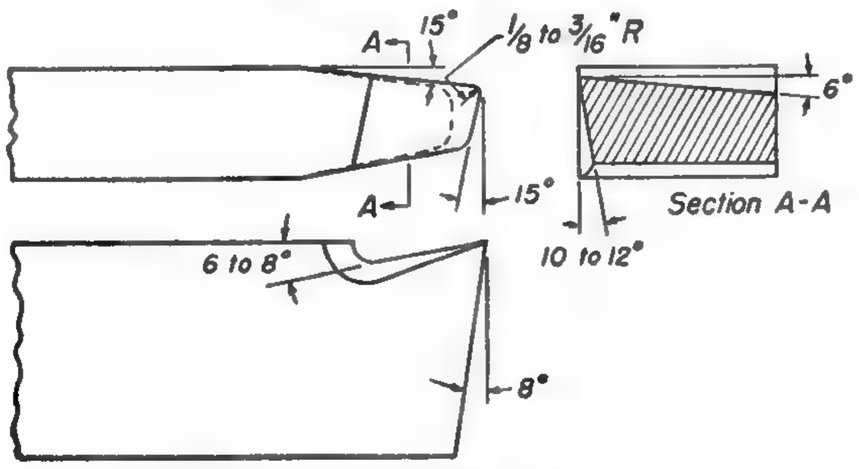

Fig. 2 Turning tool for heavy work(roughing)

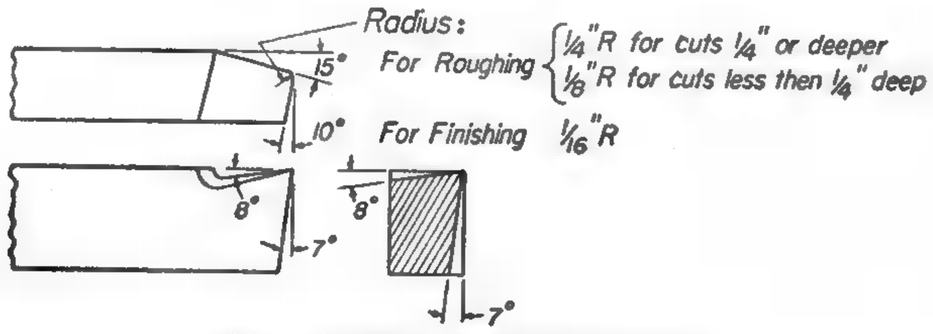

Fig. 3 General-purpose turning tool

Discoloration resulting from sulfur-bearing oil can be removed from machined parts by soaking the parts for 20 to 30 min in a cold 10% solution of sodium cyanide. *This solution is poisonous and should be handled with care.*

* Development and Research Division, The International Nickel Company, Inc., New York

All traces of the lubricant should be removed completely from machined parts that are to be subjected to high temperatures during subsequent fabrication or while in service.

Turning and Boring. The lathe setup for these operations is essentially the same as for steel. Speeds for boring should be slightly lower than those for turning, listed in Table I. Speeds and feeds for automatic screw machining are given in Table II. Representative tools for turning and boring are shown in Fig. 1 to 4 inclusive. Parting tools are illustrated in Fig. 5 and 6.

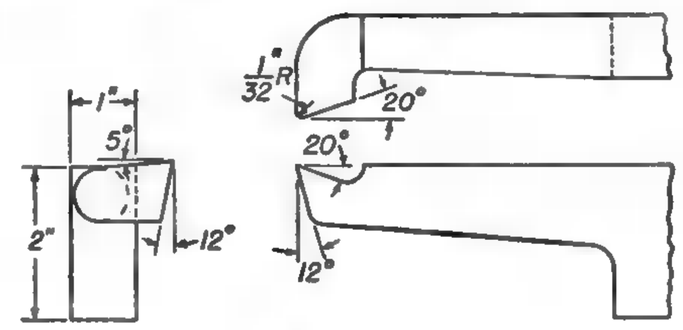

Fig. 4 Boring tool

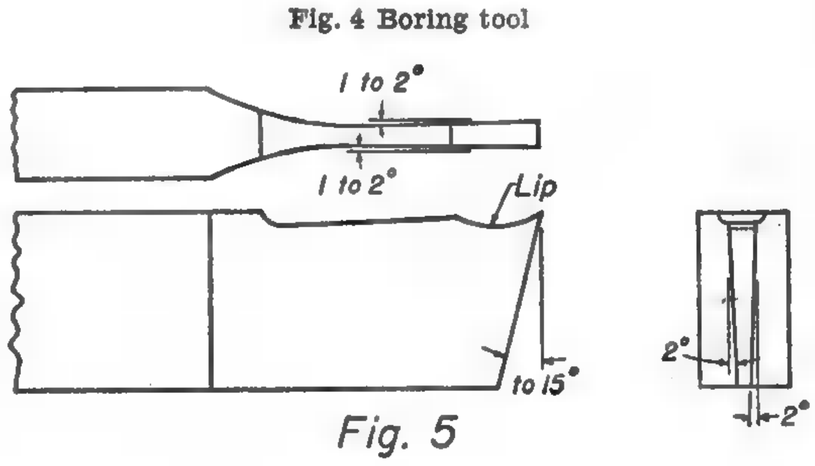

Fig. 5

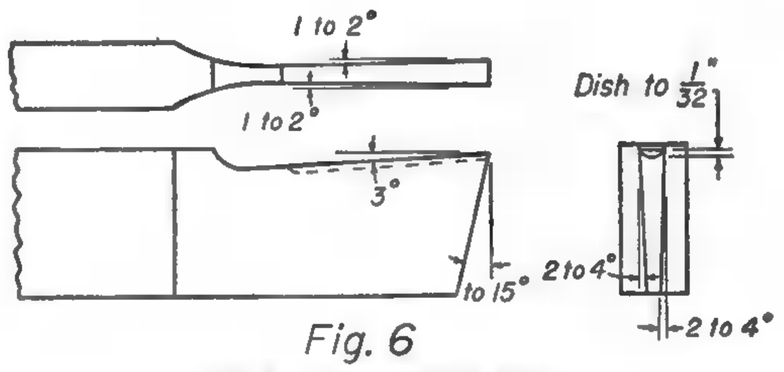

Fig. 6

Fig. 5 and 6 Parting tools

Drilling. Heavy-duty drills made from high speed steel are preferred. These drills should have heavy parallel webs and should be ground as shown in Fig. 7 to 9. Feeds and speeds for drilling are listed in Table I.

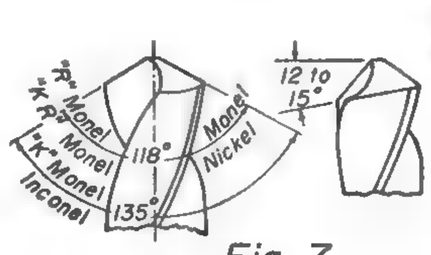

Fig. 7

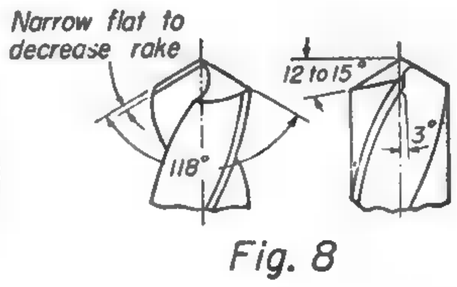

Fig. 8

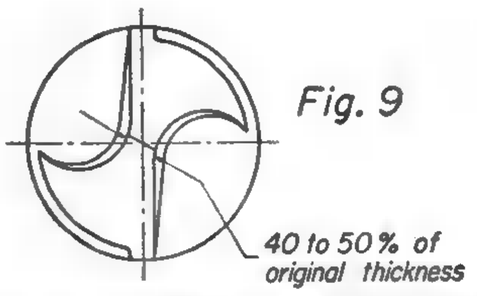

Fig. 9

Inconel	25 to 40	25 to 35	25 to 35	10 to 15	(e)	(e)
Nickel	50 to 60	40 to 60	50 to 90	15 to 25	200 to 300	300 to 350

(a) Increase speeds approximately 25% when cast cobalt-base tools are being used.
(b) Feeds approximately 0.015 in. per revolution
(c) Feeds approximately 0.005 to 0.010 in. per tooth per revolution
(d) Use speeds on the minimum side of the range for drills larger than ¾ in. and conversely for drills of smaller diameter. Feed, in inches per revolution, should increase gradually with increase in diameter of drill. Feed for a 1/16-in. diam drill would be 0.001 in.; for a ¾-in. drill, 0.007 to 0.010 in.; and for larger drills, 0.010 to 0.015 in.
(e) Not determined. (Use speeds shown for "H" Monel.)

mended. These should be as short as possible. Spiral-fluted, side-cutting reamers cut more smoothly than straight-fluted reamers. Reamers should have narrow lands, only a few thousandths of an inch wide. End-cutting reamers that have a secondary chamfer relief angle between 2 and 5 deg from the end chamfer are helpful in obtaining a smooth finish. Data for grinding reamers are shown in Fig. 10. Feeds and speeds for reaming are listed in Table III.

Table II. Feeds and Speeds for Automatic Screw Machining "R" Monel and "KR" Monel (Unhardened)

Tool and Operation	Width of Cut, inch	Feed, inch	Speed, ft per min — "R" Monel	"KR" Monel (unhardened)

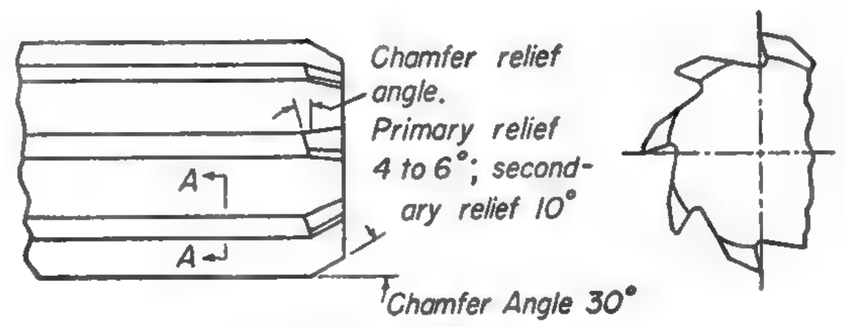
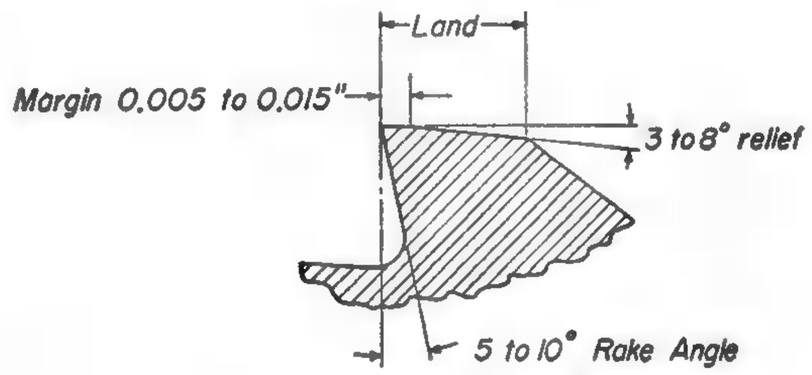
Circular Tool, Straight Tool	1/16 to ⅛	0.001	100 to 125	60 to 80
Stock less than ⅛ in. in diam	.....	0.0005	100 to 125	60 to 80
Forming Tool				
Circular	⅛ to ¼	0.0006	100 to 125	60 to 80
	⅜ to ½	0.0005	100 to 125	60 to 80
	⅝ to ¾	0.0004	100 to 125	60 to 80
	1	0.00025	100 to 125	60 to 80
Balance Turning Tool				
Turned diam less than 5/32 in.	1/32	0.006	100 to 125	60 to 80
	1/16	0.005	100 to 125	60 to 80
Turned diam more than 5/32 in.	1/32	0.012	100 to 125	60 to 80
	1/16	0.010	100 to 125	60 to 80

Tapping. Four-fluted plug or spiral-pointed taps made of high speed steel are recommended. These should have a 15-deg cutting rake angle and relief at least ⅔ the width of the land, in the angle of the thread and on the major diameter. Taps as short as possible should be used for machine tapping. Spiral-pointed taps are suggested for machine tapping through holes; plug taps are satisfactory for tapping blind holes. Skip-thread taps give excellent results in tapping holes 1¼ in. in diam or larger.



Point for end-cutting or side-cutting reamers



Tooth profile at A-A for side-cutting reamers

Fig. 10 Reamer

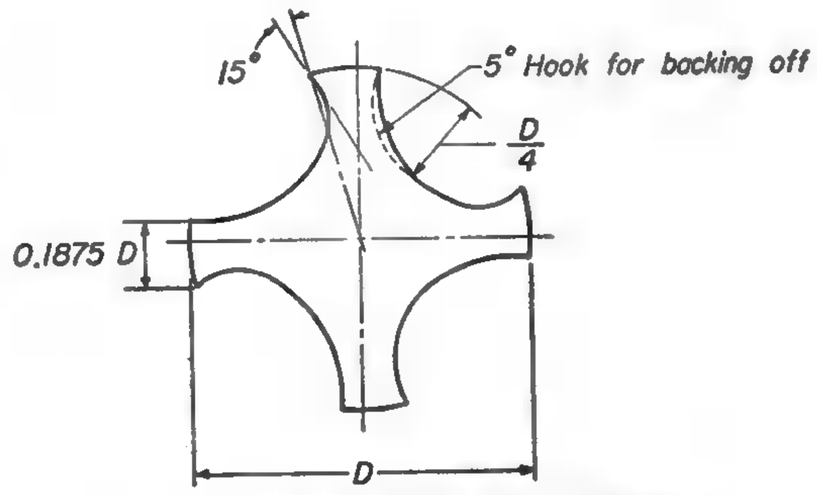


Fig. 11 Cross section of high speed steel tap

Table III. Feeds and Speeds for End-Cutting Reamers

Speed, ft per min — Monel "KR" Monel (unhardened) Nickel	"K" Monel (unhardened) Inconel	"R" Monel	Hole Diameter, inch	Feed per Revolution, inch	Material to be Removed, inch diam
25 to 35	10 to 15	30 to 40	⅛ to ¼	0.003 to 0.005	to 0.005
25 to 35	10 to 15	30 to 40	¼ to ½	0.005 to 0.009	to 0.008
20 to 30	10 to 15	30 to 40	½ to 1	0.009 to 0.020	to 0.012
15 to 20	10 to 15	25 to 35	1 to 2	1/32	1/64 to 1/32

In tapping, it is advantageous to make allowances for the toughness of the material by using a tap drill of slightly larger diameter than the standard commercial tap drill recommended for a specific thread. This practice eases the tapping operation and results in a thread of at least a 75% depth because the high ductility of these materials permits the metal to flow into the roots of the tap threads. A typical tap is shown in Fig. 11.

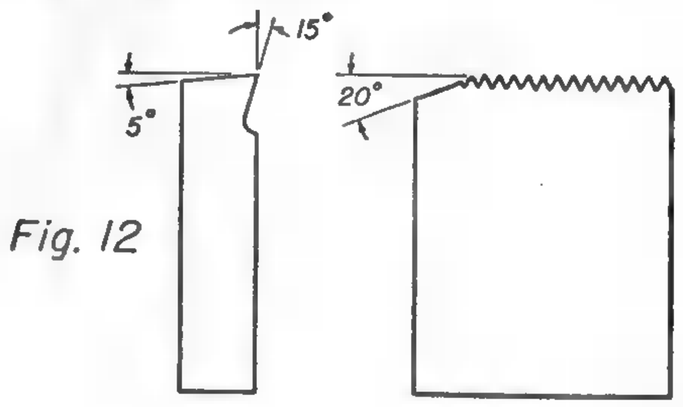

Fig. 12

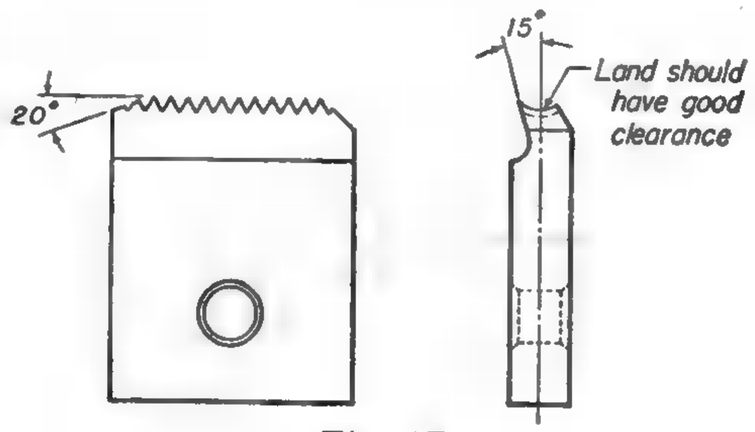

Fig. 13

Fig. 12 Thread chaser with milled type of insert
Fig. 13 Thread chaser with hobbed type of insert

Thread Chasing. Self-opening dies are preferred for thread chasing. Perfect threads can be cut with solid dies, but frequently dies are backed off before they are free and good threads are torn. The chasers should have a 15-deg rake, as shown in Fig. 12 and 13, with sufficient clearance from the cut edge to permit free cutting. A chaser-lead or throat angle of 20 deg is preferred to steeper angles. Threading speeds are listed in Table I.

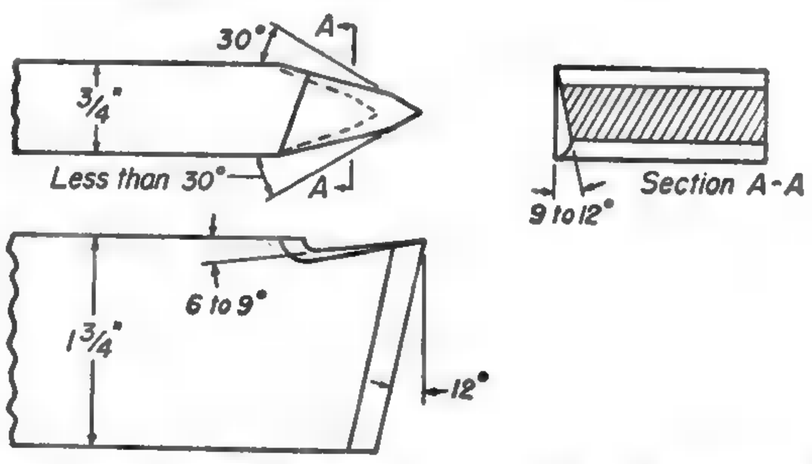

Fig. 14 Lathe threading tool for American National Form thread

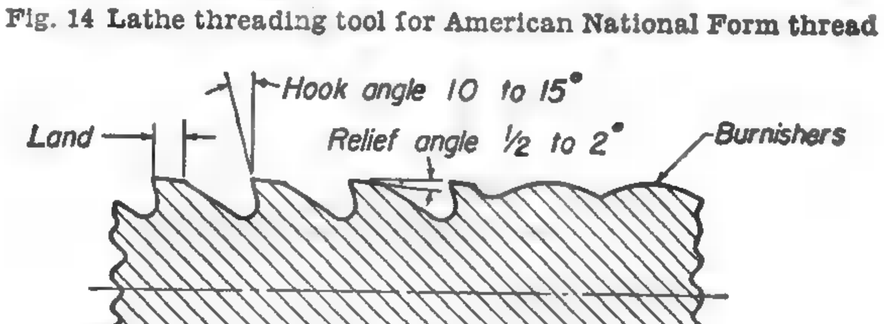

Fig. 15 Cross section of broach

Lathe Threading. The tool setup for machining threads is the same as for any other metal; that is, the tool is set straight into the metal on the cross feed with the compound set at half the included angle of the thread being cut. The depth of cut is fed with a compound feed. Figure 14 shows the recommended form of a lathe threading tool. Speeds for cutting acme threads should be about ⅔ as great as the threading speeds listed in Table I.

Fig. 20 Finishing shaper tool

Cutting-Off Operations. Bar stock is cut on power hacksaws with heavy-duty, high speed steel hacksaw blades, having from 6 to 10 (raker-set) teeth per inch. The same type of saw, having from 14 to 18 (raker-set or wave-set) teeth per inch, is used for cutting off tubing that has a wall thickness of 1/16 in. or larger.

Table IV. Feeds and Speeds for Planing Heavy Work

	Speed, ft per min							
	Roughing Tool Fig. 16				Finishing Tool Fig. 17			Parting Tool Fig. 18
Depth of Cut, inch	1/16	1/8	1/4	3/8	0.020	0.014	0.010	0.005 to 0.010
Feed, inch	3/32	1/16	5/64	3/64	11/32	5/32	3/8	.....
Forged Monel } Forged Nickel }	25	25	25	25	25	35	30	30
Forged "K" Monel (unhardened) } Forged Inconel }	15	15	15	15	15	25	20	20

Nickel, Monel and unhardened "KR" Monel are cut off at 90 strokes per minute; Inconel and unhardened "K" Monel at 60 strokes per minute; and "R" Monel at 130 strokes per minute. High speed steel blades with 24 to 32 (wave-set) teeth per inch are used in hand hacksaws for cutting off thin-wall tubing.

Where abrasive cutoff wheels are used, aluminum oxide wheels, bonded with rubber or resin, are recommended.

Flexible-back saws of alloy steel in the saw manufacturers' "A" temper are recommended for band sawing. For band sawing nickel alloys less than ¼ in. thick, general saw velocities are 75 to 85 fpm for nickel, Monel, unhardened "KR" Monel and Inconel, and 110 fpm for "R" Monel. These speeds should be decreased for sawing material heavier than ¼ in.

Cutting-off lathes equipped with high-speed cutoff blades are operated at 50 to 60 fpm for Monel, unhardened "KR" Monel and nickel; 90 to 110 fpm for "R" Monel; and 35 to 45 fpm for unhardened "K" Monel and Inconel.

Figures 5 and 6 show suggested tool grinds for lathe parting tools.

Milling. Instead of curling, the milling chips from these materials break into fine shreds or powder. To facilitate chip disposal, the cutter should be ground with a 10 to 15-deg positive rake from the cutting edge. Coarse-tooth cutters are preferred. Plain or barrel milling cutters should be of the heavy-duty spiral-fluted type. Staggered, alternate-tooth cutters of opposite helix angle, or interlocking milling cutters are best for milling grooves. For narrow slotting, high speed steel slitting saws with alternately chamfered teeth are most satisfactory. Operating speeds for milling these materials with high speed steel cutters are listed in Table I. Complete data are not available concerning the milling of these materials with carbide tools; however, as a guide, "K" Monel has been milled with carbide tools at 425 fpm using a table feed at 12½ ipm. This particular job involved straddle-milling by a method of climb-milling with half-side milling cutters ground to a negative rake angle of 5 deg and a positive helix of 10 deg. No cutting lubricant was used.

Broaching. Broaches should be made of regular or super high speed steel. The latter type of steel affords longer service between regrinding operations. Broaches should be hardened and tempered to a hardness of about 64 Rockwell C. Depth of cut per tooth should be approximately 0.002 in. The broach should be designed so that at least two teeth are always working. Helical teeth afford the smoothest cutting. Chip breakers (nicked teeth) aid in chip control and lessen the cutting pressure per tooth. A suggested broach is shown in Fig. 15.

Planing. The setup for planing or shaping is the same as for mild steel. Roughing is usually done dry, but a cutting lubricant, used for finishing cuts and parting, improves surfaces.

Designs of planer tools are shown in Fig. 16 to 18 inclusive, and for shaper tools in Fig. 19 and 20. Table IV, which lists some feeds, cuts and speeds used on production jobs, will serve as a guide in setting up for planing.

Grinding, Polishing and Buffing Nickel and Nickel Alloys

By W. F. Burchfield*

THE wheels used for the precision grinding of nickel and nickel alloys should be sufficiently soft and the grinding conditions sufficiently severe to cause the abrasive in the wheel to wear off gradually, so as to present a continually new cutting edge. A suitable grinding compound correctly mixed must be used to obtain good finishing results and to maintain cool metal.

General recommendations in regard to wheels are as shown in Table I.

Metal Finishing. *The Grinding of Welds.* To grind welds on heavy plate where the finish is unimportant, either No. 14 grit or No. 24 grit rubber- or resinoid-bonded wheels should be used. On parts that are to be given a high finish later, finer grinding wheels, such as a No. 36 grit rubber-bonded or resinold-bonded wheel, are preferred.

Avoid overheating the welds in grinding. Excessively heated grinding wheels have been known to cause cracking of welds on thin sheets.

Polishing. This series of operations includes "roughing", "dry fining", "greasing" and "grease coloring"—all accomplished with roll-head wheels or abrasive belts. Economy in polishing is obtained only by the correct selection of wheels, abrasives, and operating speed, and above all, by the correct preparation of the wheels.

Cements as well as glue are used for making up roll-head wheels, and cements are especially employed for wheels up to No. 180 grit, inclusive.

* Development and Research Division, The International Nickel Company, Inc., New York

Abrasive belts on expanding drums or with back-stand idlers are also satisfactory for polishing.

Ordinarily there should be from 40 to 60 grit numbers between successive polishing operations. When preparing a surface for a buff finish, cross the scratches of the preceding coarser wheel to remove the coarser marks.

Buffing (Loose-Disk Buff). Buffing operations performed with a high-count muslin, loose-disk wheel include the "cutting down" from the polishing scratches preparatory to obtaining a mirror finish by color buffing. The selection of wheels is highly important for buffing. The pocket-type wheels that are made from high-count muslin sheeting hold the buffing compounds well and are also stiff enough to result in good cutting action. For the highest mirror finish, Canton flannel buffs charged with chromic oxide compound are used.

Tripoli compounds are used for cutting down, and unfused alumina (white) or chromic oxide (green) compounds are used for color buffing. Lime compounds, such as are used for buffing nickel plate, or rouge used for coloring brass, do not have sufficient cutting or coloring characteristics for nickel alloys and should not be used.

Satin Finish. One method of obtaining a satin finish is to polish with a grease wheel, usually No. 150 or No. 180 grit, and then grease color, using a pocket-type buff charged with fine emery paste. A second method is to polish with a grease wheel or to rub down the part by hand with No. 180 to 220 production paper and then brush with a Tampico wheel charged with fine emery paste; or if the area is large and flat, to spread a combination of

emery flour and oil over the surface and brush with a Tampico wheel.

Another method is to buff with a high-count muslin, loose-disk wheel charged with a greaseless compound. This compound is a moist mixture of glue and abrasive in stick form, which is charged on the wheel; it is obtainable in several grades. The compounds produce a satin finish.

Cleaning. The final operation in all finishing jobs where polishing and buffing compounds have been used, is to sprinkle Vienna lime ("whiting") over the article and rub clean with a soft rag. A Canton flannel rag should be used on a mirror finish.

Table I. Abrasive Wheels for Grinding Nickel

Grinding Operation	Abrasive[a]	Bond[b]
Cylindrical	Silicon carbide	Vitrified, resinoid or rubber
Surface (rotary and reciprocating)	Aluminum oxide	Vitrified
Centerless	Silicon carbide	Vitrified or resinoid

(a) Use silicon carbide for surface-reciprocating grinding Inconel.
(b) Wheels that are bonded with resinoid or rubber are preferred for fine finish grinding.

The following are data for internal grinding, cylindrical grinding and surface grinding:

Operation Data for an Internal Grinding Job

Material	Nickel, Monel and Inconel[a]
Wheel speed	3200 surface ft per min
Wheel size	1 in. diam by ¾ in. face by ¼ in. arbor hole
Wheel	Norton 3760–K5
Work speed	156 rpm
Traverse	40 in. per min
Rate of feed	0.0003 to 0.0004 in. per pass on diam
Grinding condition	Wet
Size of material	1 in. IPS

Operation Data for a Cylindrical Grinding Job

Material	Nickel, Monel, Inconel, "K" Monel and "Z" Nickel[a]
Machine	Norton 10 in. by 36 in. "A" type
Wheel	Norton 3760-J7
Wheel size	18 in. diam by ■ in. face by 5 in. arbor hole
Wheel speed	6000 surface ft per min
Work speed	88 rpm (work 2 in. diam)
Table traverse	Roughing, 90 ft per min Finishing, 63 to 77 ft per min
Feed per pass	Roughing, 0.001 to 0.0005 in. Finishing, 0.00025 in.
Wheel truing	Diamond, wet
Grinding condition	Wet

Operation Data for a Surface Grinding Job

	Work Motion — *Rotary*	*Work Motion* — *Reciprocating*
Machine	Pratt and Whitney vertical spindle	Norton No. 1, 6 in. by 8 in.
Wheel size	8 in. diam by 3 in. face by 4 in. arbor hole, P&W cup, ⅝ in. rim	8 in. diam by ½ in. face by 1½ in. arbor hole
Wheel speed	4200 surface ft per min	5000 surface ft per min
Table speed	50 rpm	400 in. per min
Cross feed	.....	0.050 in. every other cross stroke
Rate of down feed	Roughing 0.001 in. per rpm	Roughing, 0.001 in. per pass Finishing, 0.0005 in. per pass
Dressing	Huntington, fine	Diamond, fine
Grinding condition	Wet	Wet
	Wheels (Norton)

Pickling and the Removal of Oxide From Nickel and Nickel Alloys

By W. F. Burchfield*

THE same properties that make nickel alloys resistant to corrosion make the pickling of these alloys more difficult than that of iron, steel or copper alloys. In fact, because they resist attack by the usual commercial acids, nickel alloys are used for handling equipment and for tanks employed in pickling other materials.

Type of Oxide. Since the removal of oxides from nickel alloys is so difficult, it is important to consider the type of oxide formed. Light tarnish, resulting from thermal treatment at low temperature, is removed most easily. Reduced oxides, which result from heating in a reducing atmosphere, and either cooling in the reducing atmosphere or quenching in a 2% (by volume) solution of alcohol in water, are relatively easy to pickle provided they do not contain chromium oxide, which is almost irreducible in a controlled atmosphere. Heavy oxides produced in oxidizing atmospheres (and in alloys containing chromium) are the most difficult to pickle. Sulfur in any form is injurious to nickel alloys at elevated temperatures. Sulfurous atmospheres or sulfur contamination from residual lubricants, marking paints or roof spallings, will produce discoloration very difficult, if not impossible, to remove by pickling.

To obtain the best results and to reduce the cost of pickling, it is important to control the heating procedure, and thus to control the type of oxide formed, so as to minimize the amount and severity of pickle required.

Degreasing. Oils and greases must be removed prior to the pickling operations. Petroleum spirits, carbon tetrachloride, alkaline or vapor degreasers are used satisfactorily for degreasing nickel materials.

Pickling. Pickling formulas for the nickel alloys, together with the suggested containers and operating temperatures, are given below. In the preparation of these solutions, the ingredients should be added in the order given. All these solutions should be used only in a well-ventilated location since the fumes are noxious. Extreme care should be taken when handling and mixing these acids. *Hydrofluoric acid, either in liquid or gaseous form, will burn body tissue seriously and painfully. Sodium cyanide is a deadly poison.*

Table I gives recommended formulas for pickling four classes of material with three different oxide surfaces.

Table I. Numbers of the Pickle Formulas for Nickel and Nickel Alloys

Type of Finish	Light Tarnish	Reduced Oxide	Heavy Oxide
	Material[a]		
Nickel			
Nickel and "Z" Nickel	3	4	5, 5-3
Nickel-Copper			
Monel, "K" Monel, "R" Monel	1-2	4	5-6
Nickel-Chromium-Iron			
Inconel, Nichrome, Nichrome V, Illium G	7, 8-9	7, 8-9	7, 8-9
Nickel-Molybdenum			
Hastelloy A, B, C	4	4	4

(a) For chemical compositions of these alloys, see page 1029.

Neutralizing and Drying. After the final acid dip, parts should be rinsed in hot or cold water to remove the acid, then immersed in a cold, neutralizing bath, 1 to 2% by volume, of ammonia solution (4 to 8 fl oz commercial aqua ammonia per gallon of water). After neutralizing, the parts can be dried in sawdust or dipped in boiling water and dried in air.

Coppering. A copper flash will occur on Monel if iron is in contact with the Monel in an acid dip. Copper will also plate out on nickel and Inconel if the bath has become contaminated by the pickling of alloys containing copper. When coppering occurs, it can be removed by immersing

* Development and Research Division, The International Nickel Company, Inc., New York

the parts in ■ 4 to 5% ammonia solution (approximately 1 pint commercial aqua ammonia per gallon of water) at room temperature for about 1 min.

Discoloration From Sulfur Cutting Oil. Frequently sulfur-bearing cutting oil causes a brown discoloration on Monel when it is machined at high speeds. This discoloration can be removed easily with a solution of formula 10. *Remember that cyanide is a deadly poison; handle with care. Acid must not get into this solution or deadly hydrocyanic gas will be generated.*

Molten Salt Baths. The descaling of nickel and nickel alloys in certain molten salts is very satisfactory. These processes, discussed in the article on page 283 of this Handbook, accomplish the degreasing, reducing of oxide and removing of scale by immersion of the part in a molten salt bath for a period of 15 to 30 min followed by a quench in water. The surface obtained may be satisfactory for further processing, but usually subsequent acid dips are required to give the metal a bright finish. Nickel and nickel-copper alloys can be brightened in a hot solution (160 F) of 10% nitric acid for 1 to 2 min. Nickel-chromium-iron alloys can be brightened in a cold bath of nitric and hydrofluoric acids similar to formula 7, though not so strong. Nickel-molybdenum alloys can be brightened in a hot solution (190 F) containing 8% sulfuric acid plus 0.2 lb NaCl per gal of mixture.

Formula 1. Flash Pickle. Monel and "K" Monel. First Dip.

Water	1 gal	1000 cu cm
Nitric acid (38 Bé)	1 gal	1000 cu cm
Common salt (NaCl)	½ to ¾ lb	60 to 90 ■
Temperature	70 to 100 F	21 to 38 C
Time	Not more than 5 sec	
Container	Earthenware crocks, glass, or ceramic	
Procedure	Degrease, dip in acid, rinse in hot water (180 F), formula 2.	

Formula 2. Flash Pickle. Monel and "K" Monel. Second Dip.

Water	1 gal	1000 cu cm
Nitric acid (38 Bé)	1 gal	1000 cu cm
Temperature	70 to 100 F	21 to 38 C
Time	Not more than 5 sec	
Container	18-8 stainless steel, glass or ceramic	
Procedure	From rinse above, dip in acid, neutralize, dry.	

Formula 3. Flash Pickle. Nickle. Brightener After Formula 5.

Water	1 gal	1000 cu cm
Sulfuric acid (66 Bé)	1½ gal	1500 cu cm
Nitric acid (38 Bé)	2¼ gal	2250 cu cm
	Allow to cool and add:	
Salt	¼ lb	30 ■
Temperature	70 to 100 F	21 to 38 C
Time	5 to 20 sec	
Container	Earthenware crocks, glass, or ceramic	
Procedure	Degrease, warm in hot water, dip in acid, rinse, neutralize, dry.	

Formula 4. Removal of Reduced Oxide. Nickel, "Z" Nickel, Monel, "K" Monel, Hastelloy A, B and C.

Water	1 gal	1000 cu cm
Sulfuric acid (66 Bé)	¾ pt	95 cu cm
Sodium nitrate (crude)	½ lb	65 g
Common salt (NaCl)	1 lb	110 ■
Temperature	180 to 190 F	82 to 88 C
Time	30 to 90 min	
Container	Earthenware, glass, ceramic, wood for short time	
Procedure	Degrease, pickle, rinse in hot water, neutralize, dry. Pickling is facilitated by intermediate scrubbing with pumice or a fiber brush.	

Formula 5. Removal of Oxide Film or Scale. Nickel and "Z" Nickel, Monel and "K" Monel. First Dip.

Water	1 gal	1000 cu cm
Hydrochloric acid (20 Bé)	½ gal	500 cu cm
Cupric chloride	¼ lb	30 g
Temperature	180 F	82 C
Time	20 to 40 min	
Container	Earthenware, glass, ceramic, acid-proof brick	
Procedure	Monel: degrease, dip in acid, rinse in hot water, solution 6. Nickel: degrease, dip in acid, rinse in hot water, solution 3.	

Formula 6. Removal of Oxide Film or Scale. Monel and "K" Monel. Second Dip.

Water	1 gal	1000 cu cm
Sulfuric acid (66 Bé)	1/10 gal	100 cu cm
Sodium dichromate	1 1/10 lb	132 g
Temperature	70 to 100 F	21 to 38 C
Time	5 to 10 min	
Container	Earthenware, glass, ceramic or rubber	
Procedure	From solution 5 rinse, dip in acid, rinse in cold water, neutralize, dry.	

Formula 7. Removal of Oxide or Scale. Inconel, Nichrome, Nichrome V, Illium G.

Water	1 gal	1000 cu cm
Nitric acid (38 Bé)	1 gal	1000 cu cm
Hydrofluoric acid 40%	1¼ pt	150 cu cm
Temperature	70 to 100 F	21 to 38 C
Time	15 to 90 min	
Container	Carbon brick	
Procedure	Degrease, dip in acid, rinse in cold water, neutralize, dry.	

Formula 8. Reduced Oxide Only. Inconel, Nichrome, Nichrome V, Illium G. First Dip.

Water	1 gal	1000 cu cm
Sodium hydroxide (caustic soda)	18 oz	134 ■
Sodium carbonate (soda ash)	18 oz	134 g
Potassium permanganate (permanganate of potash)	7 to 11 oz	52 to 82 g
Temperature	180 to 190 F	82 to 88 C
Time	2 hr	
Container	Steel	
Procedure	Degrease, dip in alkali, to solution 9. These formulas work satisfactorily only when these materials have been heat treated in a strongly reducing atmosphere.	

Formula 9. Reduced Oxide Only. Inconel, Nichrome, Nichrome V, Illium G. Second Dip.

Water	1 gal	1000 cu cm
Sulfuric acid (66 Bé)	½ pt	63 cu cm
Copper sulfate or copper nitrate	1½ oz	12 g
Temperature	180 to 190 F	82 to 88 C
Time	1 hr	
Container	Wood, earthenware, glass, ceramic, acid-proof brick	
Procedure	From solution 8, dip in acid, rinse in cold water, neutralize, dry.	

Formula 10. Removal of Sulfur Discoloration. Monel.

Water	1 gal	1000 cu cm
Sodium cyanide	½ to 1 lb	60 to 120 g
Temperature	70 to 100 F	23 to 38 C
Time	5 to 30 min	
Container	Earthenware, glass, ceramic	
Procedure	Degrease, dip, rinse in hot or cold water, dry.	

The Resistance of Nickel and Nickel Alloys to Corrosion

By W. Z. Friend*

THIS article describes the resistance to corrosion of nickel, nickel-copper alloys, nickel-molybdenum-base alloys, nickel-chromium alloys, and the Ni-Cr-Cu-Mo alloy known as Illium.

Nickel. Nickel does not readily discharge hydrogen from any of the common reducing acids. A supply of some oxidizing agent, such as dissolved air, is necessary in order for corrosion to proceed. Reducing conditions usually retard corrosion of nickel, while oxidizing conditions accelerate corrosion. However, nickel has the ability to protect itself against certain forms of attack by the development of a corrosion-resisting, or passive, oxide film. Consequently, oxidizing conditions do not invariably accelerate corrosion.

Atmospheric Corrosion. Indoor exposure causes virtually

* Development and Research Division, The International Nickel Company, Inc., New York

no attack on nickel. Outdoors the rate of corrosion varies with atmospheric conditions; the rate is usually less than 0.0001 and never more than 0.001 ipy.* Sulfurous atmospheres are most corrosive. Marine atmospheres are scarcely more corrosive than suburban or rural atmospheres. Nickel is free from season cracking and other forms of stress corrosion in atmospheric exposure.

Waters. Nickel is highly resistant to corrosion by waters, such as distilled water, natural waters (including those containing hydrogen sulfide or free carbon dioxide) and sea water. In sea water, conditions of agitation or flow are favorable to nickel, whereas local attack may occur under barnacles or other attached solids in stagnant exposure.

Salt Solutions. Nickel resists corrosion by neutral and alkaline salt solutions, with rates usually less than 0.005 ipy. Nonoxidizing acid salts are only moderately corrosive, with rates seldom higher than 0.02 ipy. Oxidizing acid salts, such as ferric chloride, and mixtures of oxidizing salts with mineral acids, are likely to corrode nickel severely. So are oxidizing alkaline salts, such as hypochlorites, with which nickel should not be used when the available chlorine content exceeds 3 g per liter. Alkaline solutions containing hydrogen peroxide do not corrode nickel and are not decomposed by it.

Mineral Acids. Nickel is fairly resistant to sulfuric acid in concentrations of less than 80%. Corrosion rates vary from less than 0.005 ipy in acid free from air, to about 0.05 ipy in acid saturated with air at atmospheric temperatures. Nickel is rarely useful in contact with hot sulfuric acid solutions in concentrations greater than about 15%.

With cold hydrochloric (muriatic) acid the rates of attack vary, according to the air content and concentration of the acid, from 0.01 to 0.04 ipy, in dilute acid, to 0.06 to 0.08 ipy in concentrated acid. In hot acid, nickel is rarely useful in handling solutions containing more than 2% acid.

Nickel is not corroded appreciably by chlorinated solvents or mixtures of these with water.

Nickel is resistant to pure phosphoric acid, but is corroded severely by this acid when it contains oxidizing impurities, such as ferric compounds.

Nickel is corroded strongly by sulfurous acid, except the very dilute solutions used to preserve foods.

Strongly oxidizing acids, such as nitric, corrode nickel rapidly.

Organic Acids and Compounds. Organic acids are only moderately corrosive to nickel. Neutral and alkaline organic compounds have virtually no effect.

Alkalies. Nickel resists corrosion by the strongest alkalies. For example, in boiling 50% caustic soda, rates of corrosion are less than 0.001 ipy; and in concentrations greater than 75%, nickel is second only to silver in resisting attack. Anhydrous ammonia does not corrode nickel, but ammonium hydroxide is appreciably corrosive in concentrations greater than about 1%.

Wet and Dry Gases. No dry gases are actively corrosive to nickel at atmospheric temperature. Nitric oxide, chlorine and other halogens, sulfur dioxide, and ammonia are appreciably corrosive when mixed with water or condensed water vapor. Nickel is resistant to chlorine and hydrogen chloride at temperatures up to about 1000 F, and is not affected by steam within the range of temperatures commonly encountered.

When heated in oxidizing atmospheres, nickel forms a rather superficial, tightly adherent scale at temperatures lower than 1400 F. Resistance to excessive oxidation makes the metal especially useful in the temperature range from 2100 to 2300 F.

Nickel is not resistant to mixtures of nitrogen, hydrogen and ammonia at the temperatures and pressures encountered in the commercial process for the synthesis of ammonia. However nickel is useful under the conditions that obtain during the dissociation of ammonia in nitriding equipment, providing the temperature is not higher than about 1075 F.

At temperatures higher than 600 to 700 F, nickel is subject to both general and intergranular corrosion by compounds and gases that contain sulfur. The extent of this attack is less in an oxidizing environment containing SO_2 than in a reducing environment containing H_2S. The resistance of nickel to attack by sulfur is improved considerably by additions of manganese in amounts of 5% or less.

Nickel-Copper Alloys. The nickel-copper alloys that contain more than 50% Ni are benefited by the high degree of nobility of copper and by the ability of nickel to protect itself, frequently through the development of passive oxide films. Such alloys are, in general, more resistant than nickel under reducing conditions, and more resistant than copper under oxidizing conditions.

Atmospheric Corrosion. In indoor atmospheres these alloys remain substantially unchanged. In outdoor atmospheres they remain bright only in rural districts. In sulfurous atmospheres they gradually acquire a brownish or greenish tarnish but there is no destructive corrosion. Atmospheric corrosion tests have shown corrosion rates of less than 0.0001 ipy at all test locations.

Waters. The nickel-copper alloys have excellent resistance to distilled water and natural waters, both hard and soft. These alloys find their greatest usefulness in sea water under conditions of high velocity, where resistance to effects of impingement and cavitation are important. Stagnant exposure is less favorable, since pitting may be induced under marine organisms or other solids.

Salt Solutions. Neutral and alkaline salt solutions, including chlorides, carbonates, sulfates, nitrates, acetates and others, have a negligible corrosive effect on nickel-copper alloys, with corrosion rates usually less than 0.005 ipy. These alloys also have good resistance to nonoxidizing acid salt solutions, such as zinc chloride, ammonium sulfate, aluminum sulfate and others, and have rates of corrosion usually less than 0.02 ipy.

Oxidizing acid salts, such as ferric chloride, ferric sulfate, cupric chloride, cupric sulfate and mixtures of these salts with mineral acids, are likely to be severely corrosive, except in very dilute solutions. This is also true with alkaline hypochlorite solutions, where the limiting concentration of available chloride that can be handled safely is about 3 g per liter. Alkaline peroxide solutions are not corrosive to these alloys.

Mineral Acids. In sulfuric acid free from air at atmospheric temperature, corrosion of the nickel-copper alloys is virtually nil in all concentrations less than about 80%. In acid saturated with air, and in concentrations lower than 80%, maximum corrosion occurs with 5% acid at a rate of about 0.04 ipy. In 5% acid saturated with air, the temperature of most active corrosion is about 185 F where the corrosion rate is about 0.12 ipy. Boiling sulfuric acid may be handled in concentrations less than 20%.

In cold hydrochloric acid free from air, rates of corrosion range from about 0.005 ipy in 1% acid to 0.08 ipy in 20% acid. In cold acid saturated with air, corrosion rates vary from 0.04 ipy in 1% to 0.08 ipy in 10% concentrations. Rates are about 0.04 ipy in 5% acid at 160 F and 0.04 ipy in boiling 1% acid. There is no significant corrosion in mixtures of chlorinated solvents and water.

These alloys resist corrosion by hydrofluoric acid throughout a wide range of concentrations and temperatures. They resist pure phosphoric acid also, but may be corroded by impure solutions containing ferric salts.

Sulfurous acid and bisulfites are appreciably corrosive, except in very dilute solutions.

Oxidizing acids, such as nitric acid, are highly corrosive, except in concentrations less than 1%, at temperatures lower than 80 F.

Organic Acids and Compounds. Nickel-copper alloys show good resistance to corrosion by all the common organic acids, and are virtually free from corrosion by neutral and alkaline organic compounds, and fruit and other food acids.

Alkalies. Nickel-copper alloys are virtually completely resistant to most alkaline solutions, including concentrated caustic soda solutions at temperatures below the boiling point. In ammonium hydroxide solutions, these alloys may be used at concentrations less than 3% NH_3. Nickel-copper alloys are not corroded by anhydrous ammonia.

Wet and Dry Gases. No dry gases are actively corrosive at atmospheric temperatures. Nitric oxide, chlorine and other halogens, sulfur dioxide and ammonia are corrosive

* Ipy means the depth in inches to which uniform corrosion would penetrate during continuous exposure for one year.

in the presence of water. Nickel-copper alloys are resistant to chlorine at temperatures up to about 850 F.

These alloys are usefully resistant to steam within the range of temperatures and pressures commonly used. They resist atmospheric oxidation below about 1000 F.

In reducing sulfur atmospheres (hydrogen sulfide) nickel-copper alloys are subject to intergranular attack at temperatures higher than 700 F. These alloys are attacked by mixtures of nitrogen and hydrogen under the conditions of pressure and temperature in ammonia synthesis.

Resistance of Hastelloy Alloys to Corrosion. Hastelloy A (60% Ni, 20% Mo, 20% Fe) and Hastelloy B (65% Ni, 30% Mo, 5% Fe) were developed primarily to resist corrosion by hydrochloric acid, and the extent to which they do this is their most important property.

Hastelloy C (58% Ni, 17% Mo, 15% Cr, 5% W, 5% Fe) possesses an unusual degree of resistance to oxidizing solutions, especially to those containing chlorides, in addition to other corrosive chemicals. It is unique among alloys in its resistance to hypochlorite solutions and moist chlorine.

The most important property of Hastelloy D (85% Ni, 8 to 11% Si, 3% Cu) is its resistance to corrosion in concentrated solutions of sulfuric acid at elevated temperatures.

All these materials are virtually free from corrosion under such relatively mild conditions as exposure to the atmosphere, fresh water, salt water, and neutral and alkaline salts.

Hydrochloric Acid. Hastelloy A is usefully resistant to all concentrations of hydrochloric acid at room temperature and to unaerated solutions at temperatures lower than about 160 F. Rates of corrosion in unaerated acid are usually less than 0.03 ipy at this upper temperature limit.

Hastelloy B is notable for its unusually high resistance to corrosion in all concentrations of hydrochloric acid at temperatures as high as the boiling point. It is used in contact with wet hydrogen chloride gas. Its corrosion rate is only 0.023 ipy in 20% boiling acid, one of the most severely corrosive conditions.

Corrosion of Hastelloys A and B is considerably increased by the presence of oxidizing salts, such as ferric and cupric salts, in acid solutions, so caution should be used in such applications.

Hastelloy C resists all concentrations of hydrochloric acid at room temperature, and may sometimes be used at temperatures as high as 120 F.

Hastelloy D is moderately resistant, although the maximum temperature for its use is about 100 F.

Sulfuric Acid. Hastelloy A is usefully resistant to sulfuric acid in concentrations as great as 50% at temperatures as high as the boiling point, and to higher concentrations at temperatures lower than about 160 F.

Hastelloy B is more resistant than alloys A, C and D to boiling sulfuric acid in concentrations lower than about 60%, but is less resistant than alloy D to boiling acid at higher concentrations.

Hastelloy C is somewhat superior to alloy A in resistance to corrosion, although the same limitations apply to the use of both.

Hastelloy D is usefully resistant to all concentrations of sulfuric acid at temperatures as high as the boiling point. In boiling acid evaporated to fumes, the corrosion rate of Hastelloy D is about 0.05 ipy.

Nitric Acid and Oxidizing Acid Mixtures. Hastelloy C is resistant to dilute nitric acid below about 150 F, and to acid concentrations of more than 40% at room temperature only. In addition this alloy is resistant to mixtures of oxidizing acids, such as nitric and sulfuric; chromic and sulfuric; sulfuric and copper sulfate; sulfuric and dichromates, permanganates or persulfates; and similar combinations.

Hastelloys A, B and D are not recommended for service with nitric or other strongly oxidizing acids.

Organic Acids and Compounds. All these alloys are highly resistant to organic acids and to neutral and alkaline organic compounds.

Salt Solutions. Hastelloys A, B and C are resistant to acid chlorides, such as aluminum or ammonium sulfate, and to acid phosphates.

Hastelloy C is unusually effective in resisting solutions of such corrosive oxidizing salts as ferric chloride (below 160 F), and cupric chloride (below 100 F). At moderate temperatures, it also resists corrosion by mixtures of oxidizing salts such as chromates and nitrates in sulfuric and hydrochloric acid solutions.

Chlorine and Hypochlorites. Hastelloy C is one of the few metallic materials that has useful resistance to hypochlorites and other solutions containing free chlorine in appreciable concentrations, below about 100 F.

Wet and Dry Gases. Hastelloys A, B and D are resistant to progressive atmospheric oxidation and to oxidizing and reducing flue gases, at temperatures lower than about 1450 F. Hastelloy C is resistant to higher temperatures, about 1800 F. All alloys are resistant to ammonia, wet or dry.

Alloys C and D are resistant to wet hydrogen sulfide and to sulfur dioxide at less than about 160 F.

Nickel-Chromium Alloys. A number of available alloys contain from 60 to 80% Ni and from 13 to 20% Cr, with the remainder mostly iron. Because of their nickel base, these alloys are referred to as Ni-Cr alloys to distinguish them from the stainless steels, or iron-base Fe-Cr-Ni alloys. In addition, several grades of the hard surfacing material known as Colmonoy have a nickel base (from 68 to 85% Ni, depending on the grade), with chromium boride crystals as the other essential constituent.

The corrosion-resisting characteristics of these nickel-chromium alloys are somewhat similar. Their chromium content makes them superior to pure nickel under oxidizing conditions. The high nickel content enables them to retain considerable resistance under reducing conditions and in strongly alkaline solutions. As would be expected, the most significant differences in performance among alloys of this group occur, on the one hand, in highly oxidizing solutions, such as nitric acid solutions, where higher chromium contents are most effective; and, on the other hand, in reducing acids such as hydrochloric, where increased nickel content is usually beneficial.

Atmospheric Corrosion. The nickel-chromium alloys are resistant to all types of atmospheres, including rural, urban, industrial and marine. In rural and indoor atmospheres these alloys will remain bright indefinitely. In sulfurous industrial atmospheres there may be some tarnishing but no significant attack.

Waters. The nickel-chromium alloys are virtually free from attack by the most corrosive of natural waters and mine waters. They are moderately resistant to rapidly flowing sea water but, in quiet or stagnant exposure, may be subject to pitting where barnacles or other solids become attached to the metal surface. In marine atmospheres, these alloys are among the most resistant of commonly available materials.

Salt Solutions. Nickel-chromium alloys resist neutral and alkaline salt solutions well, with corrosion rates usually less than 0.001 ipy. In acid salt solutions, corrosion rates usually do not exceed 0.02 ipy, except with such oxidizing halogen salts as ferric chloride, cupric chloride, and mercuric chloride, which are severely corrosive in all but very dilute solutions. In hypochlorite solutions the use of these alloys is generally limited to available chlorine concentrations not exceeding 3 g per liter. In hot chloride solutions corrosion may sometimes be accompanied by pitting, although this tendency is considerably less than with iron-base Fe-Cr or Fe-Cr-Ni alloys.

Mineral Acids. The nickel-chromium alloys resist sulfuric acid solutions at atmospheric temperature. Corrosion rates vary from less than 0.005 ipy in solutions free from air, to 0.06 ipy in solutions saturated with air. Attack by strong hot solutions is usually severe. The addition of small amounts of oxidizing salts, such as ferric sulfate or cupric sulfate, to acid solutions, will increase the passivity range.

In hydrochloric (muriatic) acid, the usefulness of nickel-chromium alloys is limited to dilute solutions, less than 5% in concentration by weight, at atmospheric temperature. Corrosion is usually severe at elevated temperatures.

Nickel-chromium alloys resist both pure and impure solutions of phosphoric acid at moderate temperatures, but not hot concentrated solutions.

Sulfurous acid solutions are usually corrosive, especially when hot, but nickel-chromium alloys have good resistance to the very low sulfur dioxide concentrations used in food preservation.

The nickel-chromium alloys as a group are highly resist-

ant to strongly oxidizing acids such as nitric acid, at moderate temperatures. The higher the chromium content, the wider the range of concentrations and temperatures in which passivity exists. These alloys are generally inferior to the Fe-Cr-Ni and Fe-Cr alloys in solutions of hot nitric acid.

Organic Acids and Compounds. These alloys have generally good resistance to organic acids and to neutral and alkaline organic compounds. They are particularly effective in resisting fatty acids at elevated temperatures.

Alkalies. The nickel-chromium alloys resist corrosion by caustic alkalies and alkaline solutions in most concentrations and temperaures. They also resist all concentrations of ammonium hydroxide.

Wet and Dry Gases. The nickel-chromium alloys are completely resistant to all the common gases when dry, at or near atmospheric temperature. In the presence of moisture nickel-chromium alloys do not resist chlorine or other halogens, but are resistant to such gases as ammonia, nitric oxides and hydrogen sulfide. Inconel (80% Ni, 13% Cr, 6.5% Fe) is resistant to chlorine and hydrogen chloride at temperatures below about 1000 F.

These alloys are completely resistant to all mixtures of steam, air and carbon dioxide, and are especially useful in contact with steam at temperatures above 800 F. They also resist ammonia, nitrogen and hydrogen as encountered in nitriding operations.

Inconel resists progressive oxidation at temperatures below 2000 F. In oxidizing sulfur atmospheres such as sulfur dioxide, the safe operating temperature limit is about 1500 F. In reducing sulfur atmospheres such as hydrogen sulfide, the safe upper limit is about 1000 F.

Corrosion Resistance of Illium. Illium (56% Ni, 22% Cr, 6% Cu, 6% Mo, 1% W) was originally developed as a material resistant to both sulfuric and nitric acids over a wide range of concentration and exposure conditions. It is superior in applications under highly oxidizing conditions, such as exposure to nitric acid, and has limited applications in hydrochloric acid and acid chlorides. This material is virtually free from corrosion under such relatively mild conditions as exposure to the atmosphere, to fresh water, salt water, and to neutral and alkaline salts.

Mineral Acids. Illium is usefully resistant to sulfuric acid under virtually all conditions of concentration, aeration, agitation and temperature. Tests in boiling 25% sulfuric acid have indicated a rate of corrosion of 0.017 ipy. Illium has been found useful for parts of pumps and other equipment handling chamber-process acid containing oxidizing nitrogen compounds.

Illium is resistant to hydrochloric acid in concentrations as high as 15% at atmospheric temperature, but is not recommended for use with more concentrated acid or with hot dilute solutions. Illium is highly resistant to attack by phosphoric acid and is especially useful when the acid contains fluorides or oxidizing impurities. It possesses useful resistance to sulfurous acid solutions, especially where both sulfuric and sulfurous acids are present, and is highly resistant to hydrogen sulfide and solutions containing this gas.

Oxidizing Acids. Illium resists all concentrations of nitric acid at all temperatures. Tests in boiling 25% acid indicated corrosion rates of less than 0.01 ipy, and in cold concentrated acid, less than 0.001 ipy. Illium also resists oxidizing acid mixtures such as nitric and sulfuric; chromic and sulfuric, sulfuric and copper sulfate; sulfuric and dichromates, permanganates, and persulfates.

Organic Acids and Compounds. Illium is highly resistant to organic acids and to neutral and alkaline organic compounds.

Salt Solutions. Illium is highly resistant to acid phosphates and to acid sulfates, such as aluminum and ammonium sulfate. It also resists such highly corrosive chemicals as ferric chloride and ferric sulfate, and mixtures of oxidizing salts such as chromates and nitrates, in acid solutions.

The Metallography of Nickel and Nickel Alloys

By David I. Sinizer*

In preparing specimens of nickel and nickel alloys for metallographic examination, it is important to prevent working of the surface, and care should be taken to avoid pitting and loss of inclusions.

Grinding and Polishing. Specimens to be polished should be about ½ to 1 in. sq, with the thickness somewhat less, to prevent rocking during preparation. Smaller specimens may be mounted in lucite, bakelite or mechanical clamps of various kinds. Materials used in mechanical clamps should be similar to the sample in order to prevent abnormal etching effects. Woods metal or babbitt mounts are unsatisfactory because of their etching behavior at the interfaces between sample and mounting material.

The specimen is first faced, if necessary, by filing or coarse grinding on a rotating stone, using light pressure and water lubrication to prevent surface distortion. The flat surface thus obtained is further ground on dry abrasive disks, using successively finer grits on several wheels rotating at 300 to 600 rpm. In general, a succession of emery or carborundum disks, of 180, 240, 320 and 400 grits, provide a satisfactory surface for further polishing. Specimens should be turned 90 deg as they proceed to each successive disk, in order to remove scratches from the previous operation. The specimen should be ground on each disk only long enough to remove scratches from the previous operation. Dry grinding on the last abrasive paper is the most critical step, because the wet polishing time is governed by the depth and uniformity of the scratches produced here. To prevent loss of inclusions from some alloys, it is advisable to use a well-worn or graphited paper for the final grinding step, and to omit the wet polishing on the coarse alumina wheel. Frequently, finishing by hand on the final abrasive papers keeps the specimen flatter, reduces surface distortion, and prevents pitting in later stages of preparation.

The specimens are then coarse polished on a wheel covered with flat silk crepe, revolving at about 300 rpm, and using levigated alumina (such as Fishers' No. 3) in water. This polishing is done at 90 deg to the scratches produced by the last grinding disk. Before final polishing, both specimen and hands should be carefully washed free from grit. Final polishing is done with extremely fine relevigated alumina, such as Rite-Tonnerde No. 3, on a wheel covered with flat silk crepe and rotating at about 300 rpm. At this stage the sample is rotated slowly on the wheel, opposite to the direction of wheel rotation. The specimen may be turned in the fingers through 90 deg a few times during the polishing operation. Disturbed metal on the polished surface may frequently be removed by repeated light etching and repolishing.

Preparation of Specimens for Macroscopic Examination. The surface to be etched for macroscopic examination may be prepared by surface grinding to a fine finish, or by polishing with 180-grit and 240-grit carborundum paper. Finer polishing is not necessary, but the finer the surface before etching, the better will be the final result. With finer surfaces, less drastic macro-etching is required to reveal the metal structure.

Etching for Metallographic and Macroscopic Examination. Etchants commonly used for metallographic examination of nickel and nickel alloys are listed in Table I. Representative microstructures obtained with various etchants are shown in Fig. 1 through 6.

Etchants commonly used for macroscopic examination of nickel and nickel alloys are shown in Table II.

* Metallurgist, Research Laboratory, The International Nickel Company, Inc., Bayonne, N. J.

Table I. Etchants for Metallographic Examination of Nickel and Nickel Alloys

Etchant	Composition	Directions for Use	Applications
Carapella's Reagent	Ferric chloride ..... 5 g Concentrated hydrochloric acid.. 2 ml Ethyl alcohol .....99 ml	Swab lightly or immerse with gentle agitation. Use covered dish to cut down evaporation. Time varies from 2 to 3 sec to several minutes, depending on alloy.	General use for nickel and nickel-copper alloys (Monel). Excellent definition of grain boundary and structural detail. Removes flowed metal easily. Develops grain contrast in Monel. (See Fig. 1)
Cyanide-persulfate	Equal volumes of 10% sodium cyanide and 10% ammonium persulfate	Use freshly mixed solutions. Swab or immerse for 5 to 90 sec. *Caution: Use a hood. Poisonous fumes are released when solutions are mixed.*	General use on nickel alloys, when desired to reveal the structure without removing finely dispersed inclusions such as graphite or nickel sulfide. (Fig. 2 and 3)
Modified Aqua Regia	Concentrated hydrochloric acid..10 ml Concentrated nitric acid..... 2 ml	Swab for 5 to 30 sec immediately after mixing. Use fresh white nitric acid.	General use on nickel-chromium-iron alloys such as Inconel. May pit specimens if not used fresh. Shows grain boundaries and carbides. (See Fig. 4)
Oxalic acid	10% oxalic acid solution in water	Etch anodically at 6 v for 5 to 15 sec. Four dry cells in series may be used.	Grain boundary etch for nickel-chromium alloys. (See Fig. 5)
Sodium cyanide	10% sodium cyanide solution in water	Etch anodically at room temperature at 5 to 6 v for 3 min. Voltage across cell is critical. Adjust current for proper voltage.	Carbides in nickel-chromium alloys. Longer etching, up to 20 min, will reveal general structure but oxalic acid is preferable for general structural detail. (See Fig. 6)
Monel Contrast Solution	Chromic acid ..... 3 g Concentrated nitric acid.....10 ml Ammonium chloride ..... 3 g Water .....90 ml	Immerse or swab specimen for 10 to 60 sec.	Grain contrast for measurement of grain size.

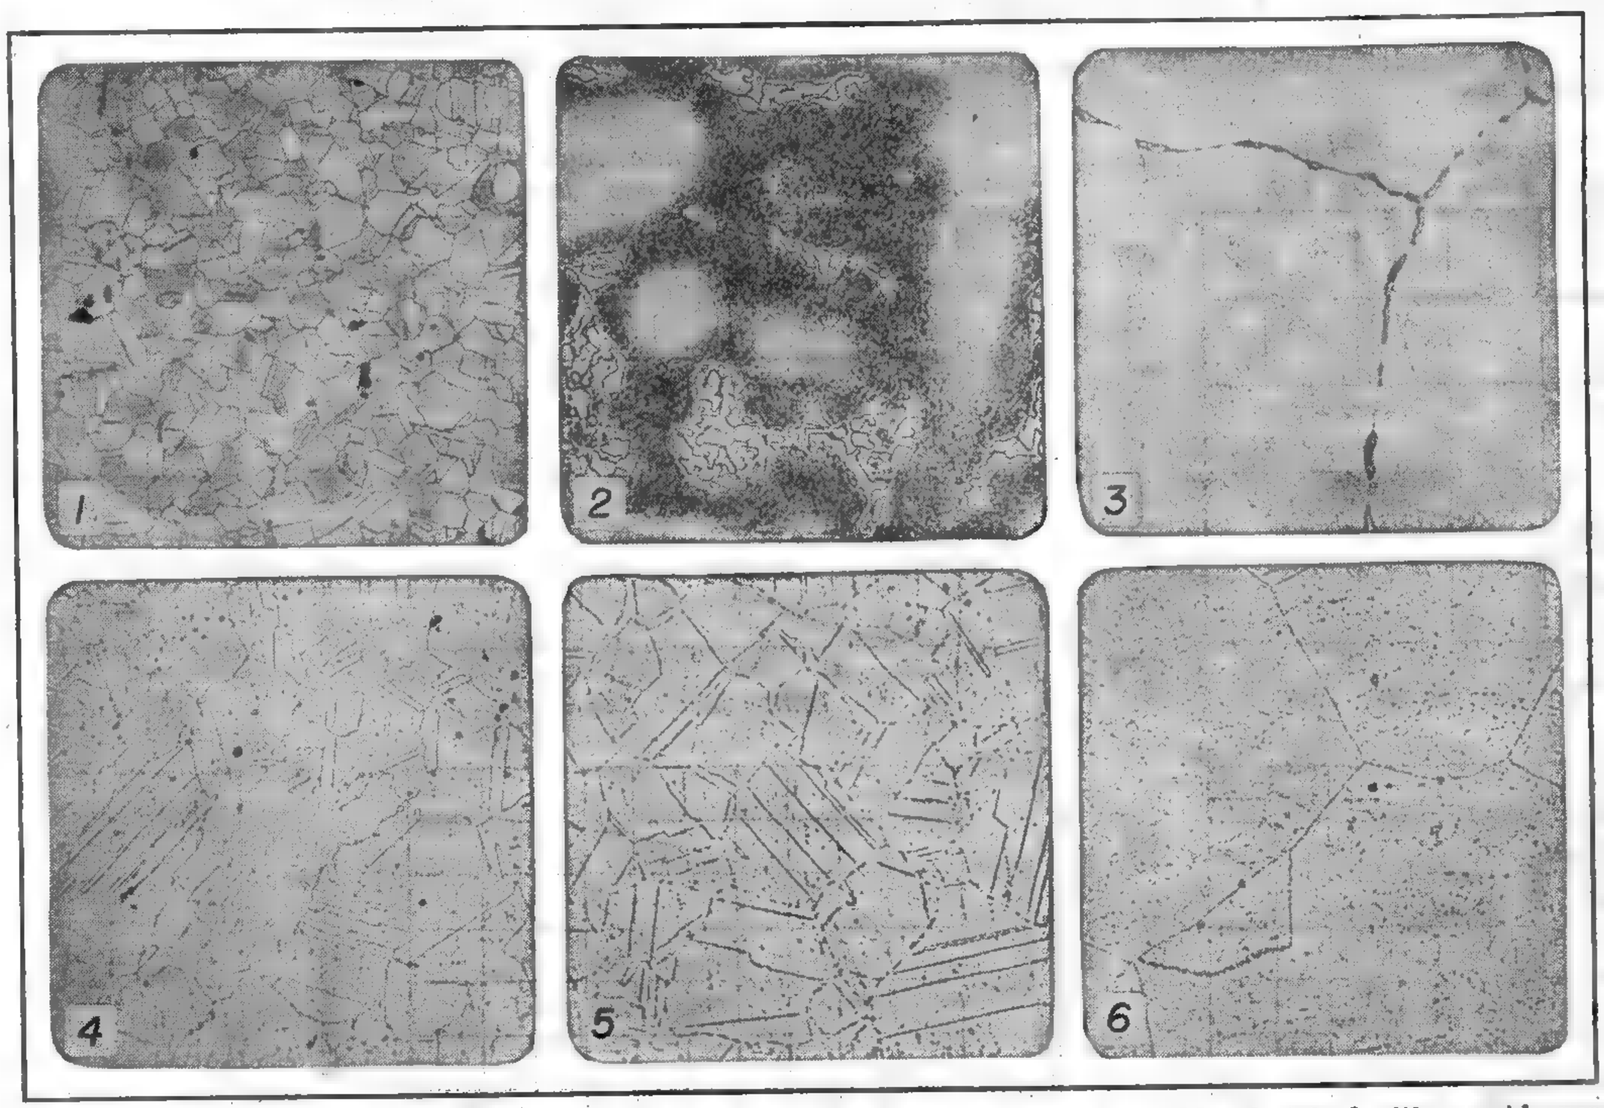

Fig. 1 Wrought Monel etched in Carapella's reagent (× 250). Fig. 2 Age hardened cast silicon Monel etched with cyanide-persulfate (× 250). Fig. 3 Sulfide inclusions in nickel etched lightly with cyanide-persulfate (× 1000). Fig. 4 Alloy 80-20 nickel-chromium etched in modified aqua regia (×250). Fig. 5 Alloy 35-15 nickel-chromium etched electrolytically in oxalic acid (× 250). Fig. 6 Carbides in Inconel etched electrolytically in sodium cyanide (× 250). Original magnifications are indicated. All micrographs were reduced to four-fifths size in making the engravings reproduced here.

Table II. Macro-Etchants for Nickel and Nickel Alloys

Etchant	Composition	Directions for Use	Applications
Nitric acid	Concentrated nitric acid	Use clear white acid to avoid staining. Immersing specimen 3 to 5 min is sufficient for structure. Longer etching required to reveal porosity or forging flow lines.	General structural detail in nickel and nickel-copper alloys. Surface and subsurface cracks; porosity; dendritic structure of cast alloy; forging flow lines. Light etching will reveal sulfur embrittlement. Monel weld deposits.
Marble's Reagent	Copper sulfate ..... 20 g Concentrated hydrochloric acid.100 ml Water .....100 ml	Immerse for 3 to 10 min.	Structure of nickel-chromium-iron alloys. Porosity; surface and subsurface cracks.
Aqua Regia	Concentrated nitric acid..... 25 ml Concentrated hydrochloric acid. 75 ml	Immerse for 3 to 10 min. Prolonged etching may pit specimen.	General use on nickel-chromium and nickel-chromium-iron alloys

PROPERTIES OF NICKEL AND NICKEL ALLOYS

Nickel (99.95 Ni+Co)

COMPILED BY E. M. WISE*

A *1 Common name.* **Pure Nickel (electrolytic)**

B *1 Typical uses.* Alloying additions, electronic devices, protective coatings

2 Precautions in use. Do not heat above 320 C (600 F) in sulfidizing atmospheres.

C *1 Density* at 25 C (77 F). 8.902 g per cu cm (0.322 lb per cu in.)

D *1 Melting point.* 1455 C (2651 F)

4 Boiling point. Approx 2730 C (4950 F)

6 Thermal expansion 0 to 100 C (32 to 212 F). 0.0000133 per °C. *See* Fig. 1 for temperature dependence.

11 Specific heat at 100 C (212 F). 0.1123 cal per g; at 500 C (932 F) 0.1265 cal per g

12 Specific heat versus temperature. See Fig 2.

13 Latent heat of fusion. 73.8 cal per g

16 Thermal conductivity at 25 C (77 F). 0.22 cal/sq cm/cm/°C/sec; at 100 C (212 F) 0.198; at 300 C (572 F) 0.152; at 500 C (932 F) 0.148

E *1 Volume conductivity* referred to standard copper. 25.2%

2 Electrical resistivity at 20 C (68 F). 6.84 microhm-cm

5 Temperature coefficient of electrical resistivity 0 to 100 C (32 to 212 F). 0.0069 microhm-cm per °C (Fig. 3)

9 Contact potential versus platinum 0 to 100 C (32 to 212 F). 1.485 mv

F *1 Reflectivity.* 0.64 at $\lambda = 5500$ A

5 Emissivity. 0.355 at $\lambda = 6500$ A (unoxidized)

G *Magnetic Properties. See* Fig. 4, 5, 6, 7 and 8.

8 Magnetostriction. -32×10^{-6} cm per cm per gauss

9 Magnetic transformation temperature. 353 C (665 F)

Effect of alloying additions. *See* Fig. 8.

J *1 Crystal structure.* Face-centered cubic; $a = 3.5167$ kX at 20 C (68 F)

K *Mechanical properties.*

Modulus of elasticity. See Fig 9.

Hardness versus annealing temperature. See Fig 10.

Tensile strength (annealed). 46,000 psi

Yield strength (annealed). 8500 psi

Elongation (annealed). 30%

95 Ni – 4.5 Mn

COMPILED BY W. A. MUDGE*

A *2 Trade name.* "D" Nickel
B *1 Typical uses.* To provide improved resistance to attack by sulfur compounds at elevated temperatures in both oxidizing and reducing atmospheres; spark plug wires.
2 Precautions in use. Do not use above 540 C (1000 F) in sulfidizing atmospheres.

* Development and Research Division, The International Nickel Company, Inc., New York

C *1 Density* at 20 C (68 F). 8.78 ■ per cu cm (0.317 lb per cu in.)
D *11 Specific heat* 0 to 100 C (32 to 212 F). 0.13 cal per g
16 Thermal conductivity 0 to 100 C (32 to 212 F). 0.115 cal/sq cm/cm/°C/sec
E *2 Electrical resistivity* at 20 C (68 F). 14 microhm-cm
G *9 Magnetic transformation temperature.* 352 C (665 F)
K *Mechanical properties.* Hot rolled: tensile strength 86,000 psi; yield strength (0.2% offset) 34,000 psi;

elongation 40%; reduction of area 60%; Brinell hardness number 147; Rockwell hardness B 70; modulus of elasticity 30,000,000 psi; torsional breaking strength 68,000 psi; torsional yield strength 26,000 psi; angle of twist 380 deg per in.; shear 2.70 in. per in.; ratio of torsional breaking strength to tensile strength 0.79.

M *Composition limits.* The alloy usually contains approximately 0.15% Fe; 0.10% C; 0.05% Cu; 0.05% Si and 0.005% S in addition to 4.5% Mn. A similar alloy having the trade name **"E" Nickel** contains 2% Mn.

N 1 *Melting temperature range.* Approx 1430 C (2600 F)
2 *Casting temperature range* (ingot). Approx 1565 C (2850 F)
3 *Alloying.* Add Mn as the metal when Ni is molten.
4 *Preferred deoxidizer.* Magnesium
5 *Type of flux.* Lime-fluorspar, reducing
6 *Precautions in melting.* Do not overheat.
7 *Hot working temperature range.* 650 to 1175 C (1200 to 2150 F)
9 *Annealing temperature.* 760 to 815 C (1400 to 1500 F)
10 *Maximum reduction between anneals.* 85%
11 *Suited to forming* by all methods of hot and cold working.
17 *Joining.*
Soft solder with Pb-base or Sn-base alloys, acid flux.
Silver solder with phosphorus-free silver alloys, fluoride flux, slightly reducing flame.
Braze with phosphorus-free and lead-free alloys, standard brazing flux, slightly reducing flame.
Oxyacetylene weld with "D" Nickel, fluoride-base flux, slightly reducing flame.
Resistance welding. All types are satisfactory.

94 Ni – 4.5 Al

COMPILED BY W. A. MUDGE*

A 2 *Trade name.* **"Z" Nickel**
B 1 *Typical uses.* For industrial applications that demand high strength and high resistance to corrosion, especially in large sections; pump rods; springs; shafts.
2 *Precautions in use.* Do not use above 320 C (600 F) in sulfidizing atmospheres.
C 1 *Density* at 20 C (68 F). 8.26 g per cu cm (0.298 lb per cu in.)
D 1 *Liquidus temperature.* 1446 C (2635 F)
2 *Solidus temperature.* 1435 C (2615 F)
6 *Thermal expansion* 0 to 100 C (32 to 212 F). 0.0000130 per °C (0.0000072 per °F)
11 *Specific heat 0 to 100 C* (32 to 212 F). 0.13 cal per g
E 2 *Electrical resistivity* at 20 C (68 F). 43.3 microhm-cm
G *Magnetic properties.* Nonmagnetic or very slightly magnetic in the soft condition. Slightly magnetic when age hardened.
K *Mechanical properties. See* Tables I and II.
L 2 *Radiography.* Technique similar to that for steel; voltage to be increased 15%.
N 1 *Melting temperature.* 1435 to 1445 C (2615 to 2635 F)
2 *Casting* (ingot). 1565 to 1620 C (2850 to 2950 F)
4 *Preferred deoxidizer.* Magnesium
5 *Type of flux.* Lime-cryolite
7 *Hot working temperature.* 700 to 1175 C (1300 to 2150 F)
9 *Annealing temperature.* 870 C (1600 F) for 1 hr, followed by quenching in water.
10 *Maximum reduction between anneals.* 85%
11 *Suited to forming* by all types of hot working and cold working methods.
15 *Heat treatment.*

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hr	Atmosphere	Cooling
To soften	870	1600	½	Reducing	Quench in water
To harden	595	1100	8 to 16	Reducing	Cool in furnace

16 *Standard finishes.* Hot rolled, cold drawn, or cold rolled. Mill products are given all finishes.
17 *Joining.*
Soft solder with Pb-base or Sn-base solder, acid flux.
Silver solder with phosphorus-free silver alloys, fluoride flux, slightly reducing flame.
Braze with phosphorus-free and lead-free alloys, fluoride-base flux, slightly reducing flame.
Oxyacetylene weld with "Z" Nickel, fluoride flux, slightly reducing flame.
Metal-arc weld with "Z" Nickel, fluoride flux, direct current.

97 Ni – 1.5 Si

COMPILED BY W. A. MUDGE*

A *1 Common name.* **Cast Nickel***

B *1 Typical uses.* Cast nickel has resistance to corrosion similar to that of wrought nickel and is useful for applications in equipment handling corrosives such as caustics, and when it is necessary to avoid contamination of a product with such metals as copper and iron. Resistance to galling under faulty lubrication can be provided by adjustment of the minor elements, including carbon.

C *1 Density* at 20 C (68 F). 8.34 ■ per cu cm (0.301 lb per cu in.)

5 Solidification shrinkage. 0.25 in. per ft

D *6 Thermal expansion* 25 to 100 C (77 to 212 F). 0.0000130 per °C (0.0000072 per °F)

E *2 Electrical resistivity* at 20 C (68 F). 21 microhm-cm

G *Magnetic properties.* Slightly magnetic at room temperature. Magnetic properties decrease with increasing silicon content.

K *Mechanical properties.* Sand cast: tensile strength 45,000 to 60,000 psi; yield strength (0.05% elongation under load) 20,000 to 30,000 psi; elongation in 2 in. 30 to 15%; Brinell hardness number 80 to 125; modulus of elasticity 21,500,000 psi; Charpy 60 ft-lb; Izod 90 to 75 ft-lb; compressive yield strength (0.00% offset) 10,000 psi, (0.01% offset) 14,000 psi, (0.2% offset) 23,000 psi.

N *1 Melting temperature range.* 1345 to 1425 C (2450 to to 2600 F)

2 Casting temperature range (sand). 1510 to 1595 C (2750 to 2900 F)

4 Preferred deoxidizer. Magnesium

16 Standard finishes. Machined or sandblasted.

17 Joining.
Soft solder with Pb-base or Sn-base alloys, acid flux.
Silver solder with phosphorus-free silver alloys, fluoride flux, slightly reducing flame.
Braze with phosphorus-free and lead-free alloys, fluoride-base flux, slightly reducing flame.
Oxyacetylene weld with nickel, fluoride flux, slightly reducing flame.
Metal-arc weld with nickel; fluoride flux; direct current.

* Nominal composition includes 0.50% Mn, 0.50% C, 0.30% Cu, 0.25% Fe, 0.015% S.

67 Ni – 30 Cu – 1.4 Fe – 1 Mn – 0.15 C – 0.1 Si – 0.01 S

COMPILED BY E. R. PATTON*

A *2 Trade name.* **Monel†**

3 ASTM numbers. B 127–41T, B 163–41T, B 164–41T, B 165–41T

4 Government numbers. QQ-N-281, Am 1, Cl A; Navy 46M7g, Cl A; 44T38; QQ-R-571, Type F (gas-welding wire); Navy 46R1, Grade 1, Cl F (gas-welding wire); Navy 17E4A (metal-arc electrode)

5 Other designations. ASME SB-127, SB-163, SB-164, SB-165

6 Foreign equivalents. British DTD-192, DTD-10B, DTD-196, DTD-200A, DTD-204A

B *1 Typical uses.* Used where high strength and resistance to corrosion are required. Widespread and diversified uses in chemical, pharmaceutical, marine, power, electrical, oil refinery, laundry, textile, pulp and paper equipment; and for household and architectural applications where appearance is a factor. Useful against many commonly encountered corrosives, such as sea water, dilute sulfuric acid, and strong caustic solutions.

2 Precautions in use. Not suitable in sulfidizing atmospheres at temperatures above 370 C (700 F). Does not oxidize at a destructive rate below approximately 540 C (1000 F) in sulfur-free atmospheres, and for some purposes may be used up to 820 C (1500 F). The scale formed is adherent. Sulfur compounds in the atmosphere lower the safe limit of temperature. Not useful in highly oxidizing acids such as nitric and nitrous, ferric salts in acid solutions, stannic and mercuric salts, alkaline hypochlorite solutions in concentrations greater than 3 grams of available chlorine per liter, in sulfur-bearing gases above about 370 C (700 F), and in molten metals such as lead, tin, zinc, aluminum and in molten sulfur.

Furnace atmospheres for heating for hot working or for open annealing should be sulfur-free and slightly reducing with 2% or more of carbon monoxide; sulfur should not exceed 0.5% and preferably should not exceed 0.2%. Avoid fluctuating or marginal atmospheres, that is, reducing to oxidizing to reducing.

C *1 Density* at 20 C (68 F). 8.84 g per cu cm (0.319 lb per cu in.)

Annealed	123	129(a)	68.0	29.5	78,350	65.9	44.0

(a) Proportional limit

Monel to lower the Curie temperature considerably, so that although Monel is usually slightly magnetic at room temperature, it will become nonmagnetic when warmed mildly. Monel that contains about 1.25% Si is nonmagnetic at room temperature; a silicon content of 4% lowers the Curie temperature to approximately minus 57 C (minus 70 F). The magnetic characteristics of Monel are not affected greatly by cold work or thermal treatment.

2 *Magnetic susceptibility.* Slightly magnetic at room temperature.

3 *Magnetic permeability.* 2000 to 10,000 cgs. Some weakly magnetic alloys have high B at very low H and consequently a high permeability.

5 *Saturation magnetization.* 1000 to 2000 gausses at 200 oersteds

9 *Magnetic transformation temperature.* 43 to 60 C

J 1 *Crystal structure.* Face-centered cubic; $a = 3.541$ kX

Shear modulus. 9,500,000 psi
6 *Creep properties.* *See* Fig. 2, 3 and 4.
10 *Short-time, high-temperature properties.* *See* Fig. 5.
L 2 *Radiography.* The procedure is similar to that for steel with approximately 15% increase of current.

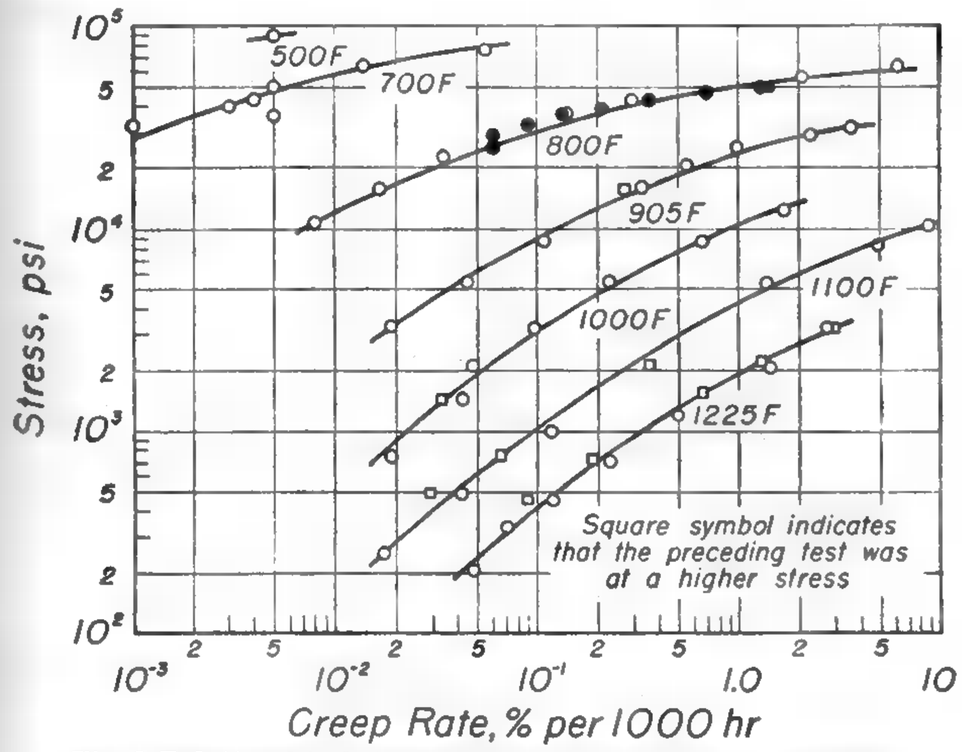

Fig. 2 Relationship between stress and creep rate at various temperatures (Bennett and McAdam[3])

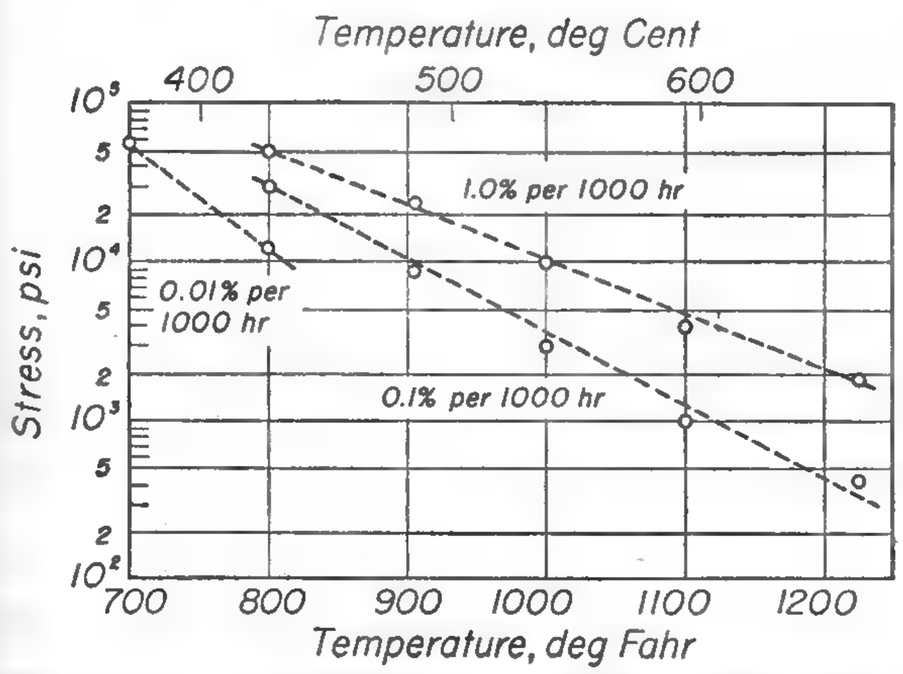

Fig. 3 Relationship between temperature and the stress required to produce certain creep rates, as derived from Fig. 2 (Bennett and McAdam[3])

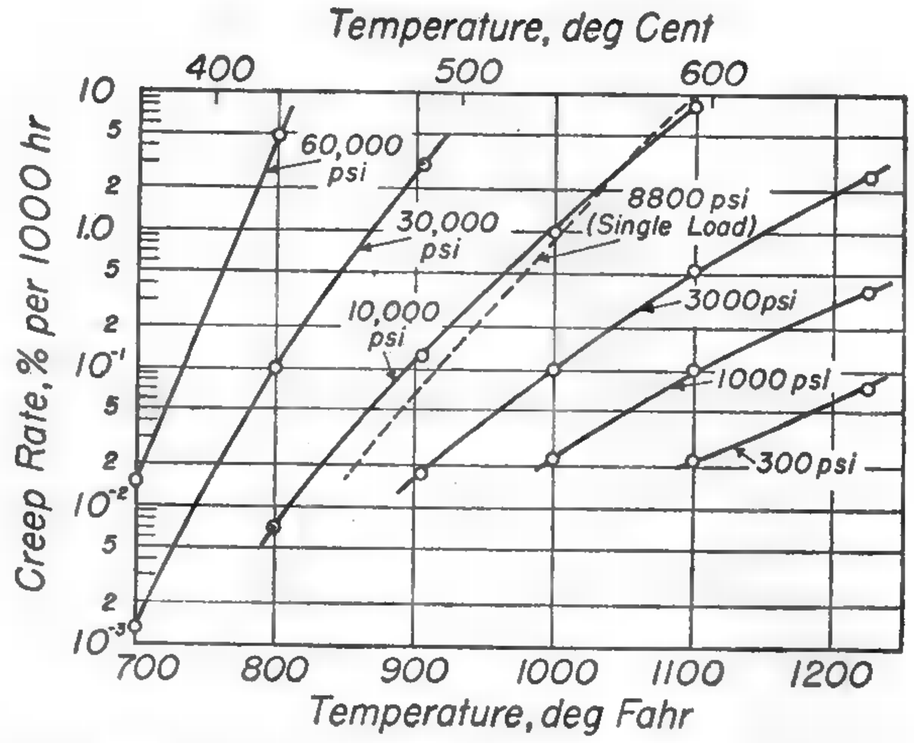

Fig. 4 Relationship between temperature and creep rate for various stresses, as derived from Fig. 2 (Bennett and McAdam[3])

M *Composition limits* (specifications: QQ-N-281; Navy 46M7g; ASTM B 164–41T; B 127–41T; B 165–41T; B 163–41T; ASME SB-164; SB-127; SB-165; SB-163).

Nickel[a]	63.0 to 70.0	Carbon	0.30 max
Iron	2.50 max	Silicon	0.50 max
Aluminum	0.50 max	Sulfur	0.02 max
Manganese	2.00 max	Copper	remainder

(a) Includes a small amount of cobalt

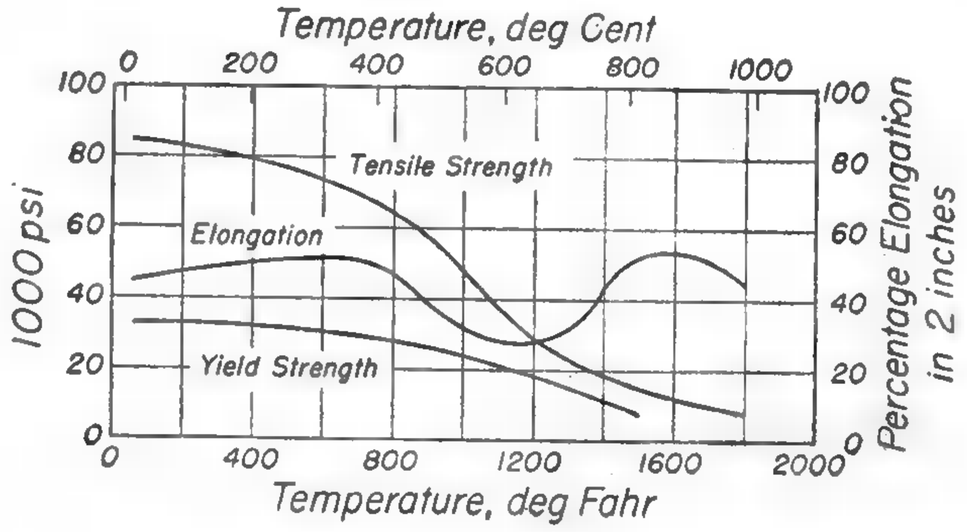

Fig. 5 Tensile properties of hot rolled Monel at elevated temperatures

N 1 *Melting temperature range.* 1300 to 1350 C (2370 to 2460 F)
2 *Casting temperature range* (sand). 1480 to 1565 C (2700 to 2850 F)
4 *Preferred deoxidizer.* Magnesium

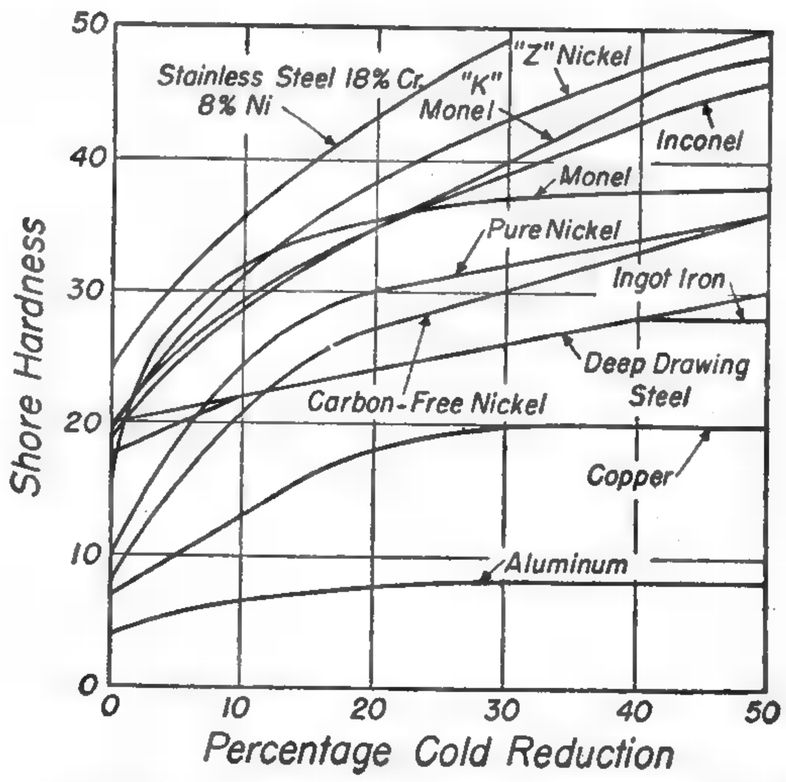

Fig. 6 Increase in hardness of various metals with cold working

7 *Hot working temperature range.*
Best bending, 1010 to 1177 C (1850 to 2150 F)
Heavy and drop forging, 926 to 1177 C (1700 to 2150 F)
High-tensile forging, 538 to 649 C (1000 to 1200 F)
8 *Shortness range.* 650 to 925 C (1200 to 1700 F)
Light forging only may be performed in this range.
9 *Annealing.* See the article on page 1031.
10 *Maximum reduction between anneals.* Up to 90% for cold rolling or cold drawing; deep drawing, up to 40% for first draw, 25% for next and 10 to 15% for subsequent reductions; spinning, up to 50% reduction. For increase in hardness with cold work, *see* Fig. 6.
12 *Precautions in forming.* The alloy should be degreased thoroughly after forming, before thermal treatment, to remove sulfur-bearing lubricants. Likewise similar precautions should be taken against contamination from "Kirksite" dies on parts formed by drop hammer. Coarse-grained materials are unsuitable for most cold forming operations, particularly for heavy cold work.
16 *Standard finishes.* Forgings: as forged, rough-turned, or finish-machined. Mill products: all types of finish.
17 *Joining.*
Rivet compositions. Soft Monel rivets
Soft solder with 50-50 or 60-40 Sn-Pb, tinned surfaces preferred, cut-acid or proprietary flux. Do not use rosin.
Silver solder with phosphorus-free low-melting-point silver alloys; neutral or slightly reducing flame.
Braze with naval brass or tobin bronze. Brazing with brass or bronze is not used frequently, since the resistance to corrosion of the bronze joints is less than that of Monel; oxyacetylene welding or silver brazing is preferred.
Oxyacetylene weld with "40" Monel gas welding rod, "1" gas welding and brazing flux, slightly reducing flame.
Resistance welding. See reference 4.
Metal-arc weld with 130X Monel electrodes
Submerged-melt weld with suitable electrodes

COMPILED BY W. A. MUDGE*

A 2 *Trade name.* **Cast Monel**
4 *Government number.* QQ-C-551; Navy 46M1
B 1 *Typical uses.* For industrial applications that demand high strength, pressure tightness, and high resistance to destructive chemical action or mechanical wear.
C 1 *Density* at 20 C (68 F). 8.63 g per cu cm (0.312 lb per cu in.)
5 *Solidification shrinkage.* 0.25 in. per ft
D 6 *Thermal expansion* 25 to 100 C (77 to 212 F). 0.0000129 per °C (0.0000072 per °F)
E 2 *Electrical resistivity* at 20 C (68 F). 53.3 microhm-cm
G 1 *Influence of treatments.* Slightly magnetic at 25 C
K *Mechanical properties.* Sand cast, as cast: tensile strength 65,000 to 90,000 psi; yield strength 32,000 to 40,000 psi; elongation in 2 in. 45 to 25%; Brinell hardness number 125 to 150; modulus of elasticity 18,500,000 psi; Charpy 70 ft-lb; Izod 80 to 65 ft-lb; compressive yield strength (0.00% offset) 19,000 psi, (0.01% offset) 23,000 psi, (0.2% offset) 29,000 psi.
M *Composition limits.* Sand cast (QQ-C-551 and Navy 46M1): 60.0% Ni min; 23.0% Cu min; 3.5% Fe max; 0.5% Al max; and 2.0% max for C plus Si.
N 1 *Melting temperature range.* 1315 to 1345 C (2400 to 2450 F)
2 *Casting temperature range.* 1480 to 1565 C (2700 to 2850 F)
4 *Preferred deoxidizer.* Magnesium
16 *Standard finishes.* Machined or sandblasted.
17 *Joining.*
Soft solder with Pb-base or Sn-base alloys, acid flux.
Silver solder with phosphorus-free silver alloys, fluoride flux, flame slightly reducing.
Braze with phosphorus-free and lead-free alloys, fluoride-base flux, flame slightly reducing.
Metal-arc weld with Monel, fluoride flux, and direct current.

66 Ni – 29 Cu – 2.75 Al – 0.9 Fe – 0.75 Mn – 0.50 Si – 0.15 C – 0.005 S

57 Ni – 20 Mo – 20 Fe

COMPILED BY BURNHAM E. FIELD*

A *2 Trade name.* **Hastelloy A**

B *1 Typical uses.* This alloy is resistant to hydrochloric acid and to other nonoxidizing acids and salts, such as phosphoric acid, sulfuric acid up to 50% concentration, aluminum chloride, cuprous chloride, and similar reducing chloride salts.

2 Precautions in use. This alloy is not recommended for use in contact with strongly oxidizing acids or salts, or for strongly aerated conditions. It is not recommended for use in boiling hydrochloric acid and seldom for temperatures above 75 C (170 F).

C *1 Density* at 25 C (77 F). 8.80 g per cu cm (0.318 lb per cu in.)

5 Solidification shrinkage. 2%

D *1 Liquidus temperature.* 1330 C (2425 F)

2 Solidus temperature. 1300 C (2370 F)

3 Minimum "burning" (liquation) temperature. 1230 C (2250 F)

6 Thermal expansion
0 to 100 C (32 to 212 F). 0.0000110 per °C
0 to 1000 C (32 to 1832 F). 0.0000154 per °C

11 Specific heat. 0.094 cal per g

16 Thermal conductivity at 25 C (77 F). 0.04 cal/sq cm/cm/°C/sec

E *1 Volume conductivity* referred to standard copper. 1.4%

2 Electrical resistivity at 25 C (77 F). 126.7 microhm-cm

5 Temperature coefficient of electrical resistivity 20 to 800 C (68 to 1472 F). zero

F *4 Color.* Silvery

G *3 Magnetic permeability.* 5 cgs

I *1 General resistance to corrosion.* This alloy should not be held in the range 500 to 800 C (930 to 1470 F) unless subsequently annealed, since these temperatures are likely to cause higher rates of corrosion. Severe hot or cold working should be followed by full annealing.

2 Resistance to specific agents. See next column.

* Manager, Union Carbide and Carbon Research Laboratories, Inc., Niagara Falls, N. Y.

N *1 Melting temperature.* 1595 to 1650 C (2900 to 3000 F)
2 Casting temperature (chill). 1450 C (2650 F)
7 Hot working temperature range. 1035 to 1230 C (1900 to 2250 F)
8 Shortness range. 600 to 870 C (1110 to 1600 F)
9 Annealing temperature. 1175 C (2150 F)
11 Suited to forming by forging; hot rolling into bars, strip, plate, sheet and rod; welding; drawing into wire; cold rolling; deep drawing; spinning; hot extrusion; machining.
12 Precautions in forming. In hot forming, temperatures from 600 to 850 C (1110 to 1560 F) should be avoided. In cold forming frequent annealing should be employed, since the alloy work hardens rapidly.
15 Heat treatment.

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Cooling
Full anneal to produce softness, machinability, and good corrosion resistance	1150 to 1180	2100 to 2150	⅓ to 1½	Rapidly in air or water
Stabilizing anneal to reduce loss of corrosion resistance because of exposure to 650 to 1040 C (1200 to 1900 F)	1050 to 1065	1925 to 1950	2 to 4	In air
Hardening anneal to produce maximum hardness	745 to 760	1375 to 1400	168	In air

16 Standard finishes. Castings are sandblasted; forgings are sandblasted or pickled; and mill products are hot rolled, annealed or pickled.
17 Joining.
Rivet compositions are not recommended.
Oxyacetylene welding with Hastelloy B rods; usually no flux; neutral flame.
Carbon-arc welding is not recommended.
Resistance welding. All types satisfactory.
Metal-arc welding. Use specially coated Hastelloy B rods, with reversed polarity. Arc is choked short. Avoid overheating weld.

62 Ni – 30 Mo – 5 Fe

COMPILED BY BURNHAM E. FIELD*

A *2 Trade name.* **Hastelloy B**
B *1 Typical uses.* This alloy is resistant to hydrochloric acid in all concentrations up to the boiling point. It is also resistant to other nonoxidizing acids and salts, such as phosphoric acid, sulfuric acid up to 50% concentration, cuprous chloride, and similar reducing chloride salts.
2 Precautions in use. This alloy is not recommended for strongly oxidizing acids or salts.
C *1 Density* at 25 C (77 F). 9.24 g per cu cm (0.334 lb per cu in.)

Precision cast.....	0.250	.....	.....	.....	.....	B 92 to 99	.....	.....	.....	.....

N *1 Melting temperature.* 1600 to 1650 C (2900 to 3000 F)
2 Casting temperature (chill). 1450 C (2650 F)
7 Hot working temperature range. 1035 to 1250 C (1900 to 2250 F)
8 Shortness range. 600 to 870 C (1110 to 1600 F)
9 Annealing temperature. 1175 C (2150 F)
Forming and heat treatment. Same as for 57 Ni – 20 Mo – 20 Fe
16 Standard finishes. Castings are sandblasted. Forgings are either sandblasted or pickled. Mill products are hot rolled, annealed, or pickled.
17 Joining.
Oxyacetylene welding with Hastelloy B rods; usually no flux.
Carbon-arc welding is not recommended.

Table III. Tensile Properties for Rolled and Annealed Forms at Subzero Temperatures

Temperature, deg Cent	Yield Strength, psi	Tensile Strength, psi	Elongation in 2 in., percentage	Reduction of Area, percentage	Charpy, ft-lb
—50	59,000	142,000	66	54	49
—100	61,000	144,000	63	53	53
—200	83,000	172,000	58	45	53

Resistance welding. All types satisfactory.
Metal-arc welding. Use specially coated Hastelloy B rods with reversed polarity. Arc is choked short. Avoid overheating weld.

58 Ni – 17 Mo – 15 Cr – 5 W – 5 Fe

COMPILED BY BURNHAM E. FIELD*

A *2 Trade name.* **Hastelloy C**
B *1 Typical uses.* This alloy is resistant to oxidizing agents such as wet chlorine, ferric chloride, nitric acid, hydrochloric and sulfuric acids at moderate temperatures or under oxidizing conditions. It has excellent resistance to acetic acid, sea water and many corrosive organic acids and salts.
2 Precautions in use. Except for weak solutions, this alloy is not recommended for use above 50 C (120 F) in nitric and hydrochloric acid and salt combinations.
C *1 Density* at 25 C (77 F). 8.94 g per cu cm (0.323 lb per cu in.)
5 Solidification shrinkage. 2%
D *1 Liquidus temperature.* 1305 C (2380 F)
2 Solidus temperature. 1270 C (2320 F)
3 Minimum "burning" (liquation) temperature. 1245 C (2275 F)
6 Thermal expansion
0 to 100 C (32 to 212 F). 0.0000113 per °C
0 to 1000 C (32 to 1832 F). 0.0000153 per °C
11 Specific heat. 0.092 cal per g
16 Thermal conductivity at 25 C (77 F). 0.03 cgs
E *1 Volume conductivity* referred to standard copper. 1.3%
2 Electrical resistivity at 25 C (77 F). 133.0 microhm-cm
5 Temperature coefficient of electrical resistivity 20 to 800 C (68 to 1472 F). Zero
F *4 Color.* Silvery
G *3 Magnetic permeability.* 4 cgs
I *1 General resistance to corrosion.* Hastelloy C should not be held for long periods of time in the range 500 to 800 C (932 to 1472 F) unless subsequently annealed, as these temperatures are likely to cause higher corrosion rates of the alloy. Severe hot or cold working should be followed by full annealing.
2 Resistance to specific agents. Except for the following, the ratings listed for 57 Ni – 20 Mo – 20 Fe apply also to this alloy. *See* Table I.
J *1 Crystal structure.* Face-centered cubic alpha
K *Mechanical properties. See* Tables II, III and IV.

Temperature, deg Cent	500	700	900	1000
Short-time tensile strength, 1000 psi	94	75	42	22

Compressive strength:
Proportional limit. 41,000 psi
Yield strength (0.2% offset). 75,000 to 79,000 psi

* Manager, Union Carbide and Carbon Research Laboratories, Inc., Niagara Falls, N. Y.

Table I. Corrosion Resistance of 58 Ni – 17 Mo – 15 Cr – 5W – 5 Fe

Corrosive Agent	Resistance
Acid hydrochloric	Resistant Any strength, up to 120 F
Acids mixed	Resistant Up to 120 F
Acid nitric	Resistant Up to 40%, 150 F; above 40%, room temperature
Acid salts	Resistant Consult manufacturer
Air	Resistant Up to 2000 F
Bleaching solutions	Resistant
Bromine	Resistant
Chlorine	Resistant Excellent resistance to wet chlorine at room temp
Copper sulfate	Resistant
Ferric chloride	Resistant Up to 160 F
Hydrogen sulfide	Resistant
Iodine	Resistant
Potassium nitrate	Resistant
Sodium chloride	Resistant Excellent resistance
Sodium nitrate	Resistant
Sulfur dioxide	Resistant Excellent resistance
Tanning solutions	Resistant
Water chlorinated	Resistant
Water sea	Resistant Excellent resistance
Rayon hardening baths (viscose)	Resistant Excellent resistance

This alloy also has good resistance to chromic acid, the permanganates, the persulfates and to sulfuric acid solutions that contain these salts.

Table II. Strength, Elongation and Reduction of Area at Elevated Temperatures
(Precision-cast specimens, 0.250-in. diam)

Temperature, deg Cent	Temperature, deg Fahr	Tensile Strength, psi	Yield Strength, psi	Elongation in 2 in., percentage	Reduction of Area, percentage
20	70	76.7 to 88.5	44.5 to 56.4	▮ to 12 10 avg	9 to 15 12 avg
540	1000	63.0 to 73.0	.....	10 to 17 12 avg	10 to 20 15 avg
650	1200	56.2 to 62.2	.....	10 to 16 15 avg	10 to 20 16 avg
815	1500	50.0 to 61.0	.....	11 to 28 18.2 avg	10 to 20 15 avg

Table III. Tensile Properties for Rolled and Annealed Forms at Subzero Temperatures

Temperature, deg Cent	Yield Strength, psi	Tensile Strength, psi	Elongation in 2 in., percentage	Reduction of Area, percentage	Charpy, ft-lb
— 50	65,000	134,000	38	33	25
—100	79,000	143,000	25	25	22
—200	96,000	160,000	24	22	27

Table IV. Mechanical Properties of 58 Ni – 17 Mo – 15 Cr – 5 W – 5 Fe

Form	Section, in.	Tensile Strength, 1000 psi	Yield Strength, 1000 psi	Elongation in ▮ in., percentage	Reduction of Area, percentage	Rockwell Hardness	Brinell Hardness Number	Modulus of Elasticity, 10^6 psi	Charpy, ft-lb	Izod, ft-lb

Precision cast	0.250	.....	.....	.....	.....	B 90 to 95	.....	.....	.....	.....

N 7 *Hot working temperature range.* 1035 to 1205 C (1900 to 2200 F)
8 *Shortness range.* 650 to 925 C (1200 to 1700 F)
9 *Annealing temperature.* 1220 C (2225 F)
11 *Suited to forming* by hot rolling into plate, sheet, bar and rod; welding; drawing into wire; cold rolling and deep drawing; spinning; machining.
15 *Heat treatment.* See table at right.
16 *Standard finishes.* Castings are sandblasted. Forgings are either sandblasted or pickled. Mill products are hot rolled, annealed, or pickled.
17 *Joining.*
Oxyacetylene welding with Hastelloy C rods; Cromaloy flux; and neutral flame.
Carbon-arc welding is not recommended.

Purpose	Temperature, deg Cent	Temperature, deg Fahr	Time, hours	Cooling
Full anneal to produce softness, machinability, and good corrosion resistance	1205 to 1220	2200 to 2225	2 to 3	Rapidly in air
Stabilizing anneal to reduce loss of corrosion resistance because of exposure to 650 to 1040 C (1200 to 1900 F)	1120 to 1135	2050 to 2075	2 to 4	In air
Hardening anneal to produce maximum hardness	860 to 870	1575 to 1600	16	In air

Resistance welding. All types satisfactory.
Metal-arc welding. Use specially coated Hastelloy C rods with reversed polarity. Arc is choked short. Avoid overheating weld.

85 Ni – 10 Si – 3 Cu

COMPILED BY BURNHAM E. FIELD*

A 2 *Trade name.* **Hastelloy D**
B 1 *Typical uses.* This alloy is resistant to all concentrations of hot sulfuric acid. It is also resistant to hydrochloric acid under mild conditions and to other nonoxidizing acids and salts. It has excellent wearing properties and freedom from galling against both soft and hard alloys.
2 *Precautions in use.* This alloy is not recommended for use under oxidizing conditions at elevated temperatures. The alloy has low impact strength.
C 1 *Density* at 25 C (77 F). 7.8 g per cu cm (0.282 lb per cu in.)
5 *Solidification shrinkage.* 2%
D 1 *Liquidus temperature.* 1120 C (2050 F)
2 *Solidus temperature.* 1110 C (2030 F)
6 *Thermal expansion*
0 to 100 C (32 to 212 F). 0.0000110 per °C
0 to 1000 C (32 to 1832 F). 0.0000181 per °C
11 *Specific heat.* 0.109 cal per g
16 *Thermal conductivity* at 25 C (77 F). 0.05 cal/sq cm/cm/°C/sec
E 1 *Volume conductivity* referred to standard copper. 1.5%
2 *Electrical resistivity* at 25 C (77 F). 113 microhm-cm
5 *Temperature coefficient of electrical resistivity* 20 to 800 C (68 to 1472 F). Virtually zero.
F 4 *Color.* Silvery with copper tinge

* Manager, Union Carbide and Carbon Research Laboratories, Inc., Niagara Falls, N. Y.

I 1 *General resistance to corrosion.* The resistance of this alloy to corrosion is not affected greatly by previous exposure to heat.
Resistance to specific agents. This alloy is resistant to iodine, it is somewhat less resistant to hydrochloric acid, sulfuric acid, and to reducing acid salts than is 57 Ni – 20 Mo – 20 Fe. The other ratings listed for 57 Ni – 20 Mo – 20 Fe apply also to this alloy.
J 1 *Crystal structure.* Alpha and silicide phases
K *Mechanical properties*

Form	Section, in. diam	Tensile Strength, 1000 psi	Modulus of Elasticity, 10^6 psi	Transverse Breaking Test, 1-in. cross section, 12-in. span
Sand cast	0.505	36 to 40.5	28.85	Breaking load 5000 psi Deflection 0.07 to 0.08 in.
Precision cast	0.250	39 to 45	.....	.....

Elongation and reduction of area, zero; Rockwell C 50 to 55; modulus of rupture, 78,000 psi.

N 11 *Suited to forming* by casting and welding; limited machining with tungsten carbide and grinding.
15 *Heat treatment.* To toughen and soften to some extent: 1050 to 1065 C (1925 to 1950 F), 2 to 4 hr, cool slowly in furnace.
16 *Standard finishes.* Castings are sandblasted.
17 *Joining. Oxyacetylene welding* with Hastelloy D rods; slight excess acetylene flame.

80 Ni – 14 Cr – 6 Fe

COMPILED BY W. A. MUDGE*

A 2 *Trade name.* **Inconel**
3 *ASTM number.* B 163-41T, B 166-41T, B 167-41T, B 168-41T
4 *Government number.* AN-N-4, AN-QQ-N-268, AN-QQ-N-271, AN-WW-T-831, AN-WW-T-833
5 *Other designations.* AMS 5540, 5580, 5665, 5683
B 1 *Typical uses.* For industrial applications that demand good strength, high resistance to corrosion, and excellent resistance to oxidation at high temperatures.

* Development and Research Division, The International Nickel Company, Inc., New York

2 *Precautions in use.* Do not use above 815 C (1500 F) in sulfidizing atmospheres.
C 1 *Density* at 20 C (68 F). 8.51 g per cu cm (0.307 lb per cu in.)
D 1 *Liquidus temperature.* 1425 C (2600 F)
2 *Solidus temperature.* 1395 C (2540 F)
6 *Thermal expansion* 20 to 100 C (68 to 212 F). 0.0000115 per °C (0.0000064 per °F)
11 *Specific heat* 25 to 100 C (77 to 212 F). 0.109 cal per g
16 *Thermal conductivity* 0 to 100 C (32 to 212 F). 0.036 cal/sq cm/cm/°C/sec (104 Btu/sq ft/in/°F/hr)
E 2 *Electrical resistivity* at 20 C (68 F). 98.1 microhm-cm

Table I. Some Mechanical Properties of Inconel

1000 psi[a]	39	22	11	5.5	3.0	1.8	1.1	0.71	0.33

(a) Creep strength for secondary creep rate of 1% in 10,000 hr

L *2 Radiography.* Technique similar to that for steel; voltage increased 5%.
M *Composition limits* (ASTM B 163, B 166, B 167, B 168; AMS 5540, 5580, 5665, 5683; AN-N-4, AN-QQ-N-268, AN-QQ-N-271, AN-WW-T-831, and AN-WW-T-833). All forms: 75.0% Ni min; 12.0 to 15.0% Cr; 9.0% Fe max; 0.5% Cu max; 1.0% Mn max; 0.5% Si max; 0.15% C max; 0.02% S max.
N *1 Melting temperature.* 1395 to 1425 C (2540 to 2600 F)
2 Casting (ingot). 1540 to 1600 C (2800 to 2900 F)
3 Alloying. Add chromium as Fe-Cr when nickel is molten.
4 Preferred deoxidizer. Magnesium
5 Type of flux. Lime-fluorspar
7 Hot working temperature. 870 to 1260 C (1600 to 2300 F)
8 Shortness range. 650 to 870 C (1200 to 1600 F)
9 Annealing temperature. 870 C (1600 F) for 3 hr, to 980 C (1800 F) for 7 to 15 min.
10 Maximum reduction between anneals. 85%
11 Suited to forming by all types of hot and cold working.
17 Joining.
Soft solder with lead-base or tin-base solder, acid flux.
Silver solder with phosphorus-free silver alloys, fluoride flux, slightly reducing flame.
Braze with phosphorus-free and lead-free alloys, fluoride-base flux, slightly reducing flame.
Oxyacetylene welding with Inconel, fluoride flux, slightly reducing flame.
Resistance welding. All types are satisfactory.
Metal-arc welding with Inconel, fluoride flux, direct or alternating current.

78 Ni – 13.5 Cr – 6 Fe – 2 Si

COMPILED BY W. A. MUDGE*

A *2 Trade name.* **Cast Inconel**
B *1 Typical uses.* For industrial applications that demand high strength, pressure tightness, and high resistance to destructive chemical action, mechanical wear and oxidation at elevated temperatures.
C *1 Density* at 20 C (68 F). 8.3 g per cu cm (0.30 lb per cu in.)
5 Solidification shrinkage. 0.25 in. per ft
D *6 Thermal expansion* 25 to 100 C (77 to 212 F). 0.0000115 per °C (0.0000064 per °F)
F *4 Color.* White
G *1 Influence of treatments.* Nonmagnetic at 25 C
9 Magnetic transformation temperature. minus 101 C (−150 F)
I *1 General resistance to corrosion.* Similar to wrought Inconel
K *Mechanical properties.* Sand cast, as cast: tensile strength 70,000 to 95,000 psi; yield strength 30,000 to 45,000 psi; elongation in 2 in. 30 to 10%; Brinell hardness number 160 to 190; modulus of elasticity 22,700,000 psi; Charpy 60 ft-lb; Izod 85 to 70 ft-lb; compressive yield strength (0.00% offset) 17,000 psi, (0.01% offset) 23,000 psi, (0.2% offset) 36,000 psi.
M *Nominal composition.* Sand cast: 77.50% Ni, 13.50% Cr, 6.0% Fe, 0.25% Cu, 0.80% Mn, 2.0% Si, 0.2% C, and 0.01% S.
N *1 Melting temperature range.* 1370 to 1400 C (2500 to 2550 F)
2 Casting temperature range (sand). 1540 to 1620 C (2800 to 2950 F)
4 Preferred deoxidizer. Magnesium
16 Standard finishes. Machined or sandblasted.
17 Joining.
Same as for wrought Inconel.

* Development and Research Division, The International Nickel Company, Inc., New York

58 Ni – 22 Cr – 6 Cu – 6 Mo – 6 Fe

COMPILED BY T. E. JOHNSON*

A *2 Trade name.* **Illium "G"**†
B *1 Typical uses.* A machinable, corrosion-resistant alloy used in resisting the attack of sulfuric, nitric, phosphoric acids, mixed acids, and salt and acid mixtures. Useful as a heat-resistant alloy where severe corrosion is encountered. Especially resistant to sea water and saline atmospheres.
2 Precautions in use. In general, not recommended where acids of the halogens are encountered; for instance, in hydrochloric acid and wet chlorine gas.
C *1 Density.* 8.58 ▮ per cu cm (0.31 lb per cu in.)
5 Solidification shrinkage (cast). $\frac{5}{16}$ in. per ft
D *2 Solidus temperature.* 1300 C (2370 F)
3 Minimum "burning" (liquation) temperature. 1200 C (2100 F)
16 Thermal conductivity at 21 C (70 F). 0.029 cal/sq cm/cm/°C/sec

* Plant Engineer, Burgess-Parr Company, Freeport, Ill.

† The nominal composition of this alloy includes also 1.2% Mn, 0.6% Si and 0.2% C.

F *1 Reflectivity.* 76% in white light

I *1 General resistance to corrosion.* Pitting type of corrosion is encountered when the metal is immersed in dilute solutions of halogen acids. Corrosion in nitric, sulfuric and phosphoric acids increases with temperature.

2 Resistance to specific agents. See Table I.

K *Mechanical properties.* Sand cast: tensile strength 60,000 to 73,000 psi; elongation 9.5 to 4.0%; reduction of area 11 to 8%; Brinell hardness number 160 to 210; modulus of elasticity 26,680,000 psi; Charpy 40 to 3 ft-lb.

L *1 Metallography.*
Polishing, same as for Inconel
Etching for grain size. Immersion in aqua regia
Etching for microstructure. 5% sulfuric acid, electrolytically

N17 *Joining.*
Soft solder with tin solder; non-acid flux.
Oxyacetylene welding with Illium rod, reducing flame.

Table I. Resistance to Corrosion of 58 Ni – 22 Cr – 6 Cu – 6 Mo – 6 Fe

The following code indicates relative ratings on the basis of resistance to corrosive attack in the various solutions listed. Data are compiled from results obtained in service and those from controlled laboratory tests.

R—Recommended for use, quantitative test not furnished
A—Not more than 0.004 in. penetration per annum
B—0.004 to 0.015 in. penetration per annum
A and B ratings are less than 1 mg per sq cm per day
C—0.015 to 0.050 in. penetration per annum, approx 1 to 3 mg per sq cm per day
D—0.050 to 0.125 in. penetration per annum
E—More than 0.125 in. penetration per annum
N—Not recommended for use, quantitative tests not furnished

NOTE 1. *Mercury.* In common with other complex alloys, this alloy may take up mercury through some intergranular capillarity. This tendency prevents use of the alloy for thermometer bulbs, where exact volumes and dimensions must be kept.

NOTE 2. *Molten sulfur.* Test conducted in molten sulfur indicates that this alloy, unlike many other corrosion-resistant alloys, does not gain in weight or dimensions from immersion in the fluid over long periods of time.

80 Ni – 20 Cr

COMPILED BY W. A. GATWARD*

A *3 ASTM number.* B 82-46
B *1 Typical uses.* Heating elements
2 Precautions in use. Avoid sulfur atmospheres at high temperatures, especially reducing atmospheres.
C *1 Density.* 8.4 g per cu cm (0.30 lb per cu in.)
D *6 Thermal expansion.* 70 to 1000 C (158 to 1832 F). 0.0000176 per °C
11 Specific heat. 0.107 cal per g
16 Thermal conductivity at 100 C (212 F). 0.134 watts per sq cm per cm per °C
E *1 Volume conductivity* referred to standard copper. 1.6%
2 Electrical resistivity at 20 C (68 F). 107.9 microhm-cm
5 Temperature coefficient of electrical resistivity 20 to 100 C (68 to 212 F). 0.000219 per °C
I *1 General resistance to corrosion.* This alloy is especially resistant to oxidation up to 1200 C (2200 F). It is subject to corrosion in sulfur atmospheres and in some corrosive atmospheres at 925 C (1700 F).
K *Mechanical properties.*

45 Ni – 55 Cu

COMPILED BY G. C. STAUFFER* AND W. A. GRAHAM*

A *1 Common name.* **Constantan**

B *1 Typical uses.* This alloy has about the highest electrical resistivity, the lowest temperature coefficient of resistance, and the highest thermal emf against platinum of any of the copper-nickel alloys. Because of these properties it is used for electrical resistors and thermocouples. This alloy is ordinarily used in the wrought condition, but is also used in the form of castings.

2 Precautions in use. Maximum temperature for use as a resistor, 500 C (930 F); maximum temperature for thermocouple use, 900 C (1650 F).

C *1 Density.*
Wrought: 8.9 g per cu cm (0.32 lb per cu in.)
Cast: 8.6 g per cu cm (0.31 lb per cu in.)

5 Patternmaker's shrinkage. ¼ in. per ft

D *1 Liquidus temperature.* 1290 C (2355 F)

2 Solidus temperature. 1220 C (2230 F)

6 Thermal expansion.

20 to 100 C (68 to 212 F). 0.0000149 per °C
20 to 500 C (68 to 932 F). 0.0000163 per °C
20 to 1000 C (68 to 1832 F). 0.0000188 per °C

11 Specific heat. 0.094 cal per g

16 Thermal conductivity. 0.0546 cal/sq cm/cm/°C/sec

E *2 Electrical resistivity.* 49 microhm-cm
Specific resistance. 294 ohms per cir mil-ft
231 ohms per sq mil-ft

5 Temperature coefficient of electrical resistivity.
Wrought: 20 to 100 C (68 to 212 F). ±0.00002
20 to 500 C (68 to 932 F). ±0.000025
Cast: 0 to 150 C (32 to 302 F). ±0.0001

The change in resistance with temperature may be either positive or negative, depending on small variations in composition and on variations in the amount of cold working. In any case, the change is small. The above values are averages for the various temperature ranges.

9 Thermal emf. The basic alloy is modified by additions of manganese and iron to give somewhat varied emf as specified by manufacturers of pyrometers. The following representative values, obtained by the National Bureau of Standards, establish the shape of the curve of emf versus temperature.

Emf of Constantan versus Platinum, Cold Junction at 0 C (32 F)†

deg Fahr	Millivolts	deg Fahr	Millivolts
−300	+5.02	+800	−17.41
−200	+3.73	900	−19.97
−100	+2.24	1000	−22.55
0	+0.57	1100	−25.15
+100	−1.27	1200	−27.77
200	−3.26	1300	−30.39
300	−5.39	1400	−32.99
400	−7.64	1500	−35.58
500	−9.98	1600	−38.14
600	−12.40	1700	−40.66
700	−14.88	1800	−43.13

K *Mechanical properties. Wrought alloy*: tensile strength 60,000 psi, annealed; tensile strength 135,000 psi, cold worked.
Cast alloy: tensile strength (0.505-in. test specimens cast in green sand mold) 55,000 psi; yield strength (0.2% offset) 21,000 psi; elongation in 2 in. 32%; reduction of area 4%; Brinell hardness number (500-kg load, 10-mm ball) 75 to 85; Rockwell hardness (100-kg load, $\frac{1}{16}$-in. ball) B 48 to 54; shear strength 43,000 psi; Charpy impact resistance (10-by-10-mm specimen) approx 30 ft-lb.

N *2 Casting temperature.* 1350 C (2460 F) minimum

3 Alloying. Pure copper and nickel are melted together, usually in an arc furnace.

4 Preferred deoxidizer. Magnesium

6 Precautions in melting. Add deoxidizer just before pouring.

12 Precautions in casting. The rate of filling the mold should be controlled by the size of the runner and not by varying the rate of pouring.

* Driver-Harris Company, Harrison, N. J.
* Westinghouse Electric Corporation, Buffalo, N. Y.

The Tin Industry

BY ERWIN VOGELSANG*

ALTHOUGH the entire world production of tin is small in tonnage, the uses of this metal are of maximum importance and are more widely spread industrially than those of almost any other metal.

Tin is derived from cassiterite (SnO_2), a mineral found in nearly all parts of the world, but with commercially important deposits in comparatively few localities. The most important tin mines are located in Malaya, Bolivia, the Netherlands' East Indies, Siam, China, the Belgian Congo and Nigeria. These areas account for more than 90% of the world's tin output. Thus far, no commercial deposits of tin have been found in the United States.

Tin deposits are of two different kinds, which may be described as *vein* or *lode* deposits and *alluvial* or *placer* deposits. The ores from lode deposits contain approximately 2 to 4% Sn, and the placer gravels contain approximately ½ to 3 lb of cassiterite per cubic yard. Bolivian mines are almost entirely in vein formations, whereas mines in other areas are mainly placer deposits.

The vein deposits are extracted by usual deep-mining methods and are concentrated by various mechanical methods to produce aggregates that contain from 18 to about 65% Sn. The placer deposits are mined by dredging, hydraulic sluicing, and other more primitive hand methods, and produce a concentrate containing 70% Sn or more.

Table I shows the different smelting and refining companies that produced tin before and during World War II, and gives names and approximate compositions of the various brands produced by each company. One important addition to the list is the smelter of Tin Processing Corporation at Texas City, Texas, which was built in 1941 and started operations in the spring of 1942. This smelter, financed by the United States government, has the greatest capacity of any existing smelter. Depending on the type of ore available, its capacity is from 40,000 to 45,000 tons per year on a mixture of low-grade and high-grade concentrates, and would be from 75,000 to 80,000 tons if only high-grade ores were treated.

Some of the plants listed in Table I were closed during the war and may not be reopened.

The principal markets for tin are in London and New York. Tin is usually marketed in the form of pigs, bars or ingots weighing between 7 and 100 lb, or in large blocks weighing between 300 and 400 lb. The price has fluctuated between wide extremes. During the period from 1931 to 1941 the price of Straits tin at New York varied from a low of 18.35 cents to a high of 63.50 cents per lb. Between September 1941 and November 1946 the maximum price at New York was set by the Office of Price Administration at 52.00 cents per pound. With the ending of price controls, the Reconstruction Finance Corporation, as the distributor for almost all the tin sold in the United States, set the price at 70.00 cents per pound, in line with the price established by the British Ministry of Supply. In April 1947, along with the increased costs of foreign concentrates, the Reconstruction Finance Corporation raised the price to 80.00 cents per pound.

A classification of the various uses of virgin tin consumed in the United States is shown below for both the war and prewar periods. These figures have been computed from records of the Bureau of Mines and the War Production Board.

	Avg 1938 to 1941, percentage of total	Avg 1942 to 1945, percentage of total
Tin plate and terneplate	50.2	46.8
Solder	15.7	14.7
Babbitt	6.4	7.9
Brass and bronze	7.3	20.7
Foil	3.5	0.5
Collapsible tubes	5.1	0.9
Chemicals	0.2	0.1
Tin oxide	1.0	<0.1
Tinning (other than tin plate)	3.6	5.0
White metal	1.5	<0.1
Type metal	0.2	0.1
Pipe and tubing	1.2	0.3
Galvanizing	1.3	<0.1
Miscellaneous	2.8	3.0
	100.0	100.0

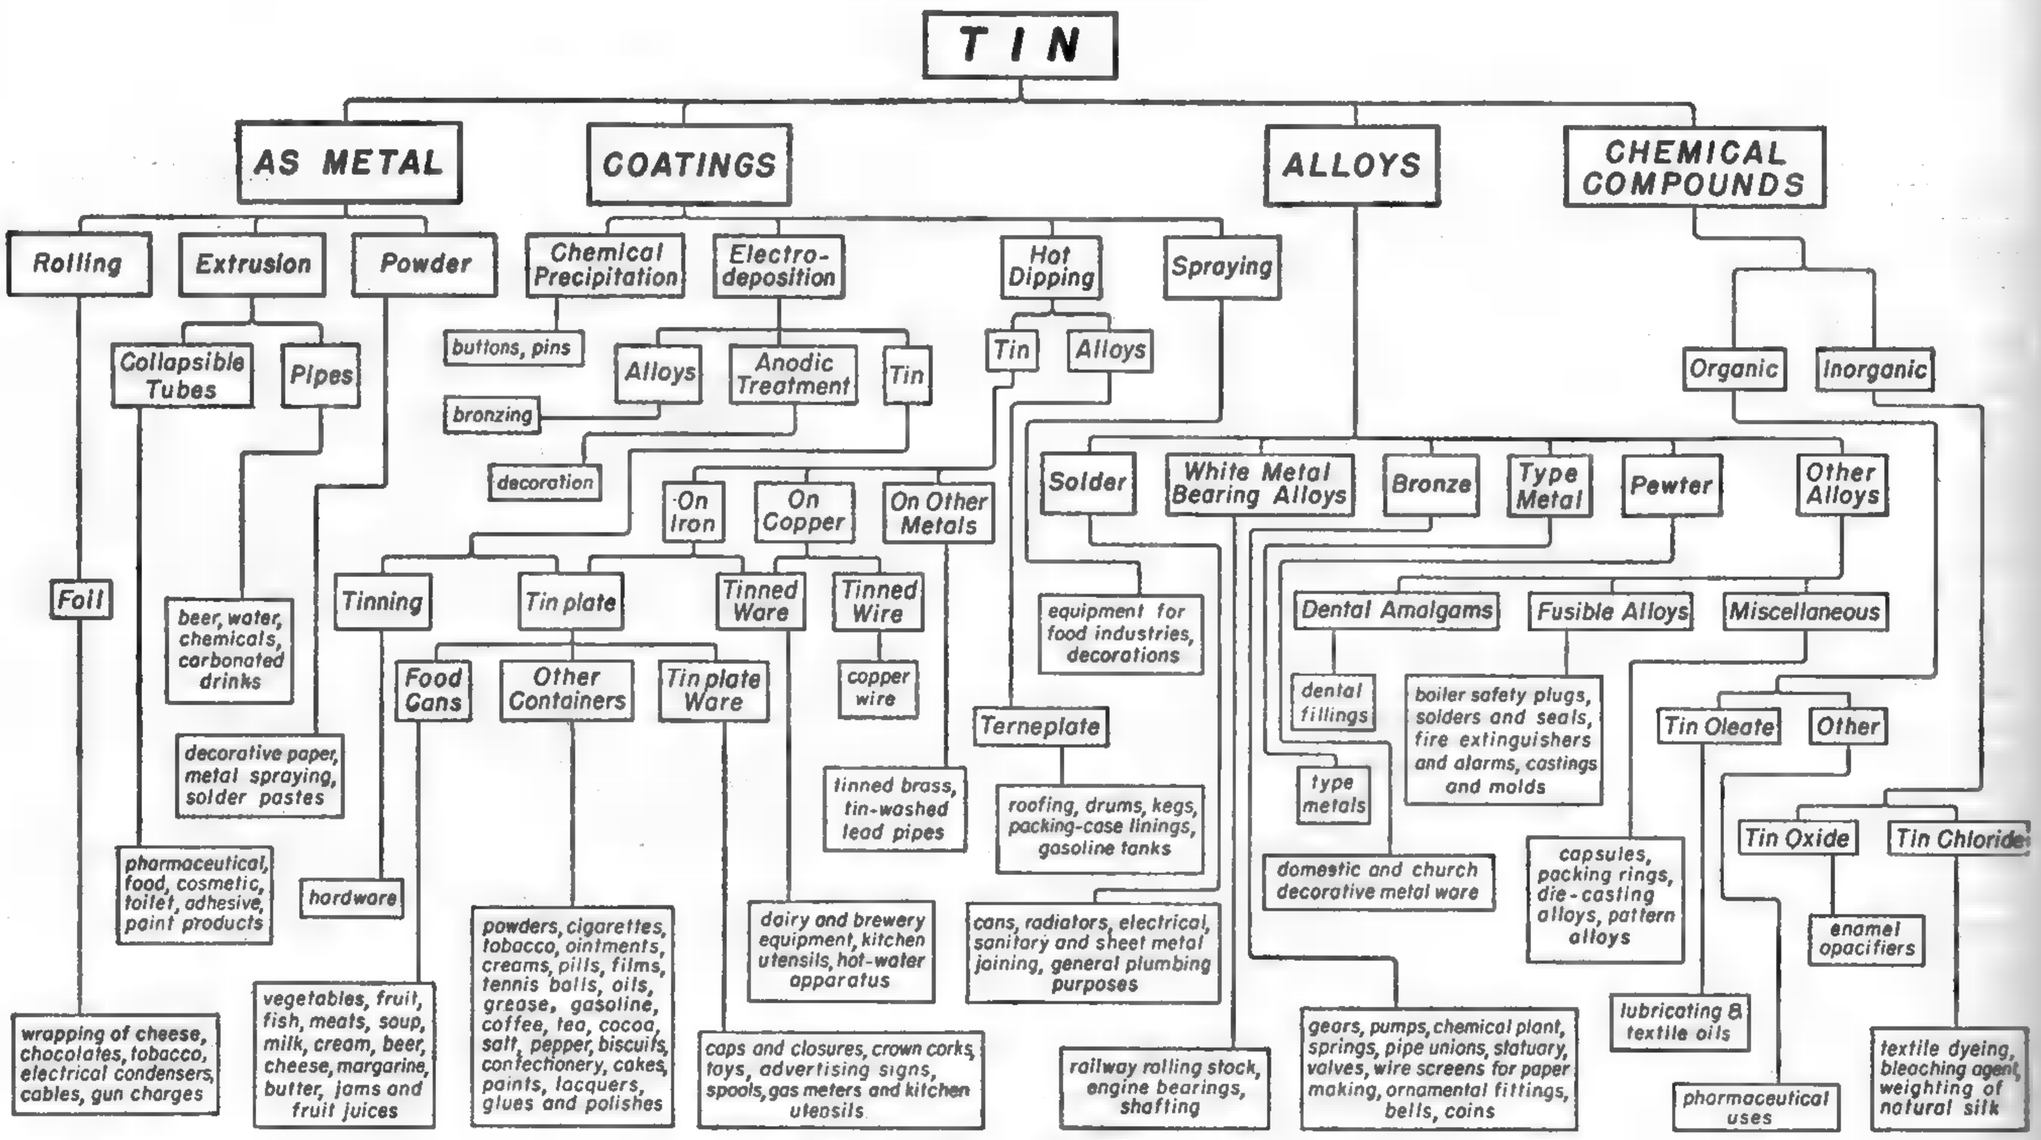

Fig. 1 The uses of tin in peacetime

The major application of tin is as a coating for steel (tin plate), which, in the form of the tin can, serves as the most efficient container for the preservation of perishable foods. Before World War II, all tin plate was produced by the hot dip method, with a coating of approximately 1½ lb Sn per base box of 112 plates, 14 in. by 20 in. With the new electrolytic method, ■ coating of any desired thickness may be applied—for example, 1/10 lb Sn per base box, or more. Although such a thin coating is not practicable for packaging wet food, the coating of ½ lb Sn per base box is used to can many wet food products. The thin-coated plate will eventually find many uses for packaging dry food and products other than food when a strong, serviceable container is required. As a packaging medium, tin is also important in the form of foil and collapsible tubes, although these uses have been greatly curtailed in recent years in favor of lead or aluminum.

A second major application of tin is as an alloying element. Tin is alloyed with copper to produce the various tin brasses and bronzes; with lead to produce solder; with

antimony, copper or lead to form babbitts, type metals, cast alloys and pewterware.

Figure 1 outlines the applications of tin, tin compounds and tin alloys during peacetime.

During the period between 1931 and 1940, world consumption of virgin tin varied between 107,400 and 169,500 long tons per year, and consumption in the United States varied between 35,477 and 93,885 long tons per year. No figures for world consumption have been available since 1940. However, during 1941, consumption in the United States was controlled by the War Production Board, and later by the Civilian Production Administration according to conservation orders. This control was intended to protect the tin required by the United States during the war and reconversion, and to ensure an orderly liquidation of reserves until the world supply and demand should balance once more.

Many of the physical and mechanical properties of tin and tin alloys are listed in the data sheets on pages 1070 to 1076. Other articles discuss specific applications of tin, such as the tinning of steel (page 709) and the use of tin alloys as bearing materials (page 745).

The Casting of Tin and Tin Alloys

By C. H. Hack*

COMMERCIALLY PURE TIN is seldom used as a casting metal, but alloyed with other metals for strength and hardness, it finds wide use in industry. The alloying elements most commonly used are antimony and copper. In varying proportions, these are added to tin for producing babbitt metals, pewter and novelty jewelry, principally as die castings and permanent mold castings.

Tin and the tin alloys lend themselves to all types of casting. At normal casting temperatures, the attack on iron is negligible; therefore these metals can be melted in an ordinary iron kettle. The casting methods depend largely on the article and its intended purpose. Casting methods are listed below, with several applications.

Gravity Casting. Both permanent and impermanent molds are used for gravity casting. Where only a few castings are wanted, impermanent plaster of Paris molds are used. Since these are very fragile, they usually serve for only one casting. The tin alloy is simply poured in, allowing sufficient head, which is cropped off later.

Where a large number of castings is required, permanent molds of bronze or iron are used, the former for ornamental designs. A hot mold is used and after casting the alloy, the shrinkage is confined to the gate end by spraying water on the outside near the bottom.

A common alloy used for gravity castings is pewter or britannia metal, 4 to 7% Sb, 1 to 2% Cu, and the remainder tin. This class of alloy is also cast in iron molds as slabs or ingots, which are later rolled out into sheet. The sheet is sold commercially in various gages and sizes for spinning or hammering later into articles of commerce—generally vases, bowls, trays and such. Because of its toxicity a considerable proportion of lead is undesirable in articles that come in contact with food.

The largest use for the tin alloys is in bearings. Gravity casting is one method of manufacturing a bonded steel-backed bearing. In such a bearing, the tinned bearing shell constitutes the outer part of the mold. A hollow mandrel is used, with an outside diameter such that when it is placed concentric with the shell, it will give a cast bearing lining much greater than required, thus affording ample metal for later machining. Provisions should be made for a fair-sized head at the pouring end to provide for the shrinkage. Half-bearings may be lined singly, in either a vertical or a horizontal position, but they are generally lined with two halves together vertically. In casting such bearings certain rules should be followed:

1 The tin or solder bonding alloy on the shell should be molten at the time of casting.
2 The shrinkage should be controlled in a way that will make it take place at the gate; otherwise holes will be present throughout the cast lining. To prevent this, the mandrel should be approximately 100 F hotter than the shell; also, the top should be hotter than the bottom. After casting the bearing, the application of a fine spray of water to the outside of the mold, first at the bottom and then progressing to the top, helps to keep the shrinkage at the gate.

If these simple rules are followed, the finished bearing should be well bonded and free from porosity.

Slush Casting. This type of casting is used for ornamental ware. The alloy—generally britannia metal—is cast in a cold bronze mold of the desired shape and design. A few seconds after casting, when the alloy has solidified against the inside of the mold, the mold is inverted to allow the metal that is still molten to run out.

Centrifugal Casting. This method, which is being used increasingly, is ideally suited to the manufacture of bearings in quantity production. In centrifugal casting, a steel cylinder is cleaned, pickled and tinned with either pure tin or a tin-lead solder. After tinning, the cylinder is immediately placed between heated end-plates in a machine very similar to a lathe. One of the end-plates has a hole in it, through which the bearing metal is poured into the shell by means of a trough. For a guide to the proper casting temperature, see Table I. Immediately after being cast, the bearing cylinder is revolved at a speed that depends on the diameter. As an example, for a 4-in. diam, a speed of 650 to 750 rpm is used. At this speed, all the molten metal is thrown evenly toward the inside wall. After approximately 5 sec, a fine water spray is directed against the outside of the revolving cylinder. This practice not only confines the shrinkage to the desired place, but also brings about rapid solidification before segregation can take place. The casting is then cut lengthwise, machined and finished as two half bearings.

Die Casting.* Because of the relatively low melting temperature of tin and tin alloys, they can be cast in dies made from cold rolled steel or 0.20 to 0.50% C steel. It is good practice to put some lubricant, such as lard oil, on a new die, until a natural oxide forms on the metal from use. No fluxes are used on the metal in the die-casting machine. Finely powdered talc, sometimes used as a mechanical covering over the metal bath in the machine, not only prevents excessive oxidation but also acts as an insulator. A good operating temperature for die casting is 50 to 100 F above the liquidus. Pressures from

12[g]	59.5	26	9.5 to 11.5	3.25	.....

(a) Physical and mechanical properties for some of these alloys are given in data sheets on pages 1074 to 1076. *See also* references 1 and 2.
(b) Permissible percentages of impurities, according to the ASTM standards, are a maximum of 0.35 Pb, 0.08 Fe, 0.08 As, 0.01 Zn, and 0.01 Al with a maximum of 0.15 As, in alloy 8 (ASTM Alloy Grade No. 3, B 102)
(c) ASTM B 102–44, Alloy Grade No. 1; similar to ASTM B 23 (White Metal Alloys) Grade No. 1; and to SAE No. 10 standard specification
(d) Similar to SAE No. 11
(e) ASTM B 102–44, Grade No. 2
(f) ASTM B 102–44, Grade No. 3; similar to ASTM B 23, Grade No. 5
(g) SAE No. 12

The shrinkage of tin-base die castings is small, and dimensional specifications can be held closely. The U. S. Army specification permits only ±0.0005 in. per linear inch variation for tin-base die castings, as compared with ±0.0025 in. for aluminum-base die castings. The figures show that tin alloys can be used where close tolerances are essential. Speedometer parts and parts wherein the wall thickness is only $\frac{1}{32}$ in. are die cast. Also threads up to 32 per inch can be die cast.

The fins and risers are easily removed from these die castings, which seldom need finishing and are easily buffed and coated. Self-threading screws are frequently used.

Most of these die castings are used because of the close dimensions to which they can be cast and because of their bearing properties. Die castings are also used in connection with certain types of food-handling equipment.

For compositions and melting ranges, see Table II.

Tin-base alloys are also widely used in costume jewelry and such pieces as ornamental handles for tableware. These are cast by gravity or are cast centrifugally in rubber molds. The molds, which may be used for 500 to 2000 castings, are made by pressing rubber around the model and then vulcanizing.

The Working and Joining of Tin

By Bruce W. Gonser*

THE SOFTNESS and plasticity of tin make it adaptable to all types of cold working where high tensile strength is not required. For such operations as making wire, tin is better suited to extrusion than to wire drawing. Alloying elements are commonly added to provide greater hardness and strength, or to improve bearing qualities or resistance to corrosion. Working at slightly elevated temperatures is also possible, and is sometimes desirable with tin-base alloys, but the heat generated in cold working is usually sufficient to assure easy working after the operation has once been started.

General Working Properties. Pure tin work-hardens to such a slight extent that for practical purposes it is considered not to harden with cold work. Since tin anneals at room temperature, heating for the purpose of softening is unnecessary unless restoration of the original hardness is required at once.

Certain impurities affect the hardness of tin, and some make it amenable to permanent work hardening. Bismuth, in amounts greater than a few tenths of a per cent, is particularly effective in hardening tin permanently; copper and cadmium are also effective, although increased hardness with cadmium gradually decreases during a period of many months. Aluminum and arsenic, even in amounts smaller than 0.1%, harden tin, but are undesirable additions. Small amounts of antimony have little effect on the hardness of cast tin, but when several per cent of antimony is present not only is the hardness as cast increased, but with moderate cold rolling, as in a reduction of 10 to 30%, further permanent work hardening is obtainable. As a result of severe cold working, however, the metal may become softer than the hardness as cast—or at least there is less immediate hardening—and the metal may self-anneal at room temperature to less than the hardness as cast.[1,2] This softening by severe cold work can be overcome and the original hardness may be regained by annealing at 225 C (437 F).

The addition of 0.05% Te or more to tin has been found to improve greatly the resistance to creep and to be effective also in increasing the work hardenability; the tensile strength may be twice that of pure tin after 50% reduction by cold rolling.[3] More severe cold work is less effective.

The tensile properties of cold worked tin and tin alloys are influenced considerably by the grain size of the metal. For example,[4] in pure tin an increase in tensile strength from 1150 to 2300 psi has been noted, without decrease in elongation, as the number of grains in the cross section of rolled specimens was increased from 1 to 20. With finer grain sizes, elongation was found to increase, but there was only a slight increase in tensile strength. Tin alloys containing antimony and cadmium behaved similarly, increasing from 1800 to 3300 psi in tensile strength with 1% Sb and from 1250 to 3100 psi with 1% Cd, as the grains in the cross section of the specimen increased from 1 to 20.

Cold Rolling. Tin is easily cold rolled with heavy reductions and with no need for annealing. Thus, the Brinell hardness of pure tin may increase from 4 or 5 in a cast slab to 10 as a result of cold reduction, but rolling can be continued down to the thinnest foil.

Ordinarily, two strips of foil are rolled simultaneously so that some slip can take place between the strips; otherwise irregularity in roll bearings could cause wrinkles and tears. In rolling tin, solder and other tin alloys to foil, lubricants may vary with different plant practices, but tallow and paraffin are generally used for coarse reductions in heavy mills; and for rolling the very light gages, a light petroleum oil is used, to which an unsaturated oil is added, such as rapeseed or linseed oil. A few per cent of antimony added to the tin gives a much stronger foil. Condenser foil of adequate strength may be rolled commercially 0.00025 in. thick from an alloy containing 83% Sn, 15% Pb, 2% Sb. This is sometimes used in preference to less expensive aluminum foil because of solderability and a tendency toward "self healing" by local melting if short circuit occurs. The eutectic alloy of tin and zinc

* Battelle Memorial Institute, Columbus, Ohio

(8% Zn) rolls readily to foil thinness and has a tensile strength several times that of pure tin.[5] Such tin-zinc foil, 0.0015 in. thick, has been used successfully in England for milk-bottle caps. Aluminum, even when present in amounts of only 0.1 or 0.2%, is a particularly undesirable impurity in tin foil, and care is required for preventing contamination of scrap tin foil that is to be remelted.

Composite tin-lead slabs can be cold rolled to produce a firmly adherent tin surface, suitable for making slugs for tin-coated lead collapsible tubes. The surfaces forming the metal interface should be clean and free from lubricant. A convenient method is to roll two sheets of tin together, separate them, and use the inner, freshly disrupted surface for contact with the lead.

Extrusion. Tin and tin alloy pipe, wire, and ornamental shapes are commonly made by extrusion, with equipment and procedure similar to those used for comparable lead products. Most important of these are various solders that may be extruded in solid or flux-cored wire, or in ribbon or angular shapes. Tin alloys are extruded usually at elevated temperatures, but considerably below the melting range. As an example, in making ornamental shapes from pewter alloys (britannia or white metal), billets 2½ in. in diam by 8 in. long are commonly extruded in a 250-ton horizontal rod-press at a temperature of 60 to 65 C (140 to 150 F), with pressures from 40,000 to 100,000 psi.[6] Speeds as low as 10 to 20 fpm are needed to prevent checking of the edges when white metal is being extruded, but 30 fpm is common for tin-lead solders. The extruded white metal shapes or "mounts" are frequently beaded or embossed by passing the uniform shape through a pattern roll.

The manufacture of collapsible tubes provides the best example of simplicity in impact extrusion. The general mechanism is approximately the same as that for lead, as described on page 949. Tin that contains 0.25 to 0.5% Cu as ■ hardener, is rolled to requisite thinness; then round slugs are stamped from the slab. After tumbling with a small amount of lubricant, the slugs are impact-extruded into tubes that have walls as thin as 0.004 in. The pressure required is about 50,000 lb for 1-in. tubes of 0.004-in. sidewall. Vertical presses of 60-ton capacity are standard for producing the most common sizes of tubes. The pressure of extrusion depends particularly on the sidewall thickness. The operation is substantially cold working, although after a few extrusions the dies become warm. A lubricant is needed that is both effective and compatible with coating enamels, such as vegetable shortening or olive oil. Tin-coated lead tubes are made similarly. As with some severely cold rolled tin alloys, tin-copper tubes produced by impact extrusion gradually increase in hardness during a period of several months by aging at room temperature.

Spinning. Pewter, or tin containing from 5 to 15% Sb and 3% Cu or less, is easily worked into utilitarian and artistic forms by spinning, as well as by forming in other ways. Although soft, pewter retains sufficient strength and ductility to permit drastic forming. The modern pewter or britannia metal remains bright after long exposure to the atmosphere, whereas the lead-containing pewter of colonial days tends to darken rather rapidly. Both types spin well, but care is needed for applying pressure cautiously in order to avoid rupture while the metal is being stretched. Fairly heavy stock should be used, since it can be spun down to any shape. An even thickness can be maintained without difficulty, and no annealing is required. Several compositions of pewter soften under severe work, but some hardening may be secured by heating the spun or beaten product to 150 to 200 C (300 to 390 F). Tallow or soap-oil mixtures are commonly used as lubricants.[7]

Working at Elevated Temperature. Tin softens with a rise in temperature (*see graphs,* page 1071); however, both tin and tin alloys cold work so easily that they seldom need to be heated. Tin that contains impurities may become embrittled at elevated temperature.[8] Intergranular fracture may result from impurities that form low-melting eutectics or solid solutions with tin. Thus, the presence of 0.005% Cu will cause tin to fracture easily at 5 C (9 F) below the melting point of tin, and the effect of only 0.001% Cu is detectable. The temperature to fracture is lowered by 12 C (22 F) when 0.02% Ag is added to tin as cast, or 0.04% Ag is added after long annealing. Addition of 0.5% Pb may cause tin as cast to fracture at 183 C (361 F).

Joining Tin Parts. Parts made from tin and tin alloys are joined most readily by soldering with ■ low-melting solder. Care must be taken not to overheat the joint members, since the fusion point of the tin or tin alloy may be only a little higher than that of the solder. The eutectic tin-lead solder (63% Sn) is frequently used.

For pewter, a composition similar to that of the base metal, or even pure tin may be desired to give a matching color. Tin-lead-bismuth solders can be used where color is not important. Rosin and olive oil are sufficiently strong fluxes, but a flux of 10 drops HCl in 1 oz glycerin is frequently used in the soldering of pewter. Parts to be joined should be made to fit well before soldering, and only enough solder should be used to fill the joint. A light flame is more convenient to use than a soldering bit and ordinarily entails less danger of local overheating.

Tin Coatings and the Resistance of Tin to Corrosion

By Bruce W. Gonser*

TIN COATINGS are applied to ferrous materials and copper alloys in order to increase the resistance to corrosion. The coating of ferrous materials with tin by hot dipping, and the manufacture of electrolytic tin plate, are discussed in the article on page 709 in this Handbook. The present article describes the hot tinning of nonferrous objects, and the application of tin coatings by hot dipping and by other methods.

The resistance of tin to corrosion in the atmosphere and in aqueous mediums is summarized briefly here. More specific information concerning the resistance of tin to commonly encountered corrosive agents is included in the compilation of the properties of tin, on page 1072.

Tin Coatings

Tin-coated copper is used for dairy and refrigeration equipment, as well as for containers and conveyers of food and beverages. Tin-coated copper tubing is useful for handling natural fresh waters that are very soft or that contain large percentages of dissolved carbon dioxide and oxygen. As a coating on copper wire and cable, tin arrests corrosion caused by sulfur in rubber insulation.

The Hot Tinning of Nonferrous Articles.[1] Copper and bronzes other than aluminum bronze are coated by hot tinning in about the same manner as ferrous articles. Ordinarily there is less difficulty in preparation, because copper objects are less likely to be coated with oil or grease. Pickling is done best by dipping the work for 2

to ▮ min in cold 15% nitric acid by volume, or in a hot solution containing 10% sulfuric acid and 2% nitric acid. After washing and immersion in a flux solution that has a zinc chloride base (for example, 3 lb zinc chloride, 0.3 lb ammonium chloride per gal of water) the articles are tinned and the surplus tin is removed by wiping or shaking.

The reaction between copper and molten tin is much more rapid than that between iron and tin; hence, the tin bath quickly becomes contaminated with copper. This contamination can be minimized by keeping the temperature of the tin bath low, preferably 250 C (480 F) and leaving the copper in the molten tin no longer than is absolutely necessary. Ordinarily only one pot of tin is used, since a double immersion merely prolongs the time of contact between tin and copper, and the only flux is that carried by the article being dipped. When large, heavy copper-base articles are to be tinned, they should be preheated after fluxing, to shorten the time of tinning.

If the tin bath or the liquid film of tin on the copper contains much more than 0.7% Cu (the eutectic alloy), enough crystals of intermetallic compound, η, are precipitated during cooling, to make the tin pasty and slow in draining. The excess of tin is commonly removed from copper articles by hand wiping with a cloth pad. It may be necessary to reheat the surface—for example, with a gas flame—to ensure smoothness after wiping. If the temperature exceeds about 280 C (545 F) during wiping, the result may be a yellowish cast to the tin and dark streaks from the wiping cloth.

So that excess copper can be removed from the tin bath, the tin should be cooled at frequent intervals, nearly to the solidification point, thus permitting crystals of η to settle to the bottom as a sludge, from which copper can be removed readily. It is not good practice to attempt to tin iron and copper articles in the same pot, since the copper picked up by the molten tin causes the coating on iron to be dull or spangled.

Brass is hot tinned by the same method as copper. Zinc dissolved from the brass adds another undesirable constituent to the tin. The zinc forms an oxide dross that remains on the surface of the bath and adheres to the articles being tinned, thus making ▮ good finish more difficult to secure. Also, the tin becomes less fluid and does not drain so well; consequently it is preferable to tin brass by electrodeposition. Aluminum bronze and other copper alloys that contain aluminum have been hot tinned successfully after heavy electroplating with copper, but electrodeposition of tin seems to be a preferred method.

Large articles that cannot be immersed easily in a tinning bath, or vessels that require a tin lining only, may be hot tinned by wiping, a method used particularly for copper and copper alloys. After being cleaned and pickled, the article is heated moderately above the melting point of tin, finely powdered ammonium chloride flux is scattered over the surface, and then solid tin is rubbed quickly over the surface. Where feasible, a little molten tin is poured into a recess of the surface and is flushed around with a wiping pad. For tinning copper sheet on one side only, the reverse side is coated with whitewash (slaked lime); then molten tin is poured over the sheet, on a heated table, which slopes to permit drainage.

Electrotinning. Miscellaneous articles are commonly electrotinned[2] in ▮ bath of 9 to 16 oz per gal sodium stannate, 1.5 to 2.5 oz per gal free caustic soda, and (optionally) 2.5 to 5 oz per gal sodium acetate, at a cathode current density of about 15 amp per sq ft, and at a temperature of 75 C (165 F). In this bath it is necessary to cover the tin anodes with a film by subjecting them temporarily to a relatively high current density in order to prevent formation of stannous tin. The film is maintained by removing the anodes whenever the current through the bath is stopped; otherwise, the filming treatment must be repeated. A modified bath of this nature, containing copper cyanide, is used in plating bronze for hard, white decorative coatings or for stop-off in nitriding.

An acid bath (13.5 oz total sulfuric acid per gallon; 4.8 oz tin, dissolved anodically, per gallon; 16 oz cresol sulfonic acid per gallon; 0.3 oz gelatin per gallon; and 0.015 oz beta naphthol per gallon) is also used successfully for general electrotinning. This bath tolerates a higher current density, operates at room temperature, and the anodes are not filmed. Both electrolytes have excellent throwing power and are used in barrel plating small articles.

Other Methods. Small copper and brass parts, such as pins, screws, hooks and eyes, and parts for switches, are commonly tinned by replacement or immersion. A number of hot tin-salt solutions are used, such as 4 to 30 ▮ per liter of stannous chloride in a saturated solution of potassium acid tartrate; ▮ dilute solution of stannous chloride containing 25 g per liter of ammonium alum; or an alkaline bath containing 15 g per liter stannous chloride, 18 g per liter sodium hydroxide, and 7 g per liter sodium cyanide. More rapid deposition takes place in a cold bath of 50 ▮ per liter sodium cyanide, 5 ▮ per liter hydrous stannous chloride, and 5.6 g per liter caustic soda. A tin thickness of 0.000004 in. can be deposited on copper in 5 min with this solution.[3]

Molten anhydrous stannous chloride, preferably diluted with other inert salts that have low melting points, forms an excellent bath for tinning copper alloys and steel very rapidly. This coating is deposited at ▮ temperature sufficiently high to form a hard alloy coating. Similarly, tin alloy coatings can be applied by "stannizing", that is, heating the articles to be tinned, in volatilized stannous or stannic chloride and hydrogen.[4]

Tin powder in a convenient flux-lacquer suspension is sometimes painted over parts to be tinned, and is then heated above the melting point by means of a torch. Wiping is usually necessary to secure reasonably good distribution. Tin is easily sprayed, also, from wire, molten metal, or powder.

Resistance to Corrosion

Tin retains its brightness well during atmospheric exposure, both indoors and outdoors. The gain in weight from tarnishing indoors has been reported as 0.004 mg per sq dm per day for tin, compared with 0.019 mg for cadmium.[5] In ASTM 10-yr exposure tests, the average gains in weight for commercial 99.85% Sn panels were 0.007, 0.067, and 0.11 mg per sq dm per day at rural, industrial and marine locations, respectively, and respective losses in tensile strength were 19, 23.5, and 30%.[6] The rusting of tin cans, often attributed to corrosion of the tin coating, is caused by iron rust that mushrooms through pinholes in the coating. In detinning, virtually as much tin is recovered from a moderately rusty can as from one that has no rust.

In aqueous mediums, tin reacts with both strong acids and strong bases, but is relatively resistant to nearly neutral solutions. Corrosion is greatly accelerated by the presence of oxygen. Normally, tin is coated with a thin invisible film of stannic oxide, which may be removed by acids or alkalies, or may be penetrated locally so that pits develop. Corrosion by pitting is more common in nearly neutral solutions than corrosion by general attack. Distilled or fresh water attacks tin negligibly, although in some hard waters, precipitated carbonate may cause localized water-line pitting. The addition of 5% Sb to the tin has prevented such localized attack by hard water.[7]

When tin is used as a protective coating over a base metal, as on tin plate or tinned copper, corrosion is usually localized at pinholes through the coating. Tin is not electroprotective to steel under oxidizing conditions; but, under some nonoxidizing conditions, the potential of the tin-iron couple reverses, which accounts for the fact that tin does prevent exposed iron from corroding.[8] The best example is on the inside of tinned cans, where partial vacuum and the presence of dilute organic acids prevent appreciable attack by many foods, even though the tin coating is porous. The presence of stannous ions, resulting from slight attack on the tin coating, also aids in inhibiting an attack on exposed iron by many foodstuffs.[9]

Rusting of tin plate or tin cans during outdoor exposure may be prevented, or at least greatly delayed, by a treatment with a hot alkaline phosphate-dichromate solution (0.20 lb crystalline trisodium phosphate per gallon, 0.08 lb sodium dichromate per gallon, 0.20 lb caustic soda per gallon, and 0.03 lb wetting agent per gallon) for

a few seconds at 60 to 85 C (140 to 185 F).[10] This solution has been effective in treating electrolytic tin plate of 0.5 lb per base box coating weight, as well as in treating more heavily coated, hot dipped tin plate. Evidently the action is on the tin coating, since the same treatment has no apparent effect in preventing the formation of rust on untinned steel.

The Metallography of Tin and Tin Alloys

By C. H. Hack* and Frances H. Clark*

THE PREPARATION of tin and tin alloys for metallographic examination requires good technique and care because of the softness and ease of formation of flowed metal on the surface of the specimens. In general, the procedure for preparation is identical with that outlined on page 955 for lead and lead alloys. The harder alloys are more easily prepared than the softer ones.

The specimens may be surfaced initially by filing, or machining on a lathe, using a sharp tool that has a sharp rake, and then by grinding on abrasive papers of decreasing fineness. If a microtome is available, it may be used advantageously in minimizing the amount of subsequent polishing. However, if a microtome is used, a check should be made to see that it possesses three requisite properties, namely, sufficient rigidity, a properly sharpened knife, and such adjustments that cuts of 2 microns in thickness may be made. If a microtome is not available, a good substitute can be made by attaching a microtome knife to the front end of the supporting arm of a milling machine. The specimen is clamped in a vise attached to a slide rest (similar to the type used for a lathe) mounted on the moving bedplate at a slightly inclined angle. Settings for cuts as thin as 1 micron may then be made by turning the screw of the slide rest. A final microtoming with cuts of 1 to 2 microns is best for tin and tin alloys.

When preparing thin sections, such as tin coatings on metals or thin sections of babbitt linings, for metallographic examination, it is generally necessary to mount the section in some molding medium. Waxy materials sometimes used have a disadvantage in that they clog the polishing papers and soften in alcoholic etching agents or in solvents used for drying. Likewise, fusible alloys used for mounting clog the polishing papers, and are usually attacked more readily than the specimen by the etching reagent. Acid-hardened bakelite is being used successfully for mounting.[7] For this procedure 10 ml of a bakelite acid-hardening solution is added to 100 ml of the bakelite resin, and the two are mixed thoroughly. The mixture is then poured into the mold containing the specimen and is heated to between 40 and 45 C, when the bakelite begins to harden. It is then heated further at 60 C for 1 to 1½ hr, until the mixture has set hard. Bubbling and too rapid hardening may take place if the temperature applied is too high; therefore, it is desirable to use the lower temperature (40 C) for setting the resin, and then to apply a higher temperature (60 C) for hardening. Just enough material should be mixed for the immediate work, because the mixture hardens while aging at room temperature. One of the advantages of the acid-hardened bakelite is that it does not require high temperatures and pressures.

Polishing. If the specimen has been machined on a lathe, the polishing should be started on 0 abrasive paper, with subsequent polishing on 00 and 000 abrasive paper, all three lubricated with paraffin dissolved in kerosene (100 g of paraffin in 200 ml of kerosene). After being polished on each paper, the specimen should be washed first in warm kerosene to remove the grit and paraffin,

Table I. Etching Reagents for Tin and Tin Alloys

No.	Etching Reagent	Composition	Remarks	Use
1	Nital	HNO_3 ..... 2 to 5 ml C_2H_5OH .... 95 to 98 ml	Swab or immerse for several minutes.	Tin-cadmium or tin-iron alloys
2	Potassium dichromate	Acidified dilute solution	.....	Tin-cadmium alloys
3	Mixed acids in glycerol[1] (*A*)	HNO_3 .....1 part $HC_2H_3O_2$ .....1 part Glycerol .....8 parts	Immerse ½ to 10 min at 38 to 42 C.	(*A*) Tin-lead alloys
	(*B*)	HNO_3 .....1 part $HC_2H_3O_2$ .....3 parts Glycerol .....5 parts	Same as for (*A*) above	(*B*) Pure tin
4	Hydrochloric acid (*A*)	HCl (conc)	Immerse for several seconds.	To remove surface flow
	(*B*)	HCl .....10 to 20 ml H_2O .....90 to 80 ml	Immerse ½ to 5 min following (*A*).	Follow (*A*)
	(*C*)	HCl .....10 ml H_2O .....90 ml	Electrolytic etch at low current density	Tin-iron alloys
5	Ferric chloride	$FeCl_3$ .....10 g HCl ..... 2 ml H_2O .....95 ml	Immerse ½ to 5 min at room temperature.	Micro-etching tin-rich babbitt metal
6	Nitric acid[5]	HNO_3 ..... 5 ml C_2H_5OH (abs) ....95 ml	.....	Pure tin
7	Picric acid and nitric acid[6]	Alcoholic solution	.....	Tin-iron alloys
8	Ammonium polysulfide[2]	Concentrated solutions	Immerse 20 to 30 min at room temperature.	Macro-etching of tin-rich babbitt metals
9	Ammonium persulfate	$(NH_4)_2S_2O_8$ ..... 5 ml H_2O .....95 ml	Blackens out the tin or tin alloy, leaving the compound as a bright contrasting layer.	Tin coatings on steel
10	Acetic acid	$HC_2H_3O_2$ .....50 ml H_2O .....50 ml H_2O_2 .....1 drop	.....	Soldered joints

Solutions of silver nitrate or 10% nitric acid plus 5% chromic acid are also used occasionally.

and then with soap and water to remove the kerosene.[3] Thereafter the specimen may be etched with HCl (10 to 20%) or any other suitable etching reagent, in order to remove any metal that may have flowed on the polished surface.[4] A specimen that has been finished by microtoming may be polished on 000 paper to remove any scratches left by the microtome blade.

The specimen is then polished on a rotating wheel covered with broadcloth. The polishing mixture—usually a suspension of levigated alundum* (grain size 600) in a soap solution—may be prepared as follows: 5 g alundum grain is added to 300 ml water. This mixture is agitated thoroughly and allowed to stand for 15 min, when the supernatant suspension is decanted. To the decanted suspension 40 g soap is added and the mixture is heated until the soap dissolves. Because this mixture is nearly solid at room temperature, it should be used warm. When poured on the polishing wheel, this polishing material forms a gelatinous mass, viscous enough not to be thrown off the wheel at 120 rpm.[3] The final steps of preparation consist in polishing on a good grade of silk velvet, on which the mixture of soap and alundum grain is used. Then the specimen is etched and polished alternately until the true structure is revealed.

In one successful method, the specimen is microtomed, then etched rather deeply and polished on a wheel covered with silk velvet, on which magnesium oxide and water are used without addition of soap. The specimen is then washed thoroughly in running water, etched and dried. Further light polishings and etchings may be performed if necessary. This method saves considerable time.

When the specimen is being prepared for examination at ■ high magnification, the following procedure may be used:[3] A 4-in. circle of wool broadcloth is cemented onto a metal lap. The cloth is moistened with water and a 30 to 40% solution of sodium hydroxide, heated to 50 C. The cloth is washed off after two minutes and is charged with a paste of relevigated alumina in water. The fibers of the cloth are softened by this procedure and a satisfactory final polish can be obtained.

As already mentioned, the structure of pure tin is likely to be distorted by mechanical polishing, even on fine abrasive paper. Such polishing often produces twinning to a considerable depth. A paper by P. A. Jacquet[9] tells in detail how to polish tin specimens electrolytically without mechanical preparation.

Etching. The reagents listed in Table I have been used successfully for etching the tin alloys indicated.

* Finer abrasives, such as alumina or magnesium oxide, may be used, although these have been reported as producing excessive burnishing action and relief polishing.[3]

PROPERTIES OF TIN AND TIN ALLOYS

COMPILED BY JOHN L. EVERHART

Battelle Memorial Institute

Pure Tin

A *1 Designations.* Straits tin (Grade A tin) has a minimum purity of 99.8% and must meet definite specifications limiting some individual impurities. Most of the tin sold is in this classification. A few brands have been consistently more pure than 99.98%, and may be considered "pure tin". A number of other brands normally have contained more than 99.90% Sn. For specific information concerning the chemical compositions of twenty brands of commercial tin, the reader may refer to the article entitled, "The Tin Industry", page 1063.

Many of the properties listed here for pure tin were determined on tin of 99.95% purity. More recent work has been with Chempur tin of 99.9918% purity, containing 0.0031 Sb; 0.0025% Pb; 0.0004% Bi; 0.0004% Cu; 0.0016% Fe; 0.0002% S; no As, Ag or Co. Small amounts of copper increase the hardness of tin; traces of iron change the color of the metal.

Under certain specific conditions at low temperature, tin can transform from the normal tetragonal metal (white tin) to a cubic form (gray tin) that has entirely different properties. Since this transformation is accompanied by a change in density from 7.30 to 5.75, the resultant expansion causes disintegration of the metal to coarse powder or to local "warts".

The equilibrium temperature of transformation is 13.2 C (55.8 F). However, there is a marked lag or undercooling before the transformation occurs, and even under very favorable conditions a much lower temperature is needed to produce gray tin. The maximum velocity of transformation is at about minus 40 C (minus 40 F). It is very difficult to initiate the change, and even after the transformation has started, the rate is slow. For example, 500 hr is required for the change to progress a distance of 1 mm in a specimen at minus 10 C (plus 14 F) in high-purity (Kahlbaum) tin, or 800 hr is required in Banka tin. Inoculation, or contact with gray tin, greatly speeds the start of transformation, and has been an important aid in experimental work on the formation of gray tin.

Many factors influence this transformation besides temperature. Most of the common impurities in tin greatly delay or, for practical purposes, inhibit the change. Bismuth is particularly potent in this respect; the addition of 0.1% Bi is sufficient to assure that no change occurs under any conditions that are likely to be encountered. Antimony and lead are also strong inhibitors of the change; gold, silver, and nickel are somewhat less effective. On the other hand, zinc, aluminum, magnesium, cobalt, manganese, and tellurium accelerate the transformation; fortunately, these elements are seldom present in commercial grades of tin. The probability of transformation is increased and the velocity of the change is accelerated greatly by drastic working of the tin, but this effect is removed by annealing the metal at an elevated temperature. Repeated transformation of the same tin to the gray form, then back to the white form, facilitates the change.

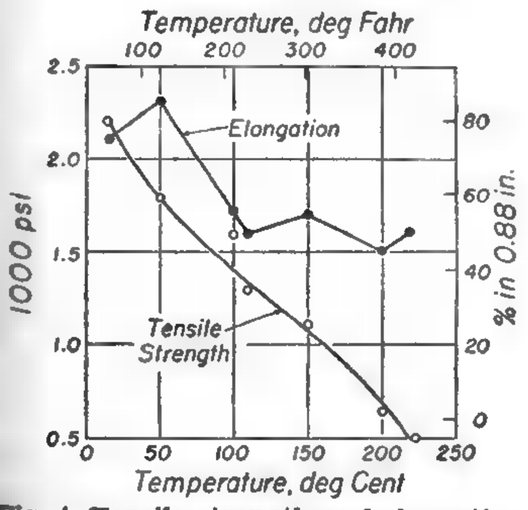

Fig. 4 Tensile strength and elongation of tin (Homer and Plummer[44])

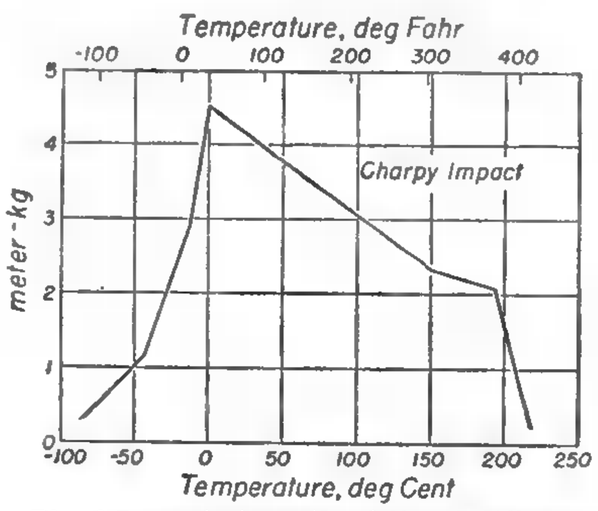

Fig. 5 Impact strength of tin at different temperatures (Greaves and Jones[45])

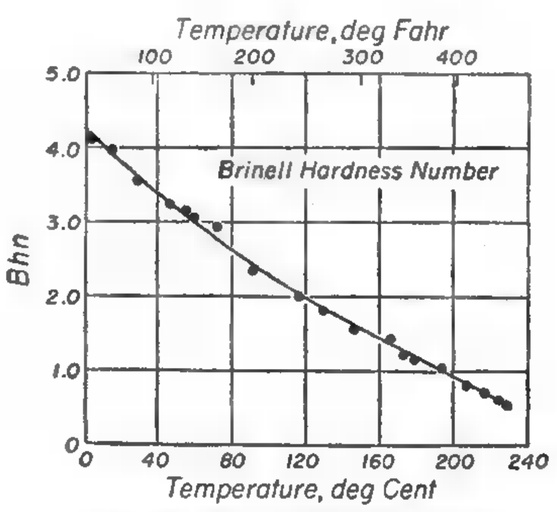

Fig. 6 Brinell hardness of tin (5-mm ball, 10-kg load, 180 sec) (Homer and Plummer[48])

Gray tin is of no commercial importance, since it does not exist in massive form or at normal working temperatures. If formed, it is readily converted to massive white tin by melting, or to white tin powder by heating. Fears of the failure of fabricated products made of block tin or of high-tin alloys at low temperatures, or of the disintegration of tin in storage, are largely unfounded, because of the inhibiting effect of the common impurities, and the difficulty in initiating the transition. Authenticated instances of the transformation taking place under natural conditions are rare. No solder or tin article containing more than 5% Pb has been found that has shown signs of transformation. As a precaution, however, the absence of aluminum and zinc should be assured, and 0.1% Bi (or at least 1 or 2% Sb or Pb) should be added to tin that is to be refrigerated continuously for long periods.

The existence of "gamma tin", a brittle modification that is sometimes mentioned in technical literature, has been rather well disproved.[48] Abrupt changes in some properties at elevated temperatures are ascribed more accurately to the presence of impurities.

Tin (99.8 Sn)

A *1 Common name.* **Straits Tin**
2 Trade name. **Grade A**
4 Government number. Federal QQ-T-371, Grade A (99.75%)
6 Foreign equivalents. German DIN 1704, Grade A2 (99.75%)

B *1 Uses.* Foil, collapsible tubes, powder, tin plate, pipe

I *2 Resistance to specific agents.*

Corrosive Agent	Resistance	Remarks
Acid acetic	Slight general attack	Increased by air
Acid butyric	Resistant	.....
Acid citric	Moderate attack	At water line
Acids fatty	Moderate general attack	.....
Acid hydrochloric	Severe general attack	In presence of air
Acid hydrofluoric	Severe general attack	In presence of air
Acid lactic	Moderate general attack	Increased by air
Acid nitric	Severe general attack	.....
Acid oxalic	Moderate general attack	Most corrosive of common organic acids
Acid phosphoric	Resistant	.....
Acid salts	Severe general attack	In presence of air
Acid sulfuric	Severe general attack	Increased with concentration and in presence of air
Acid tartaric	Slight general attack	.....
Air	Resistant	.....
Ammonia	Resistant	.....
Bromine	Severe general attack	.....
Carbon tetrachloride	Resistant	.....
Chlorine	Severe general attack	.....
Iodine	Severe general attack	.....
Milk	Resistant	.....
Motor fuel	Resistant	.....
Petroleum products	Resistant	.....
Potassium hydroxide	Severe general attack	Increased by air
Sodium carbonate	Slight general attack	.....
Sodium hydroxide	Severe general attack	Increased by air
Water distilled	Resistant	.....
Water sea	Resistant	.....

Notes. Tin reacts with both strong acids and strong alkalies but is relatively resistant to nearly neutral solutions. Oxygen greatly accelerates corrosion in aqueous solutions.

In general, with mineral acids the rate of attack increases with the temperature and concentration.

Dilute solutions of weak alkalies have little effect on tin, but strong alkalies are corrosive even in cold dilute solutions.

Salts with an acid reaction attack tin in the presence of oxidizers or air.

Tin resists soft tap waters but is slightly attacked near the water line by hard tap waters.

K *Mechanical properties.*

Form	Section, inch	Tensile Strength, psi	Yield Strength (0.2% offset), psi	Elongation, percentage	Vickers Pyramid Hardness
Cast	....	2100	....	55 (4 in.)	...
Sheet, annealed 1 hr at 370 F	0.040	2200	1300	45 (2 in.)	7.2
Sheet, cold rolled 30% reduction	0.040	2800	2000	35 (2 in.)	8.4
Foil	0.0016	2000	....	6.5	...

Cast: Modulus of elasticity 6,000,000 psi; *Izod* 14 ft-lb; *Shear strength* 2,900 psi; *Poisson's ratio* 0.33.

Reference

"Mechanical Properties of Metals and Alloys", Nat Bur Standards Circular C 447, 1943

99.6 Sn – 0.4 Cu

A *1 Common name.* **Hard Tin**

B *1 Typical uses.* Collapsible tubes and foil

D *1 Liquidus temperature.* 230 C (446 F)
2 Solidus temperature. 227 C (441 F)

I *2 Resistance to specific agents.* Resistant to attack by foodstuffs, medicinal products, cosmetics and artist's colors.

K *Mechanical properties.* Tensile strength of 0.1-in. strip: (annealed 3 hr at 100 C) 3300 psi; (annealed 3 hr at 200 C) 3100 psi; (hard—80% reduction) 4000 psi. Collapsible tube, impact extruded, 0.004-in. wall: 21 bends over 90-deg jaws (1000-g load). A tube 1-in. in diam, with 0.004-in. wall, burst under an internal pressure of 46 psi.

N *Working data.* Although copper dissolves readily in tin at temperatures of 600 C (1112 F) or higher, the alloy is usually prepared by the addition of a master alloy, such as a 10% Cu alloy. For the manufacture of collapsible tubes, the alloy is cast into slabs, ⅝ to ¾ in. thick and rolled cold to the desired thickness. Blanks are punched from the strip, and the tubes are formed by impact extrusion.

95 Sn – 5 Sb

A *1 Common name.* **Antimonial Tin Solder**

B *1 Typical uses.* Solder for electrical equipment, joints in copper tubing, cooling coils for refrigerators. High-tin solder is used for joining parts of electrical apparatus because this solder has somewhat higher electrical conductivity than high-lead alloys. High-tin solder is also used where lead may be a hazard—for instance, in contact with foodstuffs. Because of their higher melting points, the tin alloys that contain 5% Sb or 5% Ag, are suitable for use at higher temperature than the tin-lead alloys.

D *1 Liquidus temperature.* 240 C (464 F)
2 Solidus temperature. 233 C (452 F)

E *1 Volume conductivity* referred to standard copper. 11.9%
2 Electrical resistivity at 25 C (77 F). 14.5 microhm-cm

I *2 Resistance to specific agents.* Resistant to SO_2.

K *Mechanical properties.* Cast: tensile strength 5900 psi; elongation in 4 in. 38%; Izod 20 ft-lb; shear strength 6000 psi.
Soldered copper joint: tensile strength 14,200 psi; shear strength 11,100 psi.
The mechanical properties of solder metal are not so indicative of the value of the material as the strength of joints produced with them. Tension and shear tests[3,4,5] have been used in evaluating the strength of joints and, in general, the thinner the layer of solder metal, the stronger the joint. Although the references do not deal with the specific alloys under discussion here, they should be referred to for details of the testing methods that have been used. Other properties, such as those involved in "spreading tests",[3] "wetting tests",[6] and the capillary rise of solder between strips of the metal to be soldered,[5] are beyond the scope of these data sheets and reference should be made to the original articles.

N *17 Joining.* For the joining of copper alloys and low-carbon steel, zinc chloride and zinc-ammonium chloride can be used as fluxes with all four of the tin-base solders. The excess flux should be removed because the residue is corrosive. A number of proprietary organic-base fluxes are suitable also, and are stated to leave noncorrosive residues. Rosin fluxes may be used with the high-tin Sn-Pb alloys but are not satisfactory for the antimony and silver solders. A flux containing zinc-ammonium chloride, stannous chloride, and free hydrochloric acid is suitable for joints of copper alloy, low-alloy steels, stainless steels and cast iron with tin solders. The flux residue is corrosive and should be removed. These solders are not suitable for joining magnesium and aluminum alloys.

Wire, extruded, and annealed 24 hr at 225 C	0.14	7800	10	..	..	..

Effect of rolling on hardness. The alloy hardens at first on cold rolling; the maximum hardness is reached at a reduction of about 40 to 45%. Further working causes progressive softening until at about 80% reduction, the hardness approaches that of the cast alloy. Annealing at 200 to 225 C (392 to 437 F) causes the severely worked alloy to harden slightly.
6 Creep tests. Creep tests[4] conducted at room temperatures [9 to 27 C (48 to 81 F)] on rolled material (0.1 in. thick), yielded the following results:

Stress, psi	1400	1200	1100	1000	900	800	600	400
Time, days	19	54	71	155	198	360	339[a]	337[a]
Final extension, %	66	54	37	42	49	98	4.12[a]	1.06[a]

(a) These specimens did not fracture.

91 Sn – 7 Sb – 2 Cu

A *1 Common name.* **Pewter, Britannia Metal**
Pewter consists essentially of tin hardened by the addition of antimony and copper. Although a wide range of compositions has been called pewter, the usual modern alloys contain from 90 to 95% Sn, 1 to 3% Cu and the remainder antimony. Britannia metal, so called because it was first made in Great Britain, contains from 91 to 92% Sn. Although some pewter contains lead as an alloying constituent, a considerable portion of lead is undesirable in containers for foods. Lead also may impart a dullness to the ware.
B *1 Typical uses.* Vases, candlesticks, tea and coffee services and book ends.
D *1 Liquidus temperature.* 295 C (563 F)
2 Solidus temperature. 244 C (471 F)
I *1 General resistance to corrosion.* Hoar[1] found that pewter tarnishes in soft water with the production of a visible film of interference-tint thickness. In hard water there was no tarnishing, but localized attack at the water line and sometimes elsewhere occurred if a chalky deposit was formed from the water. Pewter is attacked by dilute hydrochloric and citric acids in the presence of air.
K *Mechanical properties.* See Table I.
Erichsen value, depth in mm: annealed, 9.6; cold rolled to 32% reduction, 11.6
N *2 Working data.* Plaster-of-Paris molds are used if only one casting is required.[4] Bronze is generally used for permanent molds. The permanent mold is heated to the same temperature as the pewter. Hollow objects may be made by using bronze cores, or by slush casting.
11 Suited to forming by rolling, hammering or spinning.
17 Joining. Pewter is readily soldered. Suitable solders[5] are: 50% Sn, 25% Pb, 25% Cd; 50% Sn, 25% Sb, 25% Cd; and 45% Sn, 27.5% Pb, 27.5 Bi.

The Zinc Industry

BY R. K. WARING*

THE principal ores of zinc are the sulfide, blende; the silicate, willemite; and the oxides, franklinite and zincite. The sulfide is the most widely distributed and is today the principal source of zinc. Sulfide deposits of commercial importance occur in many parts of the world. Large deposits of willemite and franklinite have been found only in New Jersey.

Manufacture.[1] The sulfide ore is first concentrated, usually by flotation. The concentrate is roasted in the presence of air, yielding zinc oxide and sulfur dioxide, which is usually converted to sulfuric acid.

Several processes are in use for producing metallic zinc from the roasted ore. The oldest is the horizontal retort process, developed in Belgium about 1806 and first used in the United States in 1859, at Bethlehem, Pa. In this process, ore mixed with coal is charged by hand into small horizontal retorts that are heated from the outside. The temperature necessary to reduce the zinc oxide to metallic zinc is above the boiling point of zinc, thus producing zinc vapor. Each retort has a condenser attached to it in which the vapor condenses. The molten zinc is tapped at intervals. When a large part of the zinc has been reduced, the charge is removed. A complete cycle usually takes 24 hours.

In recent years a new process has been developed in which the ore and coal are briquetted and charged into large vertical retorts, built of refractories with good heat conductivity and heated externally by gas. The charge moves continuously down through the retort and the zinc vapor passes in a continuous stream into a condenser. In another type of process using a vertical retort, the heating is done internally by passage of electric current through the charge.

The third commercially important method of producing zinc is by the electrolytic process, in which the roasted ore is dissolved in sulfuric acid. The resulting zinc sulfate solution is purified and the zinc is plated out by electrolysis. Very careful control of the purity of the solution is essential to successful operation.

*Research Division, Technical Department, The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

In the retort process, the purity of the product depends largely on the impurities in the ore, and can be controlled to a limited extent by the initial removal of objectionable impurities from the ore. In order to produce zinc of the high purity required for some purposes, a refining process has been developed recently in which the impure zinc is subjected to fractional distillation in a rectifying column. A large tonnage of zinc that has a purity of 99.99+% is now produced by this process. Zinc of similar purity is also produced by an electrolytic process, in which the high purity is attained by chemical purification of the zinc sulfate electrolyte.

Grades. The recognized commercial grades of zinc in the United States have been specified by the American Society for Testing Materials,[2] as follows:

Grade	Composition, max %				
	Pb	Fe	Cd	Al	Sum of Pb,Fe,Cd
(1a) Special High Grade	0.006	0.005	0.004	none	0.010
(1) High Grade	0.07	0.02	0.07	none	0.10
(2) Intermediate	0.20	0.03	0.50	none	0.50
(3) Brass Special	0.60	0.03	0.50	none	1.0
(4) Selected	0.80	0.04	0.75	none	1.25
(5) Prime Western	1.60	0.08	...	...	...

The amount and kind of impurities in the metal have an important influence on the physical and chemical properties of zinc and zinc alloys.

Uses. The consumption of zinc in the United States during 1946 is given in Table I,[3] according to uses.

Galvanizing, which constitutes the largest use of zinc, is done either by dipping the iron in molten zinc or by electroplating. Hot dip galvanizing employs chiefly the less pure grades of zinc. For some applications, such as wire, which must stand bending without flaking of the coating, High Grade or Special High Grade zinc is used. In electrogalvanizing, the zinc may be obtained either from zinc anodes or by direct solution from ore and subsequent purification of the electrolyte. High Grade and Special High Grade zinc are used to a large extent for anodes in the method mentioned first. The life of gal-

vanized material is proportional to the thickness of the coating and recent developments in both electrogalvanizing and hot dip galvanizing have been toward the application of heavy coatings that will withstand deformation without peeling. See the article "Zinc Coatings", page 712.

Table I. Consumption of Zinc in the United States, 1946

Purpose		Tons
Galvanizing (total)		319,189
Sheets	113,760	
Tubes	61,449	
Wire	43,829	
Wire cloth	100,151	
Shapes		
Brass making		147,355
Die castings		205,353
Rolled zinc		92,294
Other purposes		26,213
Total		790,404

All grades of zinc are used to some extent in brass. The grade used has considerable influence on the properties of the brass. The manufacture, properties and use of brass are discussed in the COPPER SECTION of this Handbook.

All grades of zinc are used for rolling. In general, the presence of natural impurities or added metals increases the hardness and stiffness of rolled zinc. Special combinations of lead, iron and cadmium are used to control the chemical characteristics of zinc for dry batteries and photoengraving. Rolled zinc is discussed in greater detail in the article "Working of Zinc and Zinc Alloys", page 1082.

The use of zinc-base alloys for die casting has become important in recent years and is increasing rapidly; for this work, it is essential to use Special High Grade zinc. Zinc die castings are discussed in the next article.

Other forms of zinc include zinc oxide and zinc sulfide, widely used in paint and rubber, and zinc dust, used as a pigment in priming paints for metal and as a reducing agent in chemical processes.

Casting and Production of Zinc Alloys

BY G. L. WERLEY*

IN the production of zinc alloy castings, the process of die casting is most widely used. Sand casting is employed for producing stamping dies from zinc-base alloys and certain articles are made by slush casting or by the use of permanent molds. Because it is generally more important, die casting is discussed here in considerably greater detail than is gravity casting.

Die Casting

Process. Die casting is the art of producing accurately dimensioned castings repeatedly by forcing molten metal under pressure into metal dies.

The die-casting machine consists of a melting pot, a means for forcing the alloy into the die, and a mechanism for opening, closing and locking the die. When the melting pot is an integral part of the die-casting machine,

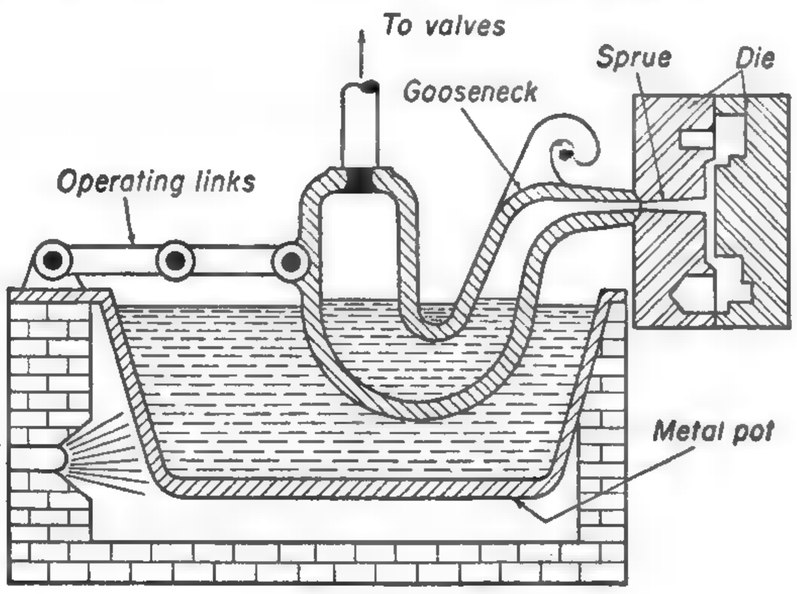

Fig. 1 Diagram showing arrangement of an air-injection machine that has a horizontal nozzle in position for filling a die by air pressure without a plunger

the injection cylinder automatically fills with alloy prior to each cast, regardless of whether the machine is designed for direct operation of air pressure on the metal (air gooseneck machine, Fig. 1) or for air or liquid operation of a plunger (plunger machine, Fig. 2). In another type, known as a "cold chamber" machine (Fig. 3) the melting furnace is a separate unit from which the alloy must be ladled into the cold pressure chamber prior to each operation (shot) of the machine, unless the equipment includes an automatic feeding device.

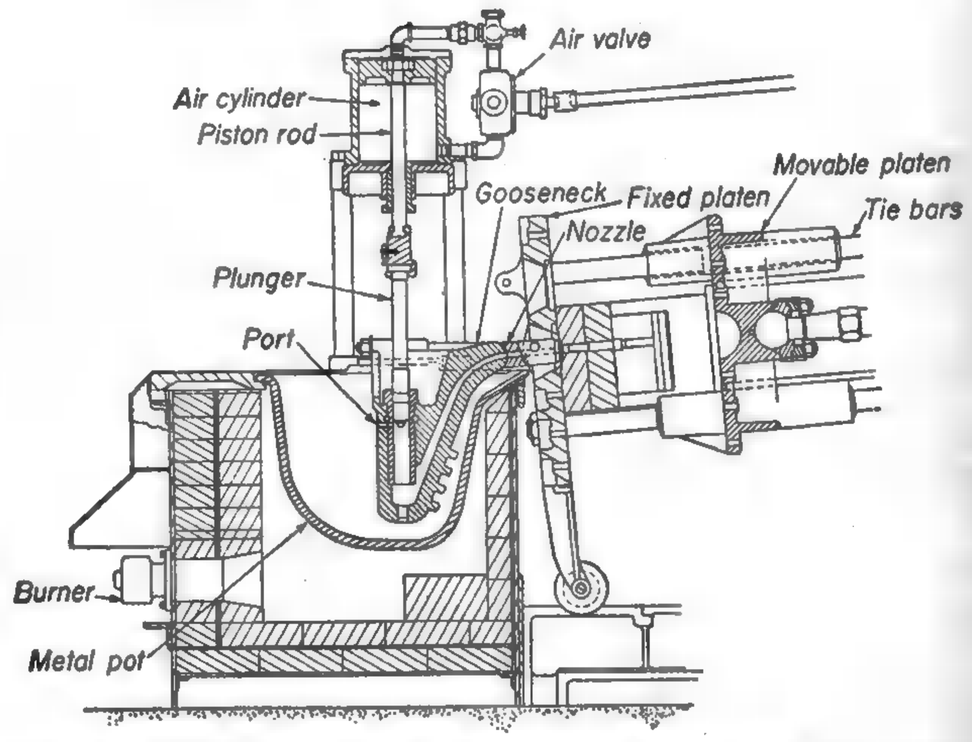

Fig. 2 Portion of a modern machine for die casting zinc alloy, showing a vertical plunger arranged for air operation

The zinc die-casting alloys can be cast in all three types of machines, but economical practice dictates the use of the plunger type.

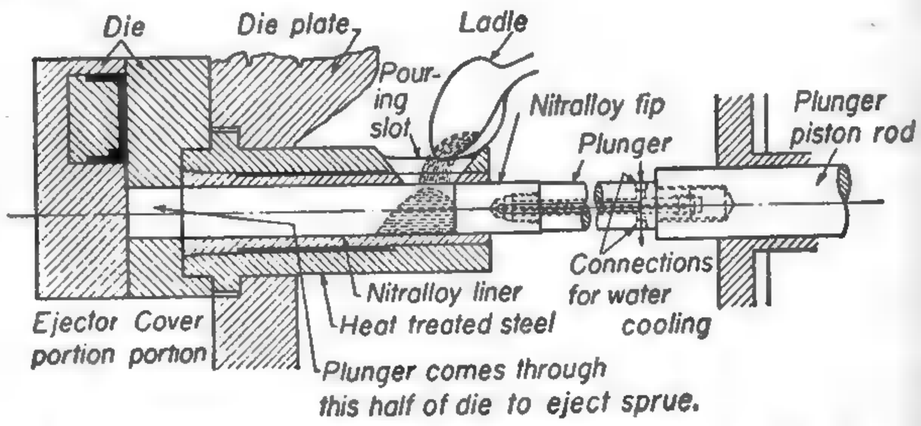

Fig. 3 Sectioned diagram showing the die, cold chamber, and horizontal plunger (in charging position) of a modern cold chamber type of die-casting machine

Alloys. The zinc alloys are low in cost of metal per casting, are easy to die cast, are cast at low temperatures,

*Development Engineering Division, Technical Department, The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

have strengths greater than all but the copper alloys, lend themselves to casting within close dimensional limits, permit the thinnest sections yet produced, and are machined at a minimum cost. Resistance to surface corrosion is adequate for a wide range of applications. Prolonged contact with moisture results in the formation of white corrosion products, but surface treatments can be applied that will prevent the formation of such products to a great extent. There are three standard zinc alloys for die casting. Specifications for these alloys have been adopted by the American Society for Testing Materials (Alloys XXI, XXIII and XXV) and by the Society of Automotive Engineers (Alloys 921, 903 and 925, respectively). *See* Table I. Only two of these alloys (ASTM XXIII and XXV or SAE 903 and 925) are in common use.

Table I
Designation and Composition of Zinc Die-Casting Alloys

	Designation		
ASTM Number	XXI	XXIII	XXV
Government Number	.....	QQ-Z-363	QQ-Z-363

Lead, maximum	0.007	0.007	0.007
Cadmium, maximum	0.005	0.005	0.005
Tin, maximum	0.005	0.005	0.005
Iron, maximum	0.100	0.100	0.100
Zinc (Special High Grade)	Remainder	Remainder	Remainder

ASTM Alloys XXIII and XXV are alike in chemical composition except that XXIII is free from copper while XXV contains 1% Cu. Both alloys are quite similar in properties and can be used interchangeably.

Alloying. The use of virgin metals is always desirable in the manufacture of the zinc die-casting alloys, in order to meet the prescribed limits of composition, although secondary materials are equally satisfactory if they are of uniform and suitable composition.

The equipment required for the manufacture of the zinc alloys consists of cast-iron melting pots, a small refractory pot for melting the copper-aluminum hardener, instruments for recording temperature, scales, pouring ladles, skimmers and molds. Three alloying pots are desirable so that virgin alloy can be held in one until it has been analyzed, while the next heat of alloy is being prepared in the second pot. The third pot is used exclusively for the remelting of sprues and rejected castings.

It is advisable to prepare alloys on a 24-hr basis, since this not only increases the hourly output of the plant but decreases the overhead and increases the life of both the refractory and the iron pots. The following is an ideal alloying practice for ASTM XXIII, assuming the use of a 2000-lb pot: For the first cycle, 500 lb of Special High Grade zinc is placed in the cast-iron pot. When the molten zinc reaches a temperature of about 500 C (932 F), 75¼ lb of ingot aluminum is stirred into the melt. After all the aluminum has dissolved, the remainder of the Special High Grade zinc charge (1259 lb) is added. When the temperature again reaches 475 C, the pot is skimmed and 3/4 lb Mg is added. The magnesium, having a specific gravity of only 1.74, must be held under the surface to prevent loss by oxidation. The melt should be stirred thoroughly after the magnesium is added; then the skimmings should be carefully removed again. The skimmings are iron-aluminum compounds of low density, together with some products of oxidation that will eventually rise to the surface. Inadequate skimming is responsible for the appearance of some surface defects, such as hard spots in the die castings. The use of a flux is not advised because it removes the magnesium from the alloy. After the alloy has been skimmed, it is ready for transfer to the pouring ladles. When the ladles are filled with about 50% of the alloy from the pot, they can be pushed aside and poured as soon as the second cycle of alloying has been started.

The second cycle of alloying is started by adding 37½ lb Al to the heel in the alloying pot. After the aluminum has dissolved, 877 lb of Special High Grade zinc is added. When the alloy reaches 475 C, the melt is thoroughly skimmed and 6 oz Mg is added. Again after thorough stirring and skimming, the melt is ready to be poured in preparation for the next alloying cycle.

The procedure for preparing ASTM XXV is identical with that described above for ASTM XXIII, except that all the alloying ingredients are added at one time, as a molten alloy hardener, to the heel in the alloying pot. The hardener—80% Al, 0.8% Mg, with the remainder copper—is melted and kept molten in a refractory crucible.

Die Casting. The temperature of the metal in the die-casting pot should never exceed 425 C, because coarse-grained castings of low shock resistance will result. The preferred range is 390 to 415 C, and many companies operate successfully within the still narrower limits of 390 to 405 C. Supplying liquid alloy to the die-casting machines eliminates a remelting cost, but it is more important that enough alloy can be supplied in this manner to keep die-casting machines operating uninterruptedly and with the metal temperature more closely controlled.

While there is a preferred range of temperatures for the dies used in producing die castings with the best surface finish, soundness and mechanical properties, few die casters use equipment to control the temperature accurately. Although such control is desirable in order to keep the number of rejected castings at a minimum, it is not an absolute requirement, because run marks appear on the castings when the die temperature is too low, and pits, blisters and similar surface blemishes develop at excessive die temperatures. A good range of temperatures for dies is 150 to 220 C.

Aside from the temperatures of metal and dies, the third major factor in the production of die castings is the pressure applied on the metal. The pressure should not be less than 1500 psi. Lower pressures will result in some porosity in the castings. Higher pressures are advantageous at times, but generally there is little to be gained by using pressures above 2500 psi. The velocity with which the metal enters the die is controlled by the pressure and the die design. The optimum velocity may differ for each casting and the only way it can be determined is by trial and error.

Inspection and Control. Inspection in the die-casting plant is usually confined to a visual examination of each casting for surface finish, disfiguring flaws and cracks; and to such gaging as may be needed to insure that the dimensions are within the required limits. Since there are no well-established standards for surface smoothness, the usual practice is for the die caster to submit sample castings which, if satisfactory, serve as reference standards for future shipments.

At present it is becoming general practice to analyze chemically each lot of alloy, to conduct some mechanical tests and to X-ray castings made in new dies until, by die changes, the porosity in critical sections has been climinated.

Important dimensions are usually checked and approved by the customer when the die is first put into service. Thereafter, dimensions are unlikely to change significantly unless some part of the die is subject to unusual wear or must be replaced.

Stabilization. Aging changes produce a maximum shrinkage of 0.0007 in. per in. for ASTM Alloy XXIII and 0.0009 in. per in. for ASTM Alloy XXV. About two thirds of the shrinkage occurs in 4 to 5 weeks; the remainder takes place over a period of years. Since these changes can be accelerated by annealing treatments at low temperatures, it is customary to use one of the following heat treatments when castings are required to maintain rigid dimension tolerances: (*a*) 3 to 6 hr at 100 C, (*b*) 5 to 10 hr at 85 C, (*c*) 10 to 20 hr at 70 C.

Castings given one of the above treatments will show an additional shrinkage, on aging, which is equal to about one third of that which occurs on untreated castings.

Assembly. All die castings have at least a light flash at the die parting, and those requiring movable cores will have some flash around the cores. Flash is also formed around ejector pins at the points at which they make

contact with the casting. The most common method of removing flash at the die parting is to force a shaving die over the casting. Flash in holes is usually removed by close-fitting punches. Other flash removal is effected generally by filing, grinding or using other cutting tools. Castings that are to be plated and must therefore be made unusually smooth often require grinding and polishing at the parting line, and sometimes on other surfaces.

Although it is often cheaper to cut threads than to cast them, in many pieces making a cast thread is more economical. Male threads are usually made with a parting parallel to the axis; this leaves a flash at the parting. The flash can be removed with a shaving tool in some instances, but in others it is necessary to perform a chasing operation.

Zinc die castings are invariably cast within quite close dimensional limits, but some machining is commonly required in addition to removal of flash, even though it may consist only of such simple operations as punching, drilling, reaming or tapping of holes. However, in general, only very light cuts are required, and the work can always be done at high speeds because of the excellent machining qualities of these alloys.

Zinc die castings can be soldered or welded, but ordinarily neither process is used except in special assembly applications or in repair work.

Soldered joints have low strength. Soldering with the usual soft solder is possible only on nickel-plated surfaces. A more satisfactory procedure is to use a soldering alloy of 82.5% Cd and 17.5% Zn, applied without a flux.

Flame welding is best done by means of a reducing flame and welding rods made from the same alloy as the die casting. Since zinc die castings have a low melting point, the flame must be held almost parallel to the casting.

In recent years, a pulsation welding technique has been developed to a point where it may be used in assembly work.

Finishing. Many of the finishes applied to other types of metal products can be applied also to die castings, although some differences in formulation are desirable, as well as occasional differences in the method of application. The types of finishes applicable to zinc die castings are as follows: (1) mechanical — buffing, polishing, brushing and tumbling; (2) electrodeposited — copper, nickel, chromium, brass, silver, and black nickel; (3) chemical — chromate, phosphate, molybdate, and black nickel; (4) organic — enamel, lacquer, paint, and varnish; (5) plastic.

Mechanical Finishes. Zinc die castings can be given mechanical finishes rather easily but, unless the surface is protected, tarnishing will occur more quickly and be more noticeable than on untreated parts. For this reason, mechanical finishes are seldom used on zinc die castings, except as a preparatory step for other types of finishes.

Electrodeposited Coatings. While virtually all metals capable of electrodeposition can be applied to zinc die castings, coatings of nickel, or of copper and nickel, finished with a thin layer of chromium, are used on a very large scale. Plated coatings are most commonly applied for decorative purposes, but they also improve resistance to corrosion and to abrasion. For increasing such resistance, direct chromium deposits are generally applied, 0.0002 in. or more in thickness. All plated coatings are somewhat porous, and when moisture penetrates through the pores, some corrosion of the base metal usually results. If the plated coatings are too thin, this corrosion will destroy the appearance in a short time; therefore the satisfaction and useful life to be expected from such coatings depends on the thickness of the deposit and the method of application. The American Society for Testing Materials has adopted specifications covering three classes of commercial coatings for zinc die-casting alloys; namely, for mild, ordinary, and severe exposures.

Chemical Treatments. Although chemical treatments sometimes take the place of other applied finishes, they are more often applied as a base for enamels and lacquers. Certain treatments are used alone as a means for inhibiting corrosion.

Organic Finishes. A great many organic finishes are available, each offering some particular advantage, such as color, hardness, gloss, adhesion and weathering. Since improvements in formulation are constantly being made, it is best to select a finish for a particular purpose by consultation with an experienced manufacturer of finishes.

Most modern finishes are baked for greater durability and adhesion. When finishes are baked on zinc alloy die castings, the properties of the castings may be adversely affected, if the castings are heated for more than 1/2 hr at 220 C; 1 hr at 190 C; 2 hr at 165 C; or 3 hr at 150 C. If the casting is copper-nickel-chromium-plated and then given a baked finish, the maximum temperature that can be used without blistering is 125 C.

Plastic Finishes. Some die castings, especially hardware for the interior of automobiles, radio grilles and instrument panels, have been used in large quantities with plastic finishes. Such finishes are often applied by repeated dipping into nitrocellulose or ethyl cellulose solutions, or by spraying with either type of solution. These finishes are several times as thick as other organic coatings and differ from similar base lacquers not only in thickness but in composition. Another type of finish is an injection molding of cellulose-acetate or acetate-butyrate plastics over a die-cast core. This gives the appearance of plastic molding but is combined with the strength of the die-cast core.

Application. Zinc die castings are used chiefly in the following applications:

Automotive Industry. The automotive industry uses by far the largest number of die castings. Some of the most important die castings for mechanical parts made of zinc alloy include the carbureter, bodies for fuel pumps, parts for windshield wipers, speedometer frames, horns, heaters, and parts for hydraulic brakes. Parts that perform both structural and decorative functions include grilles for radiators and radios, lamp and instrument bezels, hubs for steering-wheels, brackets, horn rings, exterior and interior hardware, instrument panels and body molding.

Electrical Industry. In the electrical industry, there is probably a larger diversity of die castings than in the automotive industry, because of the range of different products manufactured. Die castings are employed for numerous parts of washing machines, oil burners, stokers, motor housings, vacuum cleaners, electric clocks, kitchen equipment and utensils.

Business Machines and Other Light Machines. Die castings are used successfully in business machines and light machines of all types; for example, in typewriters, recording machines, picture projectors, vending machines, accounting machines, cash registers, cameras, slicing machines, garbage disposers, gasoline pumps, hoists and drink mixers.

Tools. Increasing quantities of tools are being made with die-cast parts. The die castings are not hard enough to serve as cutters, but steel elements are often cast in place as parts of the tools, thus saving appreciable assembly costs. Die castings are not limited to portable tools but are also used on such large equipment as drill presses and lathes.

Building Hardware, Padlocks, Toys and Novelties. These items constitute the other major uses of die castings. They consume about 10 to 20% of the total production of die castings made of zinc alloy.

Corrosion Resistance. The resistance of zinc die castings to atmospheric corrosion is similar to that of rolled zinc and galvanized iron.

In applications where die castings are used in recirculated water lines, the addition of 0.1 to 0.3% of sodium dichromate or of 1% of borax to the water greatly reduces the corrosion rate of the die castings. In general, the attack of water on zinc castings reaches a minimum under mildly alkaline conditions.

The use of zinc die castings in continuous contact with steam is not recommended; but with hot water, as in plumbing hardware, their use is satisfactory, if inserts are used on critical parts in contact with the water.

The corrosion of zinc die castings, as a result of contact with various other liquids, gases or solids, does not follow any general rules, and individual service trials are usually necessary.

Engineering Design. Engineering design involves two problems, namely, the design of the die and the design of the castings. Since the manufacturer of the castings is responsible for the design of the die and also should be consulted on the design of the casting, the following discussion of this subject is intended merely to list some of the necessary considerations rather than to explain them.

Die Design. In die design, after the parting line and the general die construction have been planned, it is highly important to gate and vent the casting cavity properly. The gates and vents, as thick as can be tolerated, must be placed at their proper positions. In addition, large overflow wells should be connected to the cavity at the vent end of the die and at other points where there is a likelihood of trapping air. Since the loss of metal is small during the remelting of overflow wells, the cost of such wells is small, considering the improved quality. In most instances a saving actually results, because overflow wells accomplish a vast reduction in the percentage of rejected castings. Gates, vents, and overflow wells, considered collectively, have more influence than any other factor in the production of uniform high strength, good surface finish and soundness in die castings.

Design of Die Castings. The rules for designing die castings have many exceptions, but the following principles generally assist in arriving at a design that is both rational and helpful in attaining low cost: (1) Keep sections at a minimum thickness and use ribs for strengthening purposes where necessary. Make a gradual transition when section thicknesses vary. Use cores to keep sections uniform and fillets to avoid sharp corners. (2) Cast studs or bosses for economical fastening aids. Bosses are stronger than threaded studs. (3) Avoid plain flat surfaces when such areas must be cast smooth for finishing purposes. (4) Allow ample drafts on cavity walls and on cores, and never specify closer tolerances than are essential. (5) Employ inserts whenever their use attains results that cannot be realized at equal cost by other means. (6) Take advantage of the ductility of zinc alloys by designing parts for bending or forming after casting.

In designing zinc alloy die castings to withstand constant loads, it must be borne in mind that these alloys do not have recognized elastic moduli or yield strengths. Hence, standard engineering formulas used in calculating cross sections of elastic materials cannot be used for zinc alloys. However, data developed from creep tests have been compiled and may be applied with satisfactory results. See "Creep Data on Die-Cast Zinc Alloy", Trans AIME, **161**, 466 (1945).

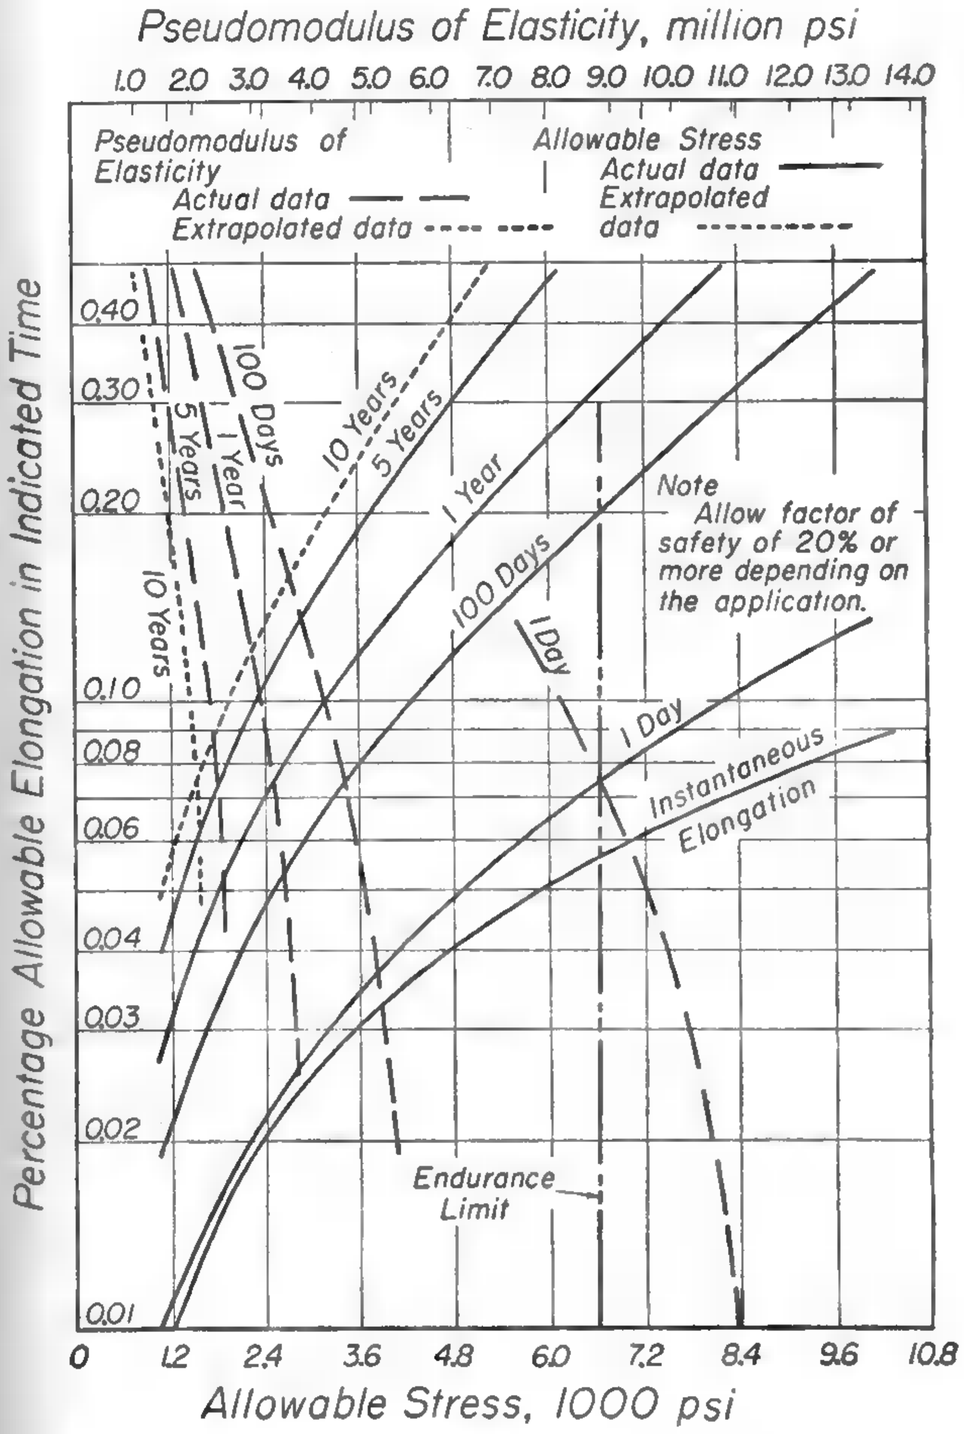

Fig. 4 Transverse creep characteristics of alloys XXIII and XXV at 25 C

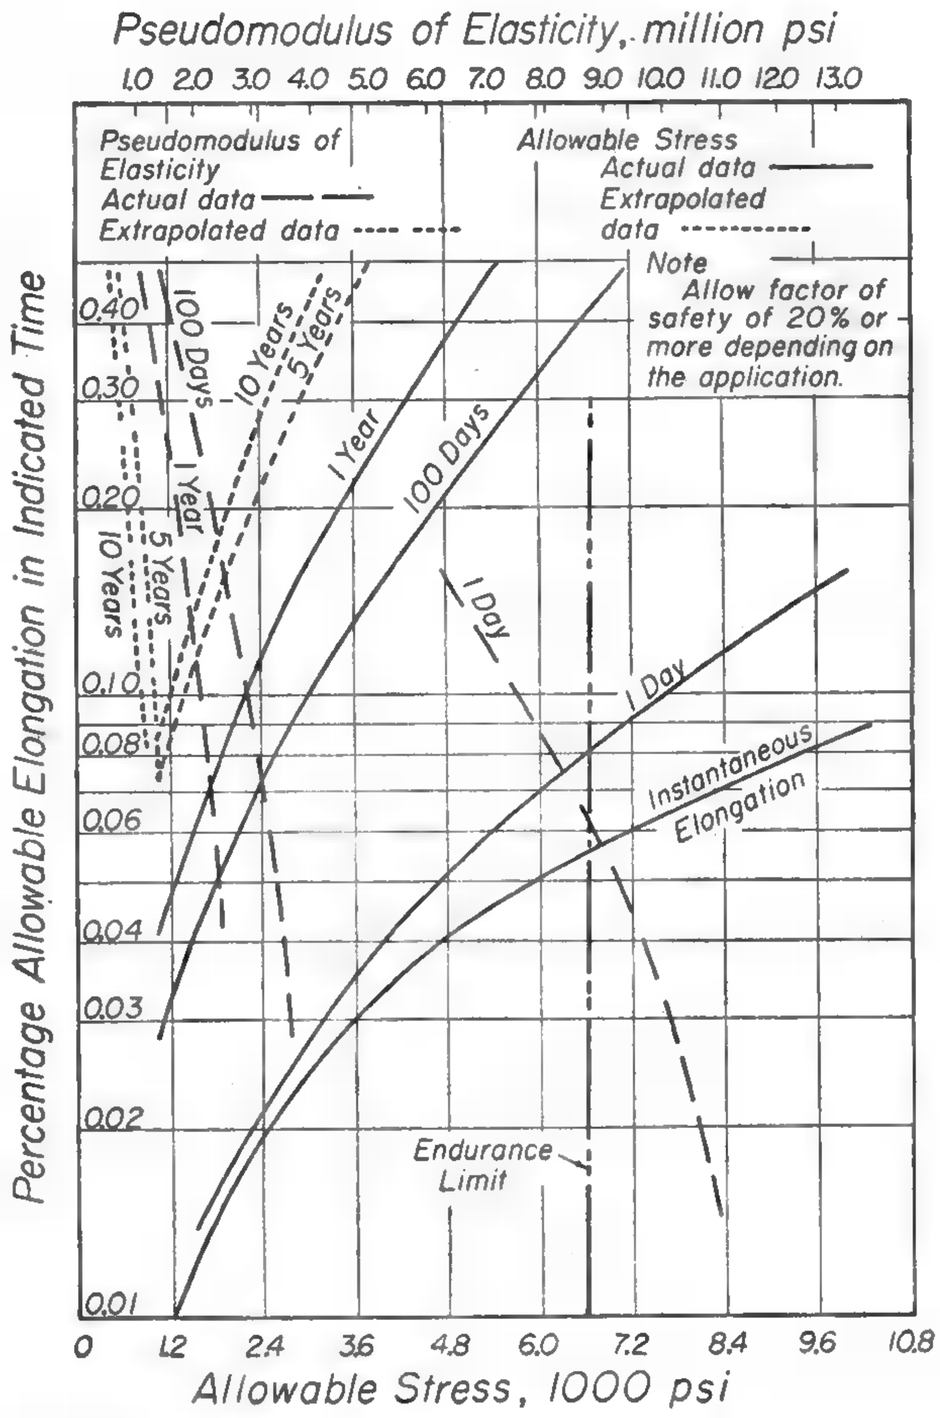

Fig. 5 Tension creep characteristics of alloys XXIII and XXV at 25 C

The creep characteristics of zinc die-casting alloys subjected to constant transverse loads may be calculated from the graph shown in Fig. 4. The method of using this graph follows. Determine the percentage of elongation that is permissible in the particular beam member in some definite period of time — for instance, 5 years.

In applications involving beams, the following approximate formulas have been found useful in determining the relations between the deflection and the elongation in the outer fiber of such members:

(1) For cantilever beams $e = \frac{150dt}{L^2}$

(2) For simple beams (concentrated load) $e = \frac{600dt}{L^2}$

where e = percentage of elongation in outer fiber of the beam
d = deflection of the beam, inches
t = thickness of the beam, inches
L = length of the beam, inches

Find this percentage of elongation on the ordinate and move across the chart horizontally until the chosen time curve is intercepted. From this point, move vertically down to the abscissa, which will indicate the permissible stress. For ordinary applications, a factor of safety of 20% is usually applied. Thus, if the permissible stress for the particular application is 2500 lb, the cross section would be designed to yield a stress of not more than 2000 lb.

The graph also shows curves of pseudomodulus. These are not true elastic moduli but the instantaneous moduli calculated from the stress-strain curves of Fig. 4 at any particular time. These values have been found useful in engineering calculations. They may be employed in standard engineering formulas instead of the true modulus, provided it is understood that the value applies only for one particular load and one particular time at the temperature specified.

Figure 4 contains a curve labeled "instantaneous elongation". This is simply the stretch that takes place immediately upon application of the load and is similar to "initial stretch" or "initial elongation", terms applied by other investigators. In this instance, the elongation is largely elastic and hence recoverable by unloading. Curves labeled "1 day", "100 days" and so on, include this "instantaneous elongation"; hence they show total deformation, part of which is elastic.

In the graph, the vertical line indicating the endurance limit is at 6600 psi. Thus, if the particular application involves cyclic loading, a working stress of 6600 psi should not be exceeded.

Zinc and zinc alloys are influenced in their creep properties by temperature. The degree of this effect may be estimated approximately by the following empirical formula derived from temperature studies:

$$S_T = \frac{(S_{25} \times 28)}{T}$$

where S_T = permissible stress at any temperature from 25 to 100 C
S_{25} = permissible stress at 25 C
T = given temperature in °C

Thus, it will be seen that for an increase of 31°C in temperature above 25 C, the permissible stress is reduced by about half. It may be noted that zinc alloy die castings are not suggested for uses involving continuous stress at temperatures above 100 C.

The chart in Fig. 4 deals only with deformation in bending. Similar data for tension stresses are shown in Fig. 5.

Gravity Casting

Stamping Dies, Uses, Alloys. Sand-cast stamping dies made from wooden or plaster patterns, for drop-hammer forming, are used in the fabrication of aluminum, magnesium, zinc, stainless steel and other sheet materials.

Unalloyed zinc was first used but later zinc alloys were found to be superior. The alloys with the greatest hardness and strength are the best.

ASTM Alloys XXI and XXV are the alloys used for drop-hammer work, and they produce from 10 to 50 times as many stampings as were obtained from unalloyed zinc.

Since many of these dies are now being stored for the manufacture of replacement parts, ASTM Alloy XXV with its greater dimensional stability may prove to be a more desirable alloy than XXI, even though slightly fewer stampings can be made before failure.

Slush and Permanent Mold Casting. The slush casting of zinc alloys is discussed in the article on page 741 in this Handbook. The same alloys are used for casting in permanent molds, and the process is similar to slush casting except that the mold is not inverted after filling, and hence the castings are solid instead of hollow.

Working of Zinc and Zinc Alloys

By E. H. Kelton*

WROUGHT zinc and zinc alloys may be obtained in the form of rolled strip and sheet, extruded rod and shapes, and drawn rod and wire. These metals have desirable resistance to corrosion for many types of service, and since the corrosion products that may form are white, other materials are not stained by them. Wrought zinc has chemical characteristics particularly adapted to certain uses, as in dry batteries and photoengraver's plate, and offers combinations of desirable physical and mechanical properties at relatively low cost. However, the wrought zincs have the characteristic of flowing under constant loads that are substantially less than the ultimate strengths; that is, wrought zincs do not have clearly defined elastic moduli, and hence creep data developed from service tests must be used in designing for strength and rigidity under conditions of continuous stress.

Virtually all commercial wrought zinc contains small amounts of natural impurities—mainly lead, iron and cadmium (*see* "The Zinc Industry", page 1077); commercial alloys may also contain additions of copper or aluminum, and sometimes smaller amounts of other elements.

Melting. When zinc is to be prepared in large quantities, it is usually melted in refractory-lined reverberatory furnaces heated with coal, gas or oil. Small quantities may be melted to advantage in low-frequency induction furnaces or in refractory crucibles. Melts should be held generally at 930 F or less to prevent loss by oxidation. No protective cover is required. Sal ammoniac is used frequently to reduce skimmings when scrap is being remelted.

Zinc alloys containing 0.5% Al or more may be melted in iron pots, since the aluminum content prevents rapid attack of the iron by molten zinc.

*Development Engineering Division, Technical Department, The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

Casting. Zinc is cast from bath temperatures that range between 840 and 930 F, depending on whether the metal is transferred directly from the melting pot to the mold or is transferred by means of an intermediate ladle. Zinc is usually cast into flat slabs, 1 to 4 in. thick and of convenient widths and lengths for rolling, or it is cast into billets of the size required for extrusion. Slab molds are generally of the open, book or tilting types made of cast iron. The molds should be kept smooth and clean to avoid cracking from hot shortness as a result of restricting the shrinkage. No dressing is needed for the mold. The temperature of the mold should be about 200 F when the metal is cast. Molten zinc must be poured smoothly to prevent inclusions of oxide film and, in open molds, the surface should be skimmed immediately after casting.

Rolling. Rolling-mill slabs should be preheated to about 400 F. Roughing should be started with a leveling pass of about 10%; after that, reductions may be increased according to the capacity of the mill. Slabs intended for strip are reduced by rolling longitudinally to a gage convenient for coiling—generally less than 1/10 in. In the production of sheet, slabs are rolled laterally until the desired width is obtained. Then the sheets are turned 90 deg and rolling is continued until a thickness is obtained that is two to four times the final gage. The temperature of the roughing rolls may vary from 150 F to about 300 F, depending on the continuity of rolling and whether or not a water stream is used to control the contour of the roll. A lubricant, such as machine oil or tallow, is applied during roughing.

Finish rolling of zinc strip varies widely, depending on the ultimate product desired. Strip is produced in widths as great as 20 in. and in thicknesses as small as 0.004 in. in regular mills. Foil 0.001 in. thick or less is produced in

special mills. For a bright surface combined with high ductility, finish rolling is performed hot; this requires that the rolls be held at temperatures ranging from approximately 250 to 300 F. Finish rolling may be started with either hot or cold coils, and finishing pass reductions will vary from 10 to 40%, depending on the structure desired and the particular flatness and gage required in the finished product.

Zinc sheet is produced by the pack-rolling method, in which as many as 30 rough rolled sheets are stacked together and rolled simultaneously. Packs must be "split" frequently, interchanging inner and outer sheets to equalize temperatures and reductions. In this type of rolling, reductions are light on each individual sheet and the temperature is low, so a cold worked product is obtained.

In finish rolling, a thin lubricant is used—ordinarily an oil that will not corrode zinc and will not oxidize readily itself. Machine oil and various types of vegetable oils are satisfactory.

Extrusion. Although it lacks a well-defined elastic modulus at low rates of deformation, zinc has a high apparent modulus under rapid deformation; consequently, extrusion pressures are higher than in most nonferrous materials. Ease of extrusion increases with temperature; hence billets for extrusion are usually heated to the maximum that will not cause hot shortness. This temperature will vary from 480 F to more than 570 F, depending on the composition. Speeds for extrusion of zinc are low compared with those for the brasses, because as the speed of extrusion increases, the temperature in the product rapidly increases to the point of hot shortness and cracking and crumbling may result. Because of the high temperature of extrusion, the ordinary zincs yield coarse, columnar structures and must be worked at lower temperatures to refine the grain size and to yield an ultimate product of good ductility. In the alloys containing about 4% Al and 0.04% Mg with or without copper, this grain-refining treatment is not necessary, since high temperatures do not result in the coarse structures described.

Drawing Rod and Wire. Rolled or extruded rod may be drawn to wire in operations quite similar to those used for other nonferrous metals. In the pure commercial grades of zinc or in the alloys similar in composition to the die-casting alloys, drawing operations can be carried out without intermediate annealing, but in the less pure commercial grades of zinc or in the alloys containing copper, intermediate anneals are desirable.

Fabrication. All severe fabricating operations on wrought zinc should be carried out at temperatures above 70 F. Warm, soapy water (made with a neutral soap to avoid staining) is the cheapest lubricant available and is as satisfactory as any.

The rolled zincs of the proper grade are readily drawn into a great variety of articles such as battery cups, eyelets, meter cases, novelties, flashlight reflectors and fruit-jar caps. Suitable grades of zinc are just as readily rolled or press-formed, stamped or spun, into items such as plates for addressing machines, buckles, ferrules, ornaments, nameplates, gaskets, weatherstripping or parts for lamps.

The 4% Al, 0.04% Mg alloy that contains as much as 3.5% Cu has been used widely in the aircraft industry, in the form of heavy rolled plate for dies employed in blanking aluminum alloy sheet and thin steel. Similar compositions are available as extruded rod, tubing and moldings.

The softer grades of wrought zinc are self-annealing at temperatures developed during fabricating; hence no annealing is required between operations. The harder grades work-harden somewhat and may require intermediate annealing. Temperatures slightly above 212 F are ordinarily sufficient for the usual commercial grades, and care must be taken not to raise the temperature much above the minimum required or to leave the article exposed to the annealing temperature for more than a few minutes; otherwise, coarse brittle structures will develop. In the 1% Cu alloys, annealing should be conducted between 350 and 400 F.

Classification. The classifications of wrought zinc used in Table I are arbitrary. The compositions shown are typical ones covering the range and do not necessarily include every variation found among the grades produced by the various companies. To accommodate special applications many producers supply special grades that are intermediate or perhaps quite different from those listed.

Mechanical Properties. It will be noted that among the specific uses listed for rolled zinc, few would ever require high strength under constant load. When zinc is employed for structural purposes, creep data developed from service tests must be applied in the design, and properties such as tensile strength and tensile elongation, ordinarily used in connection with structural materials, have little significance. The control tests—dynamic ductility, hardness, temper, and dynamic bend—permit comparison with other shipments of similar material and identify in a general way the type and the rolling treatment of samples of unknown history.

Table I. Classification of Wrought Zinc Alloys

Composition, percentage							Characteristics	Typical Uses
Pb	Fe	Cd	Cu	Mg	Al	Sn		
0.05 to 0.10	0.012 max	0.005 max	0.001 max	....	....	....	High ductility with low hardness and stiffness. Very little work-hardening possible.	Drawn battery cans, eyelets, fuse links, and a variety of articles drawn, formed and spun. Address plates, anodes for protection of underground pipe lines.
0.05 to 0.10	0.012 max	0.06	0.005 max	....	....	....	High ductility with low hardness. Can be work-hardened slightly.	Drawn battery cans, eyelets and grommets. Extruded battery cans. Address plates, laundry tags.
0.15 to 0.35	0.017 max	0.15 to 0.30	0.005 max	....	....	....	High hardness and stiffness. Uniform etching quality. Can be work-hardened.	Soldered battery cans, photoengraver's plate, lithographer's sheet, boiler and ship plates, weatherstrips.
0.05 to 0.10	0.012 max	0.005 max	0.85 to 1.25	....	....	....	High hardness and stiffness. Good ductility. Good creep resistance. Work-hardens easily.	Weatherstrips and drawn and formed articles requiring stiffness.
0.05 to 0.10	0.015 max	0.005 max	0.85 to 1.25	0.007 to 0.02	....	....	Maximum hardness, stiffness and creep resistance. Can be severely work-hardened.	Corrugated roofing. Flat or formed articles requiring maximum stiffness and strength.
0.15 to 0.35	0.014 to 0.025	0.15 to 0.30	0.005 max	0.005 to 0.025	....	....	High hardness. Can be baked without serious softening. Good etching characteristics.	Photoengraver's sheet
....	....	....	....	□ to 0.025	0.25 to 0.60	....	High hardness. Can be baked without serious softening. Good etching characteristics.	Photoengraver's sheet
0.007 max	0.10 max	0.007 max	0 to 3.5	0.02 to 0.10	3.5 to 4.5	0.005 max	High strength and hardness.	Shearing and forming dies. Extruded rod, tubing and molding.

Soldering and Welding. The ordinary grades of wrought zinc can be soldered easily by conventional methods. The usual precautions should be observed, regarding proper cleaning and fluxing, and care must be taken not to overheat the zinc to a point where it will melt. For information about the soldering of zinc alloys that contain aluminum, see "Casting and Production of Zinc Alloys", page 1078.

Pulsation welding technique may be used for joining zinc. Flame welding of zinc is an art and therefore is not used in production.

Machining. Wrought zinc is easily machined by standard methods and tools. However, if it should be necessary to machine zinc containing exceedingly coarse grains, the metal would require heating to the range between 160 and 210 F, in order to avoid cleavage of crystals.

Finishing. In general, the same methods are used for finishing wrought zinc and zinc alloys as are used for finishing zinc-base die castings. See "Casting and Production of Zinc Alloys", on page 1078. However, in bake-enameling, greater caution should be employed not to reach temperatures high enough to impair the mechanical properties. For this reason air-dried finishes are preferable.

The Use of Zinc for Cathodic Protection

By H. W. Wahlquist* and E. A. Anderson*

UNDER certain conditions zinc plates (anodes) are used for the cathodic protection of steel from corrosion in water or soil. The structures most frequently protected in this manner are underground pipe lines, hulls of ships, and boilers.

Underground Structures

Buried zinc anodes are being used increasingly for the cathodic protection of underground pipe lines from corrosion. The open-circuit or solution potential of zinc in ordinary soil is about minus 1.1 v measured to a copper sulfate half-cell electrode, which compares with a potential in the order of minus 0.6 v for the average unpolarized steel pipe line. The difference, or 0.5 v, is the driving voltage initially available to cause a flow of current when the two structures are tied together by a wire; this difference decreases to between 0.1 and 0.3 v when the pipe is polarized. The current discharges from the zinc anode to the soil, collects on the pipe line and returns to the anode through the connecting wire. The current discharged by the zinc into the soil corrodes the zinc, and the current collected by the pipe line prevents corrosion of the pipe. The action is similar to that which occurs in a short-circuited primary cell or battery where the current flows from the zinc anode through the electrolyte to the carbon cathode. In the circuit of cathodic protection the zinc is the anode, the pipe is the cathode, and the soil with dissolved salts is the electrolyte. The magnitude of the current from a given anode is governed chiefly by the resistivity of the soil and the polarizing characteristics of the pipe line, although factors such as the spacing and size of the anodes also influence the current.

Size of Anodes. Zinc anodes are used in various forms, such as bars, plates, rods and hollow cylinders. A commonly used plate is made of rolled zinc ½ in. thick, 3 in. wide, 3 to 5 ft long, and weighing 14 to 23 lb. Cast zinc rods 1⅜ in. in diam and 4 ft long, weighing 18 lb and equipped with a ¼-in. steel core, have been used extensively.

Backfill. In most soils it is necessary to provide a special backfill for the zinc anodes to prevent them from becoming passive. The condition of passivity may result from voltage polarization of the anode or from the formation of a corrosion product that has high resistance, frequently in the form of an impervious carbonate film. The tendency toward voltage polarization is increased by the presence of impurities in the zinc. Surrounding the anodes with a slurry of powdered gypsum and clay has been found effective in preventing anodes of high purity from becoming passive.

Output. The theoretical output of a zinc anode is 370 amp-hr per lb of metal consumed. The current efficiency of 99.9% pure Zn in a gypsum-clay backfill is about 90%, so an output of about 330 amp-hr per lb is realized in practice with that grade of zinc. This corresponds to a life of about 17 years for a 14-lb anode delivering a current of 30 milliamperes (Fig. 1).

*Ebasco Services, Incorporated, New York
* Research Division, Technical Department, The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

The section on Underground Structures was prepared by H. W. Wahlquist; the sections on Hull Plates and Boiler Plates, by E. A. Anderson.

Methods of Installation. *Uncoated or Bare Lines.* The methods of installation vary with the conditions and type of structure to be protected. In a long, electrically continuous pipe line without coating, usually referred to as a "bare line", anodes are distributed along the line in such a way that the potential of the soil surrounding the line will be raised and will result in fairly uniform collection of current. This method may be used in soils of either high or low resistance. Spacings of 10 ft between anodes and 5 ft between the anodes and the pipe are commonly used. For large pipes (more than 12 in. in diam) it is necessary in some soils to reduce the anode spacing to 5 ft in order to provide protection. The anodes are usually installed vertically in hand-augered holes 3 to 4 in. in diam and 6 to 8 ft deep. They are connected by a rubber-covered copper wire located in a trench about 18 in. deep; at intervals of 100 ft, connections are made from this wire to the pipe.

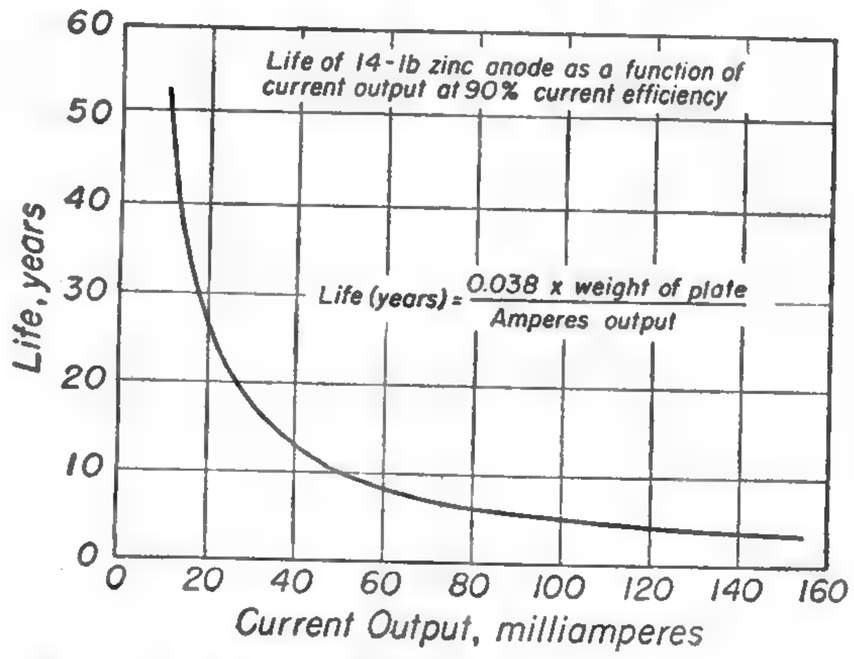

Fig. 1 Life of a 14-lb zinc anode as a function of current output at 90% current efficiency

Occasionally, where soil resistance is low, sufficient output of current is obtained to permit the installation of groups of anodes 10 ft or more from the line at intervals of 200 to 300 ft.

In other instances, corrosion may be confined chiefly to a few so-called "hot spots" or limited areas where corrosive soil exists, and the zinc requirements may be reduced by installing anodes in the corrosive areas only.

Coated Lines. For lines provided with a protective covering (coated lines), the current requirements are greatly reduced in comparison with those for bare lines, and the problem of cathodic protection is simplified. To realize the full advantages of the coating, however, it is essential to insulate the line to be protected from other underground structures that are metallically connected with the protected line. This is accomplished by using flanges, couplings or bushings of the insulating type. In this kind of installation, the zinc is usually installed in groups of 10 to 20 anodes. Where soil conditions are favorable, the holes may be drilled to a depth of 20 ft, with a stack of several anodes in each hole. The spacing between the groups may range

from a few hundred feet to several thousand feet, depending chiefly on the type and condition of the coating. The spacing to the pipe line is not significant for coated lines. It is usually advantageous to locate the groups at points where the soil is low in resistivity. Cathodic protection is obtained on these coated lines when the potential of the structure is increased to minus 0.85 v to a copper sulfate electrode.

Hull Plates

For many years zinc plates have been used to a considerable extent for the cathodic protection of the steel hulls of ships. The problem here is complicated by the presence of the bronze propeller, which is electropositive to the hull. In the absence of zinc hull plates, the steel acts as an anode to provide cathodic protection to the propeller, with the result that the normal corrosion of the steel is stimulated.

Zinc anodes, properly placed along the stern of the ship, provide the necessary cathodic protection. Depending on the current density which the potential differences can maintain against the resistances of the water and of the film produced by the corrosion of zinc, the propeller will be polarized to the potential of the hull or both the propeller and the hull will be polarized to the potential of the zinc.

If the propeller is polarized to the potential of the hull, the acceleration of the corrosion of the hull is eliminated and the steel corrodes at its normal rate. If both the propeller and the hull are polarized to the potential of the zinc, neither the propeller nor the hull will corrode. In spite of the widespread use of zinc hull plates, no data from actual installations have been published concerning measurements of polarization or performance in service.

Size of Anodes. Rolled zinc hull plates are usually supplied in thicknesses from ½ to 1 in., in widths of 12, 24, 36 or 48 in. and in lengths of 24, 36 or 48 in. Suitable holes are provided for fastening purposes. Rolled zinc weighs 0.258 lb per cu in.

Methods of Installation. In practice, plates are fastened to the rudder, to the rudder post, to the struts bearing the propeller and to the hull itself in the region around the propeller. The plates are normally insulated from direct metallic contact with the hull; the electrical circuit is completed through the fastening bolts, set in countersunk holes in the plates. These holes are later filled with insulating material to prevent local attack.

Boiler Plates

Zinc plates have been used for many years in the protection of steel boilers. The results have been satisfactory, but there is some doubt as to whether the mechanism of protection is that of cathodic polarization or something else. It has been suggested by some that the zinc acts primarily to remove the oxygen from the water, thus preventing the corrosion of the steel. Since it is known that the normal flow of current between zinc and iron reverses direction in hot water under certain conditions of experiment or service, there is some basis for the doubts as to whether the protection is really that of cathodic polarization.

Size of Anodes. Zinc boiler plates are furnished in many sizes. The most common are ½ by 6 by 12 in., 1 by 6 by 12 in., and 1 by 6 by 6 in. They are usually made from rolled metal.

Methods of Installation. Three general methods are followed for placing the plates in the boiler: (1) the plates may be placed loosely in a metal basket connected electrically with the boiler, (2) they may be hung in the boiler on hooks which make electrical contact with the steel, or (3) they may be bolted directly to the boiler.

The Metallography of Zinc and Zinc Alloys

By S. Robert Dunbar*

As with other metals, proper selection of a metallographic specimen and due care in the polishing and etching of it are necessary prerequisites to a correct interpretation of the microstructure of zinc and zinc alloys.

Polishing. Experiment has shown that while cast zinc is being polished, distortion may occur to a depth 20 to 100 times as great as the deepest scratch. Accordingly, each step of polishing should remove considerably more metal than that required for eliminating the scratches from the previous operation. Fine-grained and alloyed zincs are easier to prepare in a condition free from distortion than coarse-grained, soft zinc.

A belt sanding machine is suitable for the grinding stage, using four grades of belts—"No-lap" No. 30, 60, 120 and 240. Unavoidable local heating that results from grinding must be restricted as nearly as possible to the surface by frequent cooling of the specimen in water; otherwise heat may cause changes in the structure to a depth greater than that removed in subsequent stages of polishing.

The specimen may be hand polished on a series of three polishing papers backed by a flat surface, such as a glass plate. "Speed-wet" No. 280, 320 and 400 are satisfactory.

Methods have been described[1] for preparing specially graded wet-polishing abrasives. Commercial abrasive (alumina) dispersed in water with a peptizing agent* in a ball mill is transferred to a beaker. Portions of the supernatant suspension are drawn off at stated intervals so that particles in suspension for the respective wheels have the following maximum settling rates: No. 1 wheel, 1 in. in 20 sec; No. 2 wheel, 1 in. in 3 min; No. 3 wheel, 1 in. in 30 min; and No. 4 wheel, 1 in. in 4 hr.

The first two polishing wheels may be covered with white duck. The third wheel may be covered with a soft white felt known as "glass-polishing felt". "Gamal" polishing cloth is excellent for the fourth wheel.

The operator's hands and nails, as well as the specimen, should be washed with soap and water between wheels to avoid carry-over of the coarser grit.

Time can be saved during wet polishing by etching away some of the distorted metal between mechanical operations. The following procedure produces a surface relatively free from distortion:

Etch for 3½ min after final hand polishing
Etch for 1½ min after No. 1 wheel
Etch for 30 sec after No. 2 wheel
Etch for 10 sec after No. 3 wheel

Etching solution No. 1, in the list below, should be used. Repeated etching and polishing on the first wheel is advisable. More complete freedom from distorted structures will result. This intermediate etching procedure frequently fails to give satisfactory results where particles of another phase are present, having etching characteristics different from those of the zinc matrix.

After the polishing on the fourth wheel, the specimen may be etched for microscopic examination.

Mounting Specimens. Rolled metal is usually polished on an edge parallel to the rolling direction. A number of specimens may be mounted together conveniently in a screw clamp with thin spacers of soft zinc between the specimens and heavy strips of zinc outside the assembly. The assembly is tightly clamped to prevent seepage of etching reagents between adjacent specimens. The zinc spacers, of known structure, serve as a convenient standard of comparison for determining whether or not the specimens have been properly prepared. Most specimens other than rolled metal can be mounted in molded plastic.

*Research Division, Technical Department, The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

* An agent called "Darvan" used in the rubber trade.

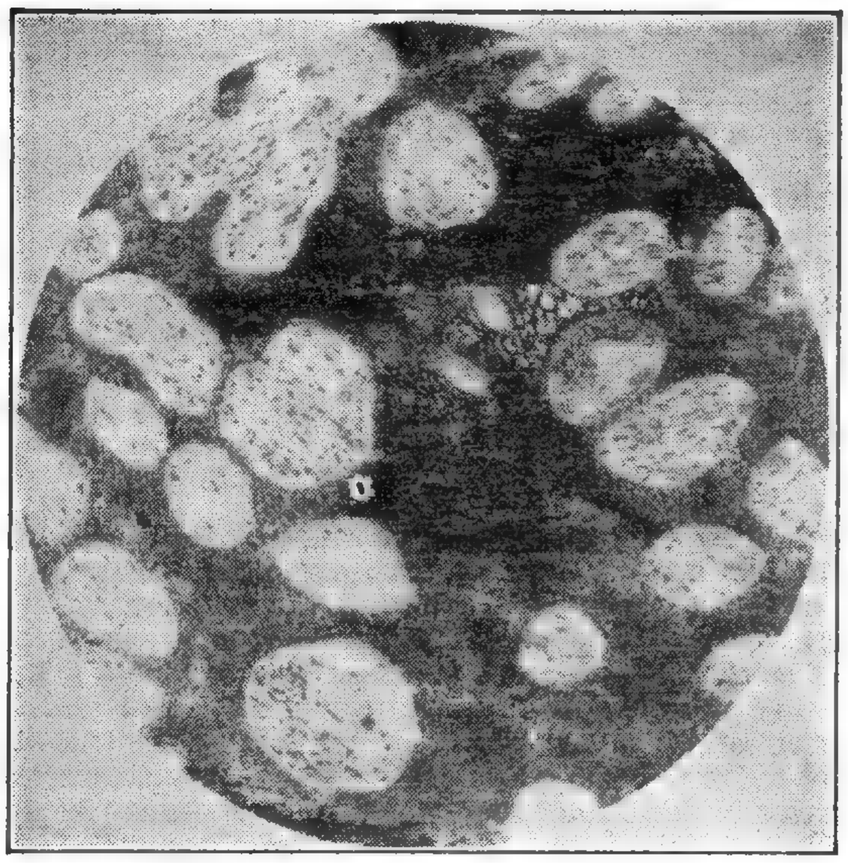

Fig. 1 ASTM alloy XXIII etched with solution No. 2 (× 1000)

Etching. The most useful etching reagent for zinc materials is pure chromic anhydride, CrO_3, to which pure sodium sulfate has been added. The grades of chromic acid used for chromium plating have been found satisfactory. The following solutions are commonly used:

Solution No. 1
200 g pure CrO_3
15 g Na_2SO_4
or 34 g $Na_2SO_4.10H_2O$
1000 ml water

*Solution No. 2**
50 g pure CrO_3
4 g Na_2SO_4
1000 ml water

Solution No. 3
200 g pure CrO_3
7.5 g Na_2SO_4
1000 ml water

Solution No. 4
200 g pure CrO_3
1000 ml water

Etching should follow soon after final polishing. The tip of the finger dipped in alcohol and rubbed over the surface of the specimen will remove any loose abrasive. The specimen should be cleaned by dipping successively in alcohol, ether, alcohol again and then in a strong stream of water. Any excess of water should be shaken off and the wet specimen should be etched. To avoid staining, the use of solution No. 1, 2 or 3 should be followed immediately by a rinse in solution No. 4. This rinse is followed by thorough washing in a strong stream of water, dipping in alcohol, then ether, and drying with a warm blast of clean air.

* Can be made by using 1 part solution No. 1 and 3 parts water.

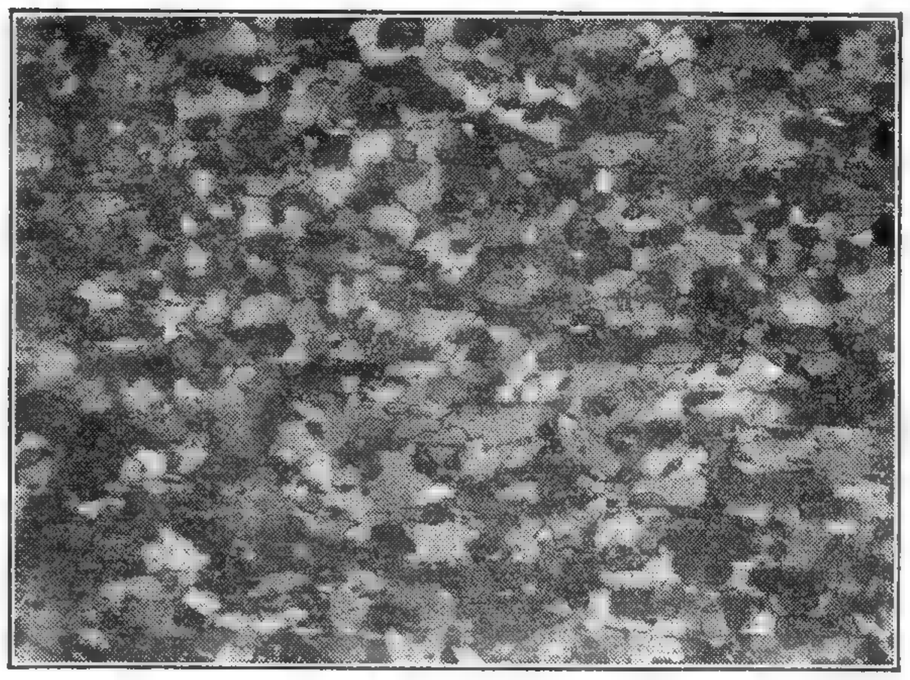

Fig. 2 Hot rolled zinc (0.1% Pb) etched with solution No. 1. Polarized light. Avg grain diam, 0.00044 in. (× 200)

Macro-etching. Concentrated hydrochloric acid produces good grain contrast on zinc.

Electrolytic Etching. Rodda[2] has described the use of electrolytic etching in studying other copper-zinc phases, particularly gamma and epsilon.

Zinc materials should be etched as follows:

Metal	Solution Number	Time, seconds: 100 Diameters	Time, seconds: 1000 Diameters
Unalloyed zinc	1	15	1
Rolled zinc-copper alloys	3	15	1
ASTM XXIII die-casting alloy	2	5	1
ASTM XXV die-casting alloy	2	5	1

Deviation from indicated etching time may be necessary.

Grain-Size Studies. It is necessary to use polarized light in making determinations of grain size in zinc. Grain boundaries are poorly defined in white light.

Typical structures of a zinc die-casting alloy and a hot rolled zinc are shown in Fig. 1 and 2 respectively.

PROPERTIES OF ZINC AND ZINC ALLOYS

Pure Zinc*

COMPILED BY E. A. ANDERSON, E. J. BOYLE AND D. C. JILLSON*

A 1 *Common name.* **Chemically pure and spectroscopically pure zinc.**

C 1 *Density*[1] at 25 C (77 F). 7.133 g per cu cm (0.258 lb per cu in.)
2 *Density versus temperature.*[2] See Fig. 1.
3 *Density versus pressure (compressibility).*[1] See Fig. 2.
5 *Solidification shrinkage.*[2] 7.28% (volume change between 469 C and room temperature)

D 1 *Melting point*[1,3,4] 410.46 C (787.03 F)
4 *Boiling point*[5,6,7] at 760 mm Hg. 906 C (1663 F)
6 *Thermal expansion*[1] (polycrystalline) 20 to 250 C (68 to 482 F). 0.0000397 per °C
$L_t = L_0 (1 + 35.4 \times 10^{-4}t + 1 \times 10^{-8}t^2)$. (Ref 8)
7 *Thermal expansion*[3] along *a* axis 0 to 100 C (32 to 212 F). 0.000015 per °C
9 *Thermal expansion*[3] along *c* axis 0 to 100 C (32 to 212 F). 0.0000615 per °C
10 *Thermal expansion (liquid)*[2] 500 to 600 C (932 to 1112 F). 0.00006 per °C
11 *Specific heat*[5,9] at 20 C (68 F). 0.0915 cal per g
12 *Specific heat versus temperature.*[5,9] See Fig. 3.

* The properties listed here are regarded as the best available for the purest zinc. The values are not necessarily the same as those for zinc of commercial form and composition.

* Research Division, Technical Department, The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

Zn*–4 Al–0.04 Mg

COMPILED BY G. L. WERLEY*

A *2 Trade name.* Zamak-3 (die casting)
3 ASTM number. XXIII
4 Government number. QQ-Z-363, dated 2/7/46
5 Other designations. SAE 903
6 Foreign equivalents. Mazak-3, Gomak-3
B *1 Typical uses.* For all zinc alloy die castings, such as automotive parts, household utensils, office equipment, building hardware, padlocks, toys, and novelties.
2 Precautions in use. Strict maintenance of specifications regarding chemical composition and intelligent use of die design to insure sound castings having uniformly high strength.
C *1 Density* at 21 C (70 F). 6.6 g per cu cm (0.24 lb per cu in.)
5 Solidification shrinkage. 1.17% (Use 0.3 to 0.6% in die design.)
D *1 Liquidus temperature.* 386.6 C (727.9 F)
2 Solidus temperature. 380.6 C (717.1 F)
6 Thermal expansion 20 to 100 C (68 to 212 F). 0.0000274 per °C
11 Specific heat 20 to 100 C (68 to 212 F). 0.10 cal per g
16 Thermal conductivity 70 to 140 C (158 to 284 F). 0.27 cal/sq cm/cm/°C/sec
E *1 Volume conductivity* referred to standard copper. 27%
2 Electrical resistivity at 20 C (68 F). 6.3694 microhm-cm
5 Temperature coefficient of electrical resistivity 0 to 100 C (32 to 212 F). 0.003774 per °C
I *1 Corrosion resistance.* This alloy can be used safely wherever zinc or zinc-coated iron or zinc-coated steel has been used successfully in the past. Corrosion penetration outdoors in inches per year is 0.000078 in Palmerton, Pa., and 0.00022 in New York City.
K *Mechanical properties. Die cast* (¼-in. section): tensile strength 41,000 psi; elongation 10%; Bhn 82; impact value, Charpy 43 ft-lb; shear strength 31,000 psi; endurance limit (10^8 cycles) 6875 psi; compressive strength 60,000 psi.
L *4 Preferred tension-test specimen.* ¼-in. diam
Preferred impact-test specimen. ¼ by ¼ by 3 in., unnotched
Preferred hardness test. Brinell, 500 kg/10-mm ball/30 sec
M *1 Composition limits* (ASTM B 86). *components,* 3.5 to 4.3% Al; 0.03 to 0.08% Mg; *impurities,* 0.1% max Cu; 0.007% max Pb; 0.005% max Cd; 0.005% max Sn; 0.100% max Fe.
2 Consequences of exceeding impurity limits. Alloy becomes subject to intergranular attack and fails prematurely by warping and cracking.
N *1 Melting temperature range.* 386.6 to 500 C (727.9 to 932 F)
2 Die-casting temperature range. 393 to 427 C (740 to 800 F)
3 Alloying. Add aluminum as unalloyed metal as soon as zinc is molten. Add magnesium as unalloyed metal when aluminum is dissolved.
4 Deoxidizers. None required.
5 Type of flux. None desired. Fluxes volatilize the magnesium.
6 Precautions in melting. Allow a 15-min resting period after the aluminum has dissolved, during which time fine particles of aluminum and silicon (believed to be oxides) will rise to the surface of the melt and must be removed by skimming. Skimming will also remove all excess iron in the form of iron-aluminum compounds.
16 Standard finishes. Mechanical, electrodeposited, chemical, organic and plastic.
17 Joining. Soft solder with Pb-Sn solder over nickel-plated surface; acidulated zinc chloride flux.
Oxyacetylene weld with Zamak-3, no flux, soft flame.
Resistance welding. Pulsation technique is usable.

Zn* – 4 Al – 1 Cu – 0.04 Mg

COMPILED BY G. L. WERLEY*

A *2 Trade name.* Zamak-5 **(die casting and sand casting)**
3 ASTM number. XXV
4 Government number. QQ-Z-363, dated 2/7/46
5 Other designations. SAE 925
6 Foreign equivalents. Mazak–5, Gomak–5
B *1 Typical uses.* For all zinc alloy die castings, such as automotive parts, household utensils, office equipment, building hardware, padlocks, toys, and novelties. In sand castings this alloy is being used for drop-hammer dies.
2 Precautions in use. Same as for Zn – 4 Al – 0.04 Mg
C *1 Density* at 21 C (70 F). 6.7 ■ per cu cm (0.24 lb per cu in.)
5 Solidification shrinkage. 1.17% (Use 0.3 to 0.6% in die design.)
D *1 Liquidus temperature.* 386.1 C (727.0 F)
2 Solidus temperature. 380.4 C (716.7 F)
6 Thermal expansion 20 to 100 C (68 to 212 F). 0.0000274 per °C
11 Specific heat 20 to 100 C (68 to 212 F). 0.10 cal per g
16 Thermal conductivity 70 to 140 C (158 to 284 F). 0.26 cal/sq cm/cm/°C/sec
E *1 Volume conductivity* referred to standard copper. 26%
2 Electrical resistivity at 20 C (68 F). 6.5359 microhm-cm
5 Temperature coefficient of electrical resistivity. 0 to 100 C (32 to 212 F). 0.003527 per °C
I *1 Corrosion resistance.* This alloy can be used safely wherever zinc or zinc-coated iron or zinc-coated steel has been used successfully in the past. Corrosion penetration outdoors in inches per year is 0.000063 in Palmerton, Pa., and 0.00028 in New York City.
K *Mechanical properties. Die cast* (¼-in. section): tensile strength 47,600 psi; elongation 7%; Bhn 91; impact value, Charpy 48 ft-lb; shear strength 38,000 psi; endurance limit (10^8 cycles) 8175 psi; compressive strength 87,000 psi.
L *Test specimens.* See Zn – 4 Al – 0.04 Mg.
M *1 Composition limits* (ASTM B 86). *components,* 3.5 to 4.3% Al; 0.75 to 1.25% Cu; 0.03 to 0.08% Mg; *impurities,* 0.007% max Pb; 0.005% max Cd; 0.005% max Sn; 0.100% max Fe.
2 Consequences of exceeding impurity limits. Alloy becomes subject to intergranular attack and fails prematurely by warping and cracking.
N *1 Melting temperature range.* 386.1 to 500 C (727.0 to 932 F)
2 Die-casting temperature range. 393 to 427 C (740 to 800 F)
3 Alloying. Add Al-Cu-Mg as an 80–20–0.8 hardener as soon as the zinc is molten.
4 Deoxidizers. None required.
5 Type of flux. None desired. Fluxes volatilize the magnesium.
6 Precautions in melting. See Zn – 4 Al – 0.04 Mg.
16 Standard finishes. Mechanical, electrodeposited, chemical, organic and plastic.
17 Joining. See Zn – 4 Al – 0.04 Mg.

*Special High Grade Zinc must be used as the basic material in making this alloy.

A *2 Trade name.* Zamak-2 **(die casting and sand casting)**
3 ASTM number. XXI
5 Other designations. SAE 921
6 Foreign equivalents. Mazak–2, Gomak–2
B *1 Typical uses.* For all zinc alloy die castings, such as automotive parts, household utensils, office equipment, building hardware, padlocks, toys, and novelties. This alloy is becoming obsolete for die casting; it is being replaced by either Zamak–3 or Zamak–5. In sand castings this alloy is widely used for drop-hammer dies.
2 Precautions in use. Strict maintenance of specifications regarding chemical composition and intelligent use of die design to insure sound and uniformly high-strength castings. This alloy is subject to embrittlement and growth on aging.
C *1 Density* at 21 C (70 F). 6.7 g per cu cm (0.24 lb per cu in.)
5 Solidification shrinkage. 1.17% (Use 0.3 to 0.6% in die design.)
D *1 Liquidus temperature.* 389.8 C (733.6 F)
2 Solidus temperature. 379.3 C (714.7 F)
6 Thermal expansion 20 to 100 C (68 to 212 F). 0.0000277 per °C
11 Specific heat 20 to 100 C (68 to 212 F). 0.10 cal per g
16 Thermal conductivity 70 to 140 C (158 to 284 F). 0.25 cal/sq cm/cm/°C/sec
E *1 Volume conductivity* referred to standard copper. 25%
2 Electrical resistivity at 20 C (68 F). 6.8493 microhm-cm
I *1 Corrosion resistance.* This alloy can be used safely wherever zinc or zinc-coated iron or zinc-coated steel has been used successfully in the past. Corrosion penetration outdoors in inches per year is 0.000073 in Palmerton, Pa., and 0.00027 in New York City.
K *Mechanical properties. Die cast* (¼-in. section): tensile strength 52,100 psi; elongation 8%; Bhn 100; impact value, Charpy 35 ft-lb; shear strength 46,000 psi; endurance limit (10^8 cycles) 8500 psi; compressive strength 93,000 psi.
L *Test specimens.* See Zn – 4 Al – 0.04 Mg.
M *1 Composition limits* (ASTM B 86). *components,* 3.5 to 4.5% Al; 2.5 to 3.5% Cu; 0.02 to 0.10% Mg; *impurities,* 0.007% max Pb; 0.005% max Cd; 0.005% max Sn; 0.100% max Fe.
2 Consequences of exceeding impurity limits. Alloy becomes subject to intergranular attack and fails prematurely by warping and cracking.
N *1 Melting temperature.* 389.8 to 500 C (733.6 to 932 F)
2 Die-casting temperature range. 393 to 427 C (740 to 800 F)
3 Alloying. Add Al–Cu–Mg as a 57–43–0.4 hardener as soon as the zinc is molten.
4 Deoxidizers. None required.
5 Type of flux. None desired. Fluxes volatilize the magnesium.
6 Precautions in melting. See Zn – 4 Al – 0.04 Mg.
16 Standard finishes. Mechanical, electrodeposited, chemical, organic and plastic.
17 Joining. Soft solder with Pb-Sn solder over nickel-plated surface; acidulated zinc chloride flux.
Oxyacetylene weld with Zamak–2, no flux, soft flame.
Resistance welding. Pulsation technique is usable.

*Special High Grade Zinc must be used as the basic material in making this alloy.

Zn*–4.75 Al–0.25 Cu

COMPILED BY G. L. WERLEY*

A *1 Common name.* **Zinc-base slush-casting alloy**
B *1 Typical uses.* For all slush and permanent mold castings, principally in the manufacture of lighting fixtures.
2 Precautions in use. Avoid contamination with lead, tin, or cadmium.
D *1 Liquidus temperature.* 390 C (734 F) approx
2 Solidus temperature. 380 C (716 F)
K *Mechanical properties. Chill cast* (½-in. section): tensile strength 28,000 psi; impact value, Charpy 3 ft-lb.
L *4 Preferred tension-test specimen.* ½-in. diam
Preferred impact-test specimen. ¼ by ¼ by 3 in., unnotched.
M *1 Composition limits* (customary). *components,* 4.50 to 5.00% Al; 0.2 to 0.3% Cu; *impurities,* 0.007% max Pb; 0.005% max Cd; 0.005% max Sn; 0.100% max Fe.
2 Consequences of exceeding impurity limits. Alloy becomes subject to intergranular attack and fails prematurely by warping and cracking.
N *3 Alloying.* Add aluminum and copper as a 95-5 hardener as soon as the zinc is molten.
4 Deoxidizers. None required.
5 Type of flux. Ammonium chloride or zinc chloride.
16 Standard finishes.
Castings: mechanical, electrodeposited, chemical, organic, and plastic.

*Special High Grade Zinc must be used as the basic material in making this alloy.
*The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

Zn*–5.5 Al

COMPILED BY G. L. WERLEY*

A *1 Common name.* **Zinc-base slush-casting alloy**
5 Other designation. Unbreakable metal
B *1 Typical uses.* For all slush and permanent mold castings, chiefly in the manufacture of lighting fixtures.
2 Precautions. Avoid contamination with Pb, Sn, or Cd.
D *1 Liquidus temperature.* 395 C (743 F) approx
2 Solidus temperature. 380 C (716 F)
K *Mechanical properties. Chill cast* (½-in. section); tensile strength 25,000 psi; elongation 1%; impact value, Charpy 1 ft-lb.
L *Test specimens.* See Zn – 4.75 Al – 0.25 Cu
M *1 Composition limits* (customary). *components,* 5.25 to 5.75% Al; *impurities,* 0.1% max Cu; 0.007% max Pb; 0.005% max Cd; 0.005% max Sn; 0.100% max Fe.
2 Consequences of exceeding impurity limits. Alloy becomes subject to intergranular attack and fails prematurely by warping and cracking.
N *3 Alloying.* Add aluminum as unalloyed metal as soon as the zinc is molten.
4 Deoxidizers. None required.
5 Type of flux. Ammonium chloride or zinc chloride.
16 Standard finishes. Mechanical, electrodeposited, chemical, organic and plastic.

*Special High Grade Zinc must be used as the basic material in making this alloy.
*The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

Zn–0.08 Pb

COMPILED BY E. H. KELTON*

A *1 Common name.* **Commercial rolled zinc**
2 Trade name. Deep drawing zinc
B *1 Typical uses.* Drawn battery cans, eyelets, grommets, laundry tags, address plates, flashing; generally any drawn, formed or spun article not requiring stiffness.
2 Precautions in use. Deforms under light, continuous load, particularly at 100 F or higher.
C *1 Density* at 21 C (70 F). 7.14 g per cu cm (0.258 lb per cu in.)
D *1 Melting point.* 419 C (786 F)
4 Boiling point at 760 mm Hg. 907 C (1665 F)
6 Thermal expansion 20 to 40 C (68 to 104 F). 0.0000325 per °C with grain, and 0.000023 per °C across grain.
11 Specific heat 20 to 100 C (68 to 212 F). 0.094 cal per g
16 Thermal conductivity at 18 C (64 F). 0.257 cal/sq cm/cm/°C/sec with grain
E *1 Volume conductivity* referred to standard copper. 28.44% (hot rolled); 28.27 (cold rolled)
2 Electrical resistivity at 20 C (68 F). 6.06 microhm-cm (hot rolled); 6.10 microhm-cm (cold rolled)
I *1 Corrosion resistance.* Excellent resistance to atmospheric corrosion. Penetration same as for next alloy.
K *Mechanical properties. Hot rolled strip:* Bhn 38; endurance limit (10^8 cycles) 2500 psi.
2 Directional properties. Finish rolled to 0.024 in. by hot rolling or cold rolling.

Condition	Tensile Strength, parallel rolling direction, psi	Tensile Strength, perpendicular rolling direction, psi	Elongation, parallel rolling direction, percentage	Elongation, perpendicular rolling direction, percentage
Hot rolled strip.....	19,500	23,000	65	50
Cold rolled strip....	21,000	27,000	50	40

L *4 Preferred tension-test specimen.* ½ in. wide by 2-in. gage length
Preferred hardness tests. Scleroscope and Rockwell Superficial
Dynamic ductility test. 3½ in. long by coil width, ASTM B 69
Temper test. 1½ by 4 3/32 in., ASTM B 69
Dynamic bend test. 1 by 4 in.
M *1 Composition limits* (strip). *components,* 0.10% max Pb; *impurities,* 0.012% max Fe; 0.005% max Cd; 0.001% max Cu; 0.001% max Sn; 0.001% max Al
2 Consequences of exceeding impurity limits. Iron or cadmium causes increased hardness and reduced ductility; copper alters the chemical characteristics; tin causes hot shortness; aluminum promotes intergranular-type corrosion.
N *1 Melting temperature.* 475 to 525 C (887 to 977 F)
2 Casting temperature. (ingot) 435 to 485 C (815 to 905 F)
5 Type of flux. Sal ammoniac
6 Precautions in melting. Use refractory crucibles and melting-pot linings. Do not raise the temperature of the metal above 525 C, preferably not above 500 C.
7 Hot working temperature. 120 to 275 C (248 to 527 F)
8 Shortness range. 300 to 419 C (572 to 786 F)
11 Suited to forming by drawing, bending, roll forming, spinning, swaging, impact extrusion.
12 Precautions in forming. Keep temperature above 21 C (70 F). Use pure soapy water or noncorrosive mineral oil as lubricant.
16 Standard finishes. See pages 1078 and 1082.
17 Joining. Soft solder with Pb-Sn, acidulated zinc chloride flux.

*The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

Zn – 0.06 Pb – 0.06 Cd

COMPILED BY E. H. KELTON*

A *1 Common name.* **Commercial rolled zinc**
B *1 Typical uses.* Drawn battery cans, eyelets, grommets; generally drawn, formed, or spun articles requiring some rigidity.
2 Precautions in use. Deforms under light, continuous load, particularly at temperatures slightly above room temperature (100 F and higher).
C *1 Density* at 21 C (70 F). 7.14 g per cu cm (0.258 lb per cu in.)
D *1 Melting point.* 419 C (786 F)
4 Boiling point at 760 mm Hg. 907 C (1665 F)
6 Thermal expansion. 20 to 40 C (68 to 104 F). 0.0000325 per °C with grain and 0.000023 per °C across grain.
11 Specific heat 20 to 100 C (68 to 212 F). 0.094 cal per g, approx.
16 Thermal conductivity at 18 C (64 F). 0.257 cal/sq cm/cm/°C/sec with grain, approx
I *1 Corrosion resistance.* Excellent resistance to atmospheric corrosion. Corrosion penetration in inches per year outdoors is 0.000064 in Palmerton, Pa., and 0.00028 in New York City.
K *Mechanical properties. Hot rolled strip*: Bhn 43; endurance limit (10^8 cycles) 3800 psi.
2 Directional properties. See Table I.
L *Test specimens.* See Zn – 0.08 Pb.
M *1 Composition limits (strip). components,* 0.05 to 0.10% Pb; 0.05 to 0.08% Cd; *impurities,* 0.012% max Fe; 0.005% max Cu; 0.001% max Sn; 0.001% max Al.
2 Consequences of exceeding impurity limits. Iron causes increased hardness and reduced ductility; copper alters chemical characteristics; tin causes hot shortness; aluminum promotes intergranular-type corrosion.

The Precious Metals Industry

By E. M. Wise*

ON THE BASIS of dollar value of world production, the precious metals, comprising gold, silver and the six platinum metals, are surpassed only by iron. Gold has the highest commercial value of the precious metals, but its industrial uses are comparatively minor. The mining of precious metals is a world-wide industry. There are hundreds of mines, ranging from small operations where one man is panning gold, to large properties employing ten thousand workers; and varying in type from surface placers to the deepest mines in operation. The concentration of precious metals contained in the ore, as well as the smelting operation, is sometimes carried out by the mining company itself, but in many instances custom smelters are employed. The alloying, final fabrication, and marketing of these precious metals in solid, clad and electroplated form is also a sizable industry.

Mining and Refining. Large amounts of gold, silver and the platinum group metals have been derived from mining operations directed primarily toward these metals; but appreciable quantities of the precious metals are sometimes found associated with base metals, and are recovered incidentally during the refining of the base metal. For example, in recent years a large amount of silver has been recovered from silver-lead-zinc ores, and even more important has been the recovery of platinum, palladium, rhodium, ruthenium and iridium from the copper-nickel ores. Indeed, this recovery has become the source of the major proportion of the platinum metals in recent years. Silver, gold, and small amounts of some of the platinum

* The International Nickel Company, Inc., New York

metals are often associated with copper minerals and are recovered in the course of electrolytic refining of copper.

It is the usual practice to refine the precious metals to the high purity suitable for general use in the arts; sometimes almost spectrographic purity is required. For gold, however, refining is frequently carried only to the point of yielding a product containing 99.5% Au.* The U. S. Mint accepts gold of this purity without refining penalty, and such gold is good delivery in international exchange. Thus it is often advantageous to sell metal of this purity, unless it contains appreciable quantities of the platinum metals. It is possible, for example, to treat gold recovered from the cyanide process, by melting it and bubbling chlorine through it to convert the silver and other metals to recoverable chlorides, leaving gold pure enough for the Mint.

Gold for use in the arts is refined electrolytically and is generally 99.95% pure; silver likewise is generally refined electrolytically. The final refining of platinum metals is done by chemical rather than electrolytic methods.

Reuse. In addition to the refining of primary material, a large quantity of gold and substantial amounts of silver and the platinum metals are recovered from manufacturing scrap, as well as from old jewelry, chemical equipment, discarded dental restorations and other products scrapped for one reason or another. An appreciable quantity of the precious metals is also recovered from relatively low-grade industrial waste, resulting from polishing operations and the like and known as "sweeps". Substantial quantities of silver are recovered from photographic fixing solutions and from old film. Considerable quantities of platinum and palladium catalysts are ultimately saved by careful refining. Where it is necessary to remove organic material from a catalyst by burning, special care is required to prevent loss by dusting. Some of these materials cannot be handled economically by themselves, but the large smelters can work them into appropriate stages of their processes so that the recovery is economic.

Solid manufacturing scrap is generally remelted by the user as a portion of a new charge. Ordinarily this is satisfactory, if the scrap is kept scrupulously clean and segregated from other types of material, but turnings are always troublesome, and clad material requires refining.

Purity. All the precious metals are commercially available in purities suitable for their ultimate use. A substantial portion of these metals is partially fabricated before being sold. In large proportion, the metals are sold alloyed with one another or with auxiliary hardeners to yield the properties required by the user in the final product. The wrought pure metals are generally too soft.

Except for solders, most of the commercially important silver alloys, or alloys based on the platinum metals, contain at least 90% of the precious metal forming the basis of the alloy, and gold coins contain 90% gold, so the nobility of these alloys does not differ greatly from that of the major component. For most other applications, gold is usually alloyed with considerable quantities (25 to 60%) of other elements. As a result of this dilution of gold, the departure from the characteristics of the pure metal with regard to color and other properties, including resistance to tarnish and corrosion, is greater in the commercial gold alloys than in other precious metals. Where resistance to corrosion is an important factor in the carat golds—for example, for pen nibs—the alloy should be not lower than 14-carat, while gold leaf for outdoor exposure should be at least 22-carat.

Regulations. In the production of these various alloys, technical and legal requirements are the determining factors, as well as custom, modified by style trends. For coinage, where obviously something harder than pure gold or pure silver is required, copper has been accepted as the desirable hardener for both these metals. In the United States, at least, the 10% Cu, 90% Ag alloy has been used for all the regular silver coins.

The State stamping laws and fair-trade practices in the United States have defined various precious metal alloys and clad products. For example, sterling silver must contain not less than 92.5% Ag; the remaining 7.5% is unrestricted, but is normally copper, because copper is an effective hardener and is tolerable in other respects.

The gold alloys used for jewelry are described by carat and color. The carat is the fractional gold content of the articles expressed in twenty-fourths. In other words, an 18-carat gold alloy would contain 18/24 Au, or 75% by weight, while a 10-carat gold alloy would contain 10/24 or 41.65% Au. In gold-clad stock, the ratio of the weight of the gold alloy cladding to the total weight of the material is indicated, together with the carat of the cladding. For example, one-tenth 12-carat "gold filled" stock is surfaced with a layer or layers of 12-carat gold alloy that weighs 10% of the weight of the composite article. Such an article, if assayed in toto, would contain 5% Au.

The designation "gold filled" is limited by stamping regulations to articles in which the weight of the coating is at least one-twentieth of the total. Lower ratios may be stamped "rolled gold plate". The quality mark cannot be applied to articles surfaced with an alloy less than 10-carat. Watchcases require rather substantial cladding to resist wear. They can be called "gold filled" if surfaced with 0.003 in. of gold on the outside and 0.001 in. on the inside, of 10-carat gold or higher. Cases with half this thickness on the outside and none on the inside can be described as made of "rolled gold plate".

For the platinum metals, regulations were initially drawn up featuring platinum with iridium as a hardener. The uses of the other platinum metals were given less consideration at the time, an unfortunate circumstance, for they are not adequately covered. Some excellent palladium alloys suitable for uses like those of the carat golds, for instance, are not specifically provided for.

Stamping laws require that soldered platinum articles must contain at least 95% platinum metals, while articles made without solder are required to contain at least 98.5% platinum metals. When these requirements are met, an article may be stamped "platinum", providing it contains not more than 5% of the platinum metals other than platinum. An article containing more than 5% of the other platinum metals may be marked "platinum", provided the name of the predominating other platinum metal precedes the word platinum, as in "iridium platinum", and provided the article contains at least 75% Pt. An article may be stamped "palladium" if it contains at least 98.5% platinum metals, if solderless, or 95% platinum metals, if soldered, provided that the total content of platinum metals other than palladium does not exceed 5%.

Alloys used for dental purposes are rather complex in composition, and metallurgical considerations are dominant in their design. Various specifications have been established by the American Dental Association and by the Federal government, and many of the alloys have been designed to conform to these specifications, particularly to the Federal specifications, since the Army and Navy have been large purchasers of dental alloys. However, many excellent alloys in wide use have compositions or properties that differ from those covered by the specifications.

Many other important alloys have been designed for specific technical purposes—for precious metal solders, contact alloys, catalysts, crucibles, electrical resistors, frangible disks and fuses. Some of those alloys are sold according to a chemical or performance specification; others are patented or trade-marked materials with properties recognized and desired by the user. Certain existing ASTM specifications concern silver solders, which offer a basis for classification; but different manufacturers, producing alloys for specific applications, will not necessarily use identical compositions.

History and Basis for Use. Gold and silver were discovered and used in pre-Biblical times, because they occurred native in small quantities in the regions that were early civilized. The search for gold stimulated exploration, particularly in the New World, and also led to the conquest of natives who were so unfortunate as to have gold or silver mines in their territory.

Gold and silver were rare but could be worked readily by the use of very crude equipment and could be melted without much difficulty. Since these metals remained bright, they became articles of adornment, and gold in

* It is general practice to express the quality of bullion in parts per thousand, which is termed the "fineness"; thus an alloy containing 99.5% Au would be termed "995 fine".

the form of beaten leaf was used for architectural ornament. Before the use of coal, very little sulfur was in the air, so it is likely that silver remained bright and untarnished for long periods of time. Silver was therefore somewhat overrated from the standpoint of atmospheric corrosion and was considered very noble, because gold was the only other metal of lasting brilliance then known.

Platinum was discovered by the natives in South America and was used for making small articles of jewelry before it was known in Europe. The grains of platinum were cemented together by fusing with particles of gold that occurred in the same alluvial deposit as the platinum. It was not until 1741 that platinum became known in Europe, but it then aroused the attention of leading scientists, and in little more than 100 years, the other metals of the platinum group were discovered, separated and utilized. The difficulty of fusing platinum led to the development of pressing and sintering techniques, which became the standard method of producing massive platinum until about 1856. At that time the use of a lime refractory in conjunction with the oxyhydrogen torch, made it possible to melt and cast platinum. Cast ingots could be rolled and fabricated in about the same manner as gold and silver. Palladium could be handled in the same way, but the other metals of the platinum group offered special working difficulties, so no real production in wrought form has been possible until recently. During the past 15 years considerable quantities of wrought rhodium have been produced for scientific purposes. Iridium also can be hot worked with much difficulty, but ruthenium and osmium are virtually unworkable.

The use of gold and silver for coinage was a natural result of the limited production and general desire for these metals, principally for personal adornment. Later the fact that a bracelet could either be worn or be sold became important, for with the constant wars and migrations, it became necessary to have some rather compact means of carrying one's savings, and these metals were admirably suited to the need. Uses for coinage and for ornamentation have continued, but in addition, large industrial applications for the precious metals have developed, depending entirely on the unique properties of one or another of the metals.

Silver. The use of silver in photography is based on the photosensitivity and ease of reduction of certain silver salts. In silver solders the controlling factor is the rather low melting temperature and excellent properties of the silver-copper eutectic and the silver-copper-zinc alloys. In electrical contacts, the resistance of silver to oxidation, coupled with thermal and electrical conductivities of the order of those of copper, justifies the use of silver-base materials. The susceptibility of silver to sulfur, however, limits the use of silver contacts at low currents and voltages. In aircraft engine bearings, moderate hardness, good thermal conductivity, and low solubility in iron, all contribute to the worth of silver. The quick formation, the good mechanical properties, and the small dimensional changes that occur during the setting of certain silver-tin-mercury alloys, are the basis for the use of silver in dental amalgams.

Sterling silver retains its long-established position in uses where an elegant appearance is of paramount importance. For jewelry and tableware high reflectivity makes silver particularly attractive. Much work has been done to develop a nontarnishing sterling silver, but no such alloy appears to exist. Various thin, protective coatings have been used on objects not likely to be scratched. Among these coatings rhodium has been best.

Silver-clad copper, known as Sheffield plate, was once widely used for food-serving dishes and the like, as a substitute for solid sterling silver. These products have now been supplanted by electroplated ware. Silver-clad copper was also the basis of most daguerreotypes. Silver-clad copper, brass, nickel and iron are produced for a variety of modern uses, ranging from electrical conductors and contacts to chemical equipment. Silver is employed also in various chemical processes, including certain catalytic applications. Silver coatings are being applied to glass, ceramics and mica by spreading on a special silver-content paste and then warming to red heat. These coatings are widely used in electronic devices and also as a conducting base for subsequent electroplating. Other methods of applying conducting coatings to plastics and glass are also used as the base for electroplates. Finely divided silver, in the form of a paste applied to high-temperature bolting, is effective in preventing galling at temperatures as high as 1200 F.

The electrodeposition of silver from a double alkali metal cyanide, a process discovered a little more than 100 years ago, was the first commercially important electroplating process and halted the production of Sheffield plate. This process continues to be important; silver-plated ware, generally on a nickel silver base, is widely used for table service. Electrodeposited silver is also used for surfacing ultra-high-frequency conductors for radar. Heavy electrodeposits from this or other baths can be used for surfacing chemical equipment and for bearings. The high reflectivity in the visible range and the facility with which silver can be reduced chemically from certain unstable (and sometimes explosive) compounds, are the reasons for using silver for surfacing mirrors for use in the visible range.

Gold. Among the gold alloys, the Au-Ag-Cu-Pt-Pd alloys are used in dentistry because of their good mechanical properties, response to age hardening treatments, nobility and moderate melting point. Custom, the colors available, the relatively good resistance to tarnishing and corrosion, and adequate mechanical properties of the Au-Ag-Cu (yellow) golds and Au-Ni-Cu-Zn (white and sun-tan) golds, account for their use for jewelry, optical eyeglass frames and rings, as well as for certain rubbing contacts in small electrical devices. Gold-silver alloys containing about 70% Au, generally with a few per cent of platinum, are resistant to both oxidation and sulfidation, and have other properties that make them useful for low-current electrical contacts. In this field, however, they have generally been replaced by palladium.

Pure gold can be electrodeposited readily, and this metal, as well as rhodium and palladium, has been used for surfacing certain high-frequency conductors in environments where siver, which is often used for this purpose, corrodes. A considerable range of gold alloys also are electrodeposited on jewelry and other items where appearance is important. In some instances several layers of gold and other metals are deposited successively, and the article is subsequently heated to produce an alloy by diffusion. Pure gold has high reflectivity in the red and infrared spectral ranges, and therefore is sometimes used for surfacing infrared reflectors.

Although pure gold is resistant to nitric, sulfuric and hydrochloric acids and to many other corrosives, the use of pure gold in the chemical field is limited because of its susceptibility to attack by halogens (particularly when it is used as an anode), its softness and relatively low melting point and, to some extent, its cost. However, gold is sometimes used as a lining for small calorimeter bombs and as a corrosion-resistant solder. The 70% Au, 30% Pt alloy is quite hard and has been used widely for rayon spinnerets, but is being replaced by the platinum-rhodium alloy.

Platinum Metals. The jewelry uses of platinum and palladium hardened with one of the other platinum metals, are inspired by the pleasing color, good mechanical properties, resistance to tarnish, and known rarity (about 100 times that of gold). Rhodium is used in jewelry because of its high reflectivity and immunity to tarnish, plus the fact that it can be electrodeposited readily in thin coatings over silver or other metals. These same properties are responsible for its use in surfacing 60-in. anti-aircraft searchlight reflectors, and also reflectors for moving-picture and television equipment. Palladium can be electrodeposited readily in both thick and thin coatings, while platinum and rhodium baths are best suited to the production of thin deposits.

Platinum (generally hardened with ruthenium or iridium), pure palladium, and small amounts of rhodium-osmium alloy are used for electrical contacts where thoroughly reliable operation is desired at currents up to about one ampere. The resistance of these metals to sulfidation and to other types of corrosion renders them particularly valuable where the voltage, current or actuating force

is low, since other metals are unsuited for such applications.

In chemical work, palladium, platinum and occasionally ruthenium are useful for hydrogenation or dehydrogenation. Platinum is the outstanding catalyst for high-temperature oxidation and is in universal use for the production of nitric acid from ammonia (using 10% Rh-Pt). Platinum is widely employed also in the production of sulfuric acid from SO_2. The platinum versus 10% Rh-Pt thermocouple, and the platinum resistance thermometer are standard for precise measurement and control of temperature. Platinum equipment is the basis of the fiber-glass industry, and for the production of various single-crystal salts and glasses for the optical industry. Insoluble anodes of platinum or platinum-clad base metal are used for the production of persulfuric acid, yielding hydrogen peroxide, and also for producing perchlorates, and are used also for certain large-scale commercial electroplating processes. Platinum alloys, either 30% Pt, 70% Au or 10% Rh, 90% Pt, are used for spinnerets in the production of (xanthate) rayon. The use of 4% W-Pt and Pd-Ru-Pt alloy for aircraft spark plug electrodes, became extensive during World War II and continues because these alloys permit smooth operation with a leaner fuel mixture and consequent increase in efficiency. This type of plug is being used increasingly in busses and other vehicles.

The precious metal alloys, developed to meet these diverse requirements, are described in the following articles. The physical properties that can be attained differ greatly. The Brinell hardness number, for example, ranges from 25 for pure gold, to more than 600 for the hard, pen-tipping alloys; and the melting point, from less than 650 C for some of the silver solders to about 2700 C for osmium.

Melting Precious Metals

IN THE MELTING of precious metals various techniques have been employed, ranging from the use of a 200-ton furnace in melting silver for rolling into bus bars, to the torch melting of small buttons of platinum or palladium or dental gold alloys. Besides these differences in the size of the charge, the differences in the melting points and optimum melting atmospheres and refractories for the precious metals influence the practices employed.

Melting Silver and Silver Alloys for Rolling

By John L. Christie*

SILVER and silver alloys are regularly melted in gas-heated, oil-heated, and electrically heated crucible furnaces. The crucibles are made of conventional clay-graphite or other refractory material. The size of the melting unit depends on the magnitude of the operation. Melts of 1000 and 2000 oz are common. Large producers regularly use furnaces holding 10,000 to 15,000 oz, and the cakes cast for conversion into silver bus bars were melted in a 200-ton furnace normally used for melting copper.

In the melting of fine silver, the charge may consist entirely of silver bars, or it may contain large amounts of clean scrap. The charge is melted down as rapidly as possible under a charcoal cover, is heated to about 1100 C, and is poured into cast-iron molds that have been dressed with a mold oil. Molten silver may absorb considerable oxygen and, if allowed to do so, will give it off during solidification, with resulting unsoundness.

In the melting of silver-copper alloys, such as sterling silver and coin silver, relatively large amounts of scrap are likely to be utilized, resulting from the manufacture of tableware, coins and the like. Heavy scrap and finely divided light scrap are introduced directly into the crucible. Light, bulky scrap is frequently "cabbaged". In the use of scrap, care must be taken to prevent contamination. In some instances where meticulous care supplants knowledge and control, no scrap is remelted, but generally this involves unnecessary expense.

Silver-copper alloys are melted under a charcoal cover. A deoxidizer is added, and the stream of metal to the mold is protected from oxidation by the burning mold dressing, aided sometimes by a gas flame around the stream at the top of the mold. Various deoxidizers are used—phosphor-copper, sodium-zinc, calcium boride, and cadmium. Phosphorus forms a ternary Ag-Cu-P eutectic that has a low melting point (640 C); therefore the residual phosphorus should be held considerably below 0.05% to prevent hot shortness. With all deoxidizers, allowance must be made for the effect of their presence on the fineness of the alloy.

The size and shape of the casting depend obviously on the subsequent operations involved in producing sheet and strip, rod and wire, and tubing. In coinage, the metal is cast into bars—small to minimize the segregation effect.

Pouring temperatures, which depend on the alloy and on the pouring technique, should be as low as will permit the last of the charge to be poured. Ordinarily, 170 C superheat above the liquidus is sufficient.

Other alloys present various problems. The temperature of silver-cadmium alloys should be kept low and should be controlled carefully to prevent a variable loss of cadmium through volatilization. Alloys containing the small percentage of nickel that can be introduced into silver alloys, should be kept free from phosphorus to prevent the formation of a hard nickel phosphide.

In general, the relatively high value of silver calls for good housekeeping, careful handling to prevent spilling, and control to keep the composition close to the nominal.

Crucible Melting of Gold and Silver Alloys

By J. Ogden*

THE RANGE of gold and silver alloys includes the alloys employed in jewelry, dental and industrial needs, as well as the solders for use with these alloys, and encompasses alloys that have a liquidus temperature ranging from 650 to 1100 C. The dental alloys generally have the highest melting points and contain the most gold, plus palladium, platinum, silver, copper and usually about 0.5 to 1.5% Zn. The jewelry alloys melt at lower temperatures and contain less gold; normally the alloying elements for the colored golds are silver, copper and zinc, often with a small percentage of nickel, while the white golds contain nickel, copper and zinc as the alloying elements. Sterling silver contains copper as a hardener and requires about the same procedure as copper to secure ingots that are free from oxygen. Besides the above alloying elements, the solders may contain a little tin, which causes no special melting trouble, and sometimes cadmium, which is volatile and somewhat toxic.

For ensuring homogeneous alloys, the addition elements, sometimes minus part or all of the silver, may be melted, cast and rolled, as a preliminary step, or may be melted and shotted, taking care to secure sound shot that will not explode during remelting. This addition then is remelted with gold to produce the final alloy, or at times the complete gold alloys may be melted, cast and remelted to produce a uniform alloy. Under all circumstances, metal of high purity is required, low in lead, bismuth, antimony and sulfur, and the metal is melted in such a manner that undesirable elements are not introduced.

About 50% of *clean* manufacturing scrap is often introduced in the melt. Sheet scrap is satisfactory, but turnings are always a source of trouble, even when considerable care has been taken to minimize mixing with other alloys or base metals. The base metals can be removed more or less completely by pickling.

Clay-graphite crucibles are suitable for most of the

* Metallurgical Manager, Handy & Harman, Bridgeport, Conn.

* I. Stern & Co., New York

gold and silver alloys, but under some conditions use of such crucibles may lead to a pickup of silicon, which will render most of these alloys extremely hot short. The high-palladium gold alloys should be melted in lined crucibles to avoid this difficulty.

The furnaces generally employed are fed with gas and air under pressure, and the melting atmosphere is kept slightly reducing to prevent the oxidation of the base-metal alloying elements, and for other reasons. Induction melting is employed increasingly and some use is made of electrical resistance furnaces, which are generally equipped with carbide resistors or, for small units, with platinum resistors.

Boric acid, a good melting flux for most of the alloys, should be skimmed off and replaced with fresh flux just before the metal is poured. In the melting of alloys that are free from zinc and other deoxidizers, a charcoal cover is employed, and sterling silver may be melted under a cover of old bone buttons. Some of the high-copper alloys and the silver-copper alloys may require deoxidation with about 0.05% P, just before being poured. Calcium boride is occasionally useful in some of the higher-melting gold alloys, particularly the dental alloys, but generally reliance is placed on the presence of 1% Zn or more, to maintain a low final content of oxygen. Occasionally indium is used for this purpose instead of zinc. In alloys that are subject to difficulties caused by gas, preliminary solidification in the crucible, before remelting and pouring, is often very helpful. The use of a protected noble metal thermocouple of the immersion type is desirable for controlling the final pouring temperature, which should be about 50 C above the liquidus.

The alloys are poured directly into warmed, greased cast-iron split molds, which have long life. During pouring, particularly where boric acid is not used as a flux, it is often desirable to use a reducing flame for covering the metal stream as it enters the mold. The rate of pouring is low, just equal to the rate of solidification, so that no appreciable shrinkage pipe develops. To pour slowly, without producing laps and cold shuts on the ingot surface, is a skill that requires some years to perfect.

Torch Melting of Platinum Metals

By E. M. Wise*

IN MELTING finely divided platinum metals, it is desirable to press them first into masses of convenient size. This reduces the mechanical loss during torch melting, and generally makes the metals good enough electrical conductors for satisfactory induction melting.

Torch Melting for Poured Ingots. In torch melting for casting, a furnace made from two blocks of compressed lime is generally used despite the limited life of such a refractory and its rapid deterioration if left exposed to the atmosphere. The lower block is scooped out to form the hearth, and the upper block has a central hole through which the flame of the oxyhydrogen or oxy-city-gas enters. Oxyhydrogen is required for melting platinum of the highest purity. A horizontal channel is cut in the lower block to provide an exit for the burned gas and a channel through which to pour the metal.

A torch is required that has been designed specifically for this type of melting and is preferably equipped with a nozzle of high melting point. (Platinum is best for the purpose.) This torch should ensure as complete and uniform a mixture of combustible gas and oxygen as possible. Flow meters for both gases are required, and the mixture should be quite strongly oxidizing for platinum, and slightly oxidizing for palladium during all but the final period. At least 30 to 45% more oxygen than required for complete combustion, is recommended for pure platinum. If a neutral or reducing flame is used, appreciable amounts of calcium may be reduced, damaging the platinum and causing unsoundness; if this does happen, remelting under oxidizing conditions, with the addition of a trace of silica, will slag off the calcium. It may be necessary to melt platinum alloys under less oxidizing conditions, in order to avoid loss of some of the more oxidizable components of the alloy.

After the material has been completely melted, the flame is cut down until the metal just solidifies, giving off considerable gas meanwhile. The flame is then increased to remelt the metal and bring it to pouring temperature. A slightly oxidizing flame is satisfactory for remelting platinum, but palladium requires a strongly reducing flame at the end of the melting cycle; three volumes of hydrogen to one of oxygen is about right. Palladium sometimes requires supplementary solid deoxidizers, such as calcium boride, added in minute amounts just before pouring. The pouring temperature should always be as low as possible.

Warmed graphite molds are generally employed, but nickel molds also are used when previously oxidized by heating and then coated with a little zirconia. Sometimes pure copper molds are used but care is required in order to avoid cold shuts with this type of mold. In any event, the mold should be placed and the pouring should be done in such a way that the stream of metal does not impinge on the side of the mold more than momentarily.

Torch Melting for Producing Buttons. A special high-silica crucible, cut off at an angle, is employed for melting and solidifying small quantities of platinum to produce a button. The platinum, generally in the form of small pieces of previously worked material, is cleaned and stacked against the higher wall of the crucible, and an oxygen-city-gas torch, designed to produce a large uniform flame and adjusted to be oxidizing, is played against the cavity in the crucible and the back wall. The nozzle of the torch must be heavy and of high thermal conductivity, so that it will not overheat. The torch is played on the charge until the metal is completely molten, forming a pool in the bottom of the crucible. The flame is cut down slightly, or is lifted away from time to time, to permit the metal to solidify. The torch flame should be directed in such a way that solidification of the platinum will progress upward. If gas is evolved during cooling, the top of the button may be remelted to give a good surface. After solidification is complete, the button is lifted out and most of the clinging refractory is removed. The button is then placed, bottom side up, on a silica refractory and is rapidly heated just to the point of fusing the surface, smoothing it up, and melting any residual refractory.

Palladium should not be melted in this way, since there is danger of contaminating it with silicon reduced from the silica crucibles during the later part of the melting operation. For this reason magnesia- or alumina-lined crucibles are recommended. A strongly reducing flame—three volumes of hydrogen to one of oxygen—is desirable, and at the end of the melting period, the oxygen can be cut still lower to cool the flame and permit progressive solidification. Even more satisfactory is an oxyacetylene flame, which may be operated nearly neutral, except at the end of the melt. Remelting may be required in order to secure solidity. In some instances the presence of a little charcoal during melting, or the final addition of about 0.03% calcium boride or aluminum may be required. These additions must be weighed, not estimated.

The buttons of platinum or palladium generally require preliminary forging at bright red heat, after which they can be rolled and annealed in the usual way. Cast ingots of platinum or palladium also are generally forged and hot rolled; but with highest quality metal, forging is not really necessary, except for the harder alloys.

* The International Nickel Company, Inc., New York

Induction-Furnace Melting of Precious Metals

By E. M. Wise*

HIGH-FREQUENCY induction furnaces are being used increasingly for melting precious metals.

High-Frequency Melting of Gold and Silver Alloys. The conductivity of these alloys is quite high and most of the units are fairly small, so that relatively high frequencies are desirable if nonconducting crucibles are used. Excessively high frequencies, however, cause too great heating of the metal where it is in contact with the crucible wall.

* The International Nickel Company, Inc., New York

Magnesia-lined or alumina-lined clay-graphite or even solid graphite crucibles can be used for the lower-melting alloys, but zircon is better for the higher-melting alloys. A graphite cover may be employed to maintain a reducing atmosphere; or a jet of reducing gas, such as hydrogen, may play on the surface of the melt, and pouring may be done under a cover of gas. Melting followed by solidification in the crucible, and the use of low final pouring temperatures, minimize difficulties from gas. Because of convenience in control, ease of observation of the metal, and comfort to the operator, this method of melting is being used increasingly.

High-Frequency Melting of Platinum Metals. This method of melting is particularly desirable for platinum and the higher-melting metals, such as rhodium and iridium. Zircon and zirconia crucibles are suitable for platinum; thoria crucibles have been used for iridium and rhodium, although zirconia can be used for rhodium. These crucibles do not behave like lime, in aiding in the slagging of traces of impurities. Nevertheless, an oxidizing atmosphere is desirable throughout the initial melting period—at least for platinum—but cannot be used with alloys that contain oxidizable elements. A preliminary solidification followed by remelting is also desirable. Slight reduction with CO is sometimes advisable just before pouring, and minute amounts of deoxidizers, such as calcium boride, may also be required at the time of pouring. However, if the metal is poured at minimum temperature above the liquidus, gas difficulties are minimized. Molds similar to those used with lime-block torch melting are generally suitable.

During small-scale melting in vacuo, thoria will be serviceable without much reduction at the melting point of iridium.

Arrangements for casting in a moderate vacuum have also been utilized. This type of melting is particularly suitable for alloys that contain oxidizable metals, or alloys subject to gas absorption and evolution It must be emphasized that some crucible materials, entirely suitable for melting in air, may be reduced, damaging the platinum metals, when used in vacuo. Melting in vacuo probably has slight advantages over melting in a controlled atmosphere or in an inert atmosphere, but thus far the use of this method has been very limited.

Electrical Resistance Melting

By R. C. Brumfield*

VARIOUS TYPES of electrical heating resistors have been employed for melting precious metals for centrifugal casting. Platinum-wound muffles have been found satisfactory up to about 1250 C. In this arrangement, a horizontal tubular carbon crucible is placed within the muffle, with the hot junction of a protected thermocouple close to the end of the crucible. The small difference between the temperature of the metal and that of the thermocouple is determined by experiment. With this arrangement the metal is normally in direct contact with the carbon crucible, which provides a strong reducing condition. For most alloys melting between 500 C and 1250 C, particularly for gold alloys and silver alloys, these conditions are satisfactory, but a refractory lining could be employed in special instances.

This arrangement, with about 600-watts input, is used for melting from five pennyweight to a pound of metal. In a hot furnace the melting times for a casting temperature of 1100 C are 8 to 15 min. A superheat of 50 to 100 C above the liquidus is generally suitable.

Jewelry Casting

By Sam Tour*

THE ART of casting jewelry is centuries old. Some of the fine jewelry displayed in museums was made from castings. Cellini's work represents the high state of the art in the sixteenth century. The starting point was often a casting made with dimensions corresponding as nearly as possible to the size and shape of the finished piece.

The basic processes have changed little since then and include the lost-wax process, perfected by dentists during the last 40 to 50 years and employed for the last 15 years for producing rings and other items of jewelry. This process is the most important, although precious metals are cast also in molds made by pressing a pattern into cuttlefish bone or by packing fine sand or plaster of Paris mixtures around a permanent pattern. Since the lost-wax process permits the reproduction of fine detail and minimizes the amount of hand finishing, it is preferred, particularly where a moderate number of pieces is required.

Lost-Wax Process. The lost-wax process may be divided into seven steps as follows:

Initial Model. A model of the finished piece is required. It is generally metallic and may be the original artist's sample. When multipart molds are to be made of soft metal, the model must be made of material that will not be deformed by casting the soft metal around it nor by pressing the mold subsequently against the model to reshape it. When rubber molds are to be made, it is sometimes desirable to tin plate the model to prevent excessive adherence of the rubber.

Mold for Wax. The mold is a split form containing a cavity, conforming to the model, into which the molten wax is forced to produce replicas of the model. For very simple pieces or where very large production is involved, the metal molds may be machined, but generally metal molds are made by casting a soft metal alloy around the model. A suitable plane of parting of the mold halves must be selected, and mold frames are employed to ensure registry of the two halves. The alloys used for molds range from bismuth alloys, melting at 71 C, to alloys of the type metal class, melting at 230 C. These soft molds require reconditioning, from time to time, by placing the model in the cavity and pressing. Where undercuts are involved, as in rings set with gems, two or three loose pieces are required, in addition to the external mold halves, to reproduce the model and permit removing the replica.

Rubber molds are also employed where the model is complicated and has undercuts, and where only moderate accuracy is required. They can be used with wax cast at temperatures up to about 90 C, and with pressures of a few pounds per square inch. Rubber molds may be made in a frame, the two halves of the mold being made and vulcanized successively; or the mold may be made by coating the whole model and its sprue with a rubber paste, which is dried and cured. The model with its rubber jacket is then mounted in a frame where it is supported

* Sam Tour and Company, Inc., New York

by plaster, and the rubber is cut at the desired parting line to permit the removal of the model and subsequently the wax replicas.

In jewelry castings, minor departures from the dimensions of the model are unimportant, so that shrinkage of the wax, changes in the investment, and shrinkage of the final cast metal need not be considered; but in dental and industrial castings, these factors must be considered and compensated for.

Wax Replicas or Patterns. The wax employed is required to solidify rapidly but not to adhere to the mold; to be strong but to break before bending; to run out readily at a moderate temperature; and finally to burn out completely. Generally the mold is very lightly lubricated, and the wax, 20 to 55 C above its melting point, is injected by a syringe, centrifugally, or by air pressure. Pressures of a few ounces per square inch are provided by the syringe, while from 5 to 20 psi is used with the air-pressure method. Higher pressures cause swelling and blistering in the wax castings. In a fourth mode of injection, the wax, only 10 to 15 C above its melting point, is forced into the mold by a plunger, under a pressure of several hundred pounds per square inch. This method can be used, however, only with metal molds, well clamped together to avoid fins and similar imperfections.

Changes in injection pressure, wax or mold temperature alter results, and the time of removal of the wax from the mold is quite critical because of possible warpage and change of dimensions. Where it is necessary to store wax replicas, constant temperature is desirable.

The replicas are attached with wax to the gate in a treelike or other array; the type of investment employed and the nature of the casting determine the spacing. The gate may be of an inexpensive wax made for the purpose or of wax recovered in the run-out. It is important to employ material that does not react with the investment to cause flaking.

Investing. For casting gold and silver alloy jewelry, a simple mixture of 50% plaster of Paris and 50% graded quartz is used, but this breaks down at the high temperatures required for platinum and palladium, so that investments similar to those developed for the high-melting base metals are employed. These include mixtures containing 80 to 95% of graded quartz bonded with silica, silicates, aluminates, and phosphates. Some of these latter investments are air-setting, but others become fully hard only during the firing cycle.

It is important that the investment be free from bubbles, particularly where it is in contact with the wax, for bubbles cause rough castings. Various vacuum and mechanical treatments are employed to prevent this trouble while mixing investments, and at times the wax pattern is coated by brushing on a thin layer of investment before surrounding it with the major investment. Some of the investments are rather expensive and a 5-in. diam flask requiring about 3 lb of solids costs a considerable amount.

Generally the flasks are of stainless steel, with a ring-grooved rubber base that can be removed after setting has taken place. The wax or metal runner to which the replicas are fastened, is secured to this rubber base. It is customary to allow for a ½-in. clearance between the wax replicas and the inside wall of the flask.

Firing the Mold. After standing long enough to be thoroughly set, the flasks are ready for drying, baking and firing. This is usually done in electrically heated or gas-heated ovens. The flasks are inserted at some elevated temperature (95 to 150 C) and held until the wax and free moisture are largely eliminated. Usually the wax is not recovered, but from 50 to 65% may be recovered in a properly controlled system, which must be operated below about 100 C to avoid degradation of the wax. The recovery may or may not be economical.

After moisture and wax have been eliminated, the mold is fired as rapidly as is possible without producing cracks in the investment.

Firing is continued to temperatures of 760 to 870 C for plaster of Paris investments and to 1100 C for the more refractory types. During firing, which may require 4 to 14 hours, the atmosphere should be kept oxidizing and circulating to burn out any residual wax completely.

After firing, the molds are allowed to cool to the temperature desired for casting, usually 370 to 650 C.

Casting. Several varieties of centrifugal casting arrangements and two air-pressure devices are in use. The centrifugal types include those in which the metal is melted by torch or electric furnace in a crucible adjacent to the mold. The metal is then forced into the mold as the assembly rotates in a horizontal or vertical plane. In another centrifugal type, the metal is melted in a crucible in a separate furnace and is either poured into a preheated reservoir adjacent to the mold, or is left in the crucible, which itself may be clamped to the mold; and the assembly is rotated in a horizontal or vertical plane. There is also a machine carrying a number of radially dispersed molds connected with a common central pouring chamber into which metal is poured after the device is up to speed.

Pressure casting is employed in one arrangement, in which the flask is securely fastened to the pouring spout of the melting unit in a vertical upward position; the assembly is rotated so that the metal can run into the flask; and air pressure is applied to force the metal into the flask. In another arrangement, used to some extent in the dental field, the required amount of metal is melted in place, by torch, in the sprue depression in the top of the flask. A cup is then brought down over the molten metal and air pressure is applied to force the metal downward into the mold cavities.

In the past, emphasis has been placed on the speed of introducing the metal into the mold, but too great speed results in general solidification with consequent shrinkage porosity, rather than in progressive solidification toward the sprue, a mode that can result in good, solid castings. The right pouring temperature and mold temperature, and degasification of the metal also are required to produce sound castings, and attention to these essentials will greatly reduce the percentage of rejects.

In general, with gold, silver, platinum and palladium, the same alloys are employed for cast and wrought jewelry, although it is quite certain that improvement would result if alloys were developed specifically for casting. However, trade practices and stamping regulations impose some restrictions in this direction.

Finishing. In many types of work, the castings may be removed and partially cleaned simply by quenching in water. Where this is not feasible, some variety of knocking-out process may be used, ranging from simple hand tapping of the flask until the investment disintegrates, to pneumatically operated vibrating rams. Remaining fragments of the investment that adhere to the castings are removed by hand picking, air blast, live-steam blast, or sandblast, tumbling or pickling, and this may serve as the finishing operation also. Where the cleaning and final finishing are one operation, the gates and sprues are removed before treatment. Usually final finishing operations —buffing, filing, hand-tooling, for example—are necessary, as in fabrication of other types of jewelry.

Casting by the Cuttlefish Process. The casting of metals into molds made of the porous, internal calcified shell of the cuttlefish (Sepiidae, a relative of the octopus) is an old jewelry practice, suitable for making men's heavy rings. Pieces of cuttle 1 by 2 by 3½ in. are suitable and cost about 20 cents each. One end is sawed off so that the shell can stand. The shell is carefully sectioned through the middle, and the halves are smoothed by rubbing them on the fine sandpaper supported on a flat surface.

The object to be reproduced is then pressed gently into one plane surface just far enough to seat it firmly, whereupon the other plane surface is pressed against the other half of the object. A gentle, slightly rocking pressure is exerted by hand until the halves meet. The cut end is then made smooth with a file or by rubbing on emery, and index marks are scribed across the parting line.

The mold is then opened gently, and the gate routed in with any convenient hand tool. The model is then carefully removed, a little more gating is done, and the mold is closed to match the scribe marks. It is then held closed, gently but firmly, by soft iron wire. Fine detail is not attained nor are undercuts possible by this method. For simple coring, a frequent practice is to cut additional

pieces of cuttlebone to size and place them in position between the two mold halves.

The usual casting is made of carat gold, but platinum has sometimes been cast. The average casting is far from a precision object. Filing and tooling are required to bring the casting to the size of the model, because of the rapid but uniform washing action of the molten alloy on the mold. This is always accompanied by some charring. However, for casting one or two objects of one type or size, the cuttlefish process is a most economical procedure, especially when there are no facilities for sand casting or lost-wax casting.

After cooling, which is usually speeded by quenching the mold in water, the casting is removed and the remains of the mold discarded.

Jewelry Casting by the Pattern-Molding Process. Where undercuts are not involved, where exceedingly fine detail is not required in the casting, and where models or patterns of the article desired are available, the pattern-molding process is sometimes used.

The patterns or models are best when cut in half so that they may be mounted on pattern plates as in ordinary foundry practice. When split patterns or models are not available, match plates are made of hydrocal or dental stone, in which the pattern or model is half-embedded up to the desired parting line. By using cope and drag flasks, the two halves of the mold are made in the customary way, depending on the molding material used.

If the molding material is sand, a fine grade of parting powder is used, and then a fine grade of French sand is used as a facing. This fine sand, suitably tempered with water, is backed with a somewhat coarser sand, and the flask is hand-rammed quite hard. Gates, sprues, runners and such are usually cut by hand into the cope half of the mold. Gravity casting is employed.

If the molding material is of the plaster of Paris type, sometimes strengthened with asbestos fiber, the process is somewhat similar except that gates, sprues and runners are molded in place. After the plaster of Paris has taken its initial set, usually in about 30 min, the plate and patterns are withdrawn and the mold is put aside to dry in air and to set harder for a few hours. The mold halves so set are placed in an oven to dry out the free water, and then are heated for an hour or so at higher temperatures for skin drying. When the hot, skin-dried mold halves have been assembled, the metal is cast in place while the molds are still above room temperature.

These procedures have been used for years for sterling silver castings. They are particularly suitable for objects such as pins, brooches, and pendants, where one side is relatively flat. The flat side is usually in the drag or bottom half of the mold as cast.

Dental Casting

By W. A. Crawford*

In 1907 William Taggart introduced the method of producing dental castings by the disappearing wax pattern procedure. Few procedures, if any, have so revolutionized dentistry as the casting process. Previously only two types of metallic fillings had been available—amalgam and welded or malleted pure gold foil. Both materials are still used extensively; however, in regard to strength and convenience, amalgam and gold foil both have serious disadvantages, which were overcome by the casting procedure.

Fundamentally the procedure for making a dental casting is the same as for other applications, except for the fact that the dimensions of the casting must be identical with those of the original pattern (that is, the cavity) and only one casting will be made, but it must be a good one. Inlays are usually made to replace tooth structure lost as a result of decay. The steps in making an inlay begin with the preparation of the cavity—the pattern; the decay is removed and the cavity is slightly tapered so that a wax pattern may be removed. No undercuts can exist, yet walls must be so nearly parallel that the inlay will be retained by friction when inserted. The cavity is also extended to protect the delicate enamel rods, of which the outside of the tooth crown is composed, and to bring margins where metal is to join the tooth, to positions on the surfaces of the tooth normally rubbed by the tongue and cheeks, or in other words, to self-cleansing areas. This operation requires meticulous care to avoid damaging the pulp (nerve) and is one of the most difficult operations performed on living tissue, since nature will neither correct any errors nor heal the tooth structure.

Much of the work in preparation of the inlay cavity must be done in a part of the mouth that is difficult to illuminate and difficult to see even if illuminated. The dentist must guide most of his cutting by means of indirect vision, watching the results of his cutting instruments through a mirror. His work is done in an awkward position, yet he knows that if his margins are not perfect, his work will fail.

The Pattern. The pattern for the dental casting is the exact counterpart of the cavity and no "patternmaker's shrinkage" can be provided for. Hence the cavity must be reproduced exactly as to size and shape. This is in contrast with industrial castings, now being made by the dental process, where the pattern can be made oversize to compensate for casting contraction, or with jewelry, where slight variation in dimension is of no significance.

The contraction of gold in the dental mold is about 1.25%. By 1932, investments containing SiO_2 as cristobalite, had been developed that would provide an expansion as great as 1.4% (at 700 C), which is more than is actually needed to compensate for the contraction of the gold alloy during casting.

The wax pattern may be secured by modeling it directly on the tooth, or on a model in the hand. Regardless of how the pattern is made, it is impossible to produce one without strain, because the softened wax will contract during cooling. Furthermore, if the wax has been forced into the cavity in a semisolid condition, it will contain residual stresses. These stresses and those resulting from contraction of wax during cooling, will cause distortion of a wax pattern after it has been removed from the cavity. The amount that the pattern will change will depend on three factors: (1) the amount of stress in the pattern, (2) the length of time between the removal of the pattern from the cavity and the investing, and (3) the temperature at which the pattern is stored.

Stress. The amount of stress in a wax pattern depends on the stiffness of the wax when it was forced into the cavity, and will be least when the wax is melted and poured into the cavity and held under pressure as it is cooled. By this method, only the contraction of wax during cooling is involved. Any amount of stress may be present, from this minimum to a large amount if the wax was relatively stiff when forced into the cavity.

Stress in a wax pattern will change the shape of a pattern in less than an hour in a normally heated room. Dentists have learned that they cannot store patterns overnight, or even a few hours, before investing, if they expect the castings to fit. Patterns must be invested as soon as they have been removed from the cavity, or stored in a refrigerator after they have cooled to room temperature. In a room hotter than 90 F, a pattern will change its shape in a few minutes.

Sprues. One or more wire sprues must be attached carefully to a wax pattern in the right locations to introduce the metal during casting and must be of adequate size to ensure good feeding. A long thin sprue, in bulky inlays or crowns, will freeze before the inlay and thus prevent flow during the solidification of metal in the mold. In all probability this would not impair the strength

* Dean, Dental School, University of Minnesota, Minneapolis

sufficiently to cause failure, but porous areas on the surface of restorations will discolor very quickly in the mouth.

For bulky inlays a 14-gage wire should be used for the sprue. This wire should be inserted into the bulkiest part of the wax pattern because that is where freezing will occur last and therefore is the place where new molten metal will be needed last. Larger sprues can be used in the centrifugal type of casting machine but, where the metal is melted over the sprue hole, the sprue should be no larger than 14-gage; otherwise some metal may run in prematurely.

The sprue should also be short, not more than $\frac{3}{16}$ in. from the crucible former or sprue base to the inlay. Long sprues are unnecessary since it has been shown that dense castings can be secured with 15-lb casting pressure, regardless of the thickness of investment beyond the mold.

The Investment. The selection of the investment will depend on the amount of expansion desired. Most dentists are of the opinion that different inlays should be slightly different in size in order to seat completely in different shaped cavities and still have frictional retention. Investments have therefore been made available that provide thermal expansion levels from 0.7 to 1.4% at 700 C. More than any other factor, the length and parallelism of the cavity walls indicate the investment expansion required to produce a casting that will seat easily in the cavity but still have frictional retention.

All investments for small dental castings are plaster of Paris and silica mixed with water, which must be added to the investment according to manufacturer's directions. The proportions must be strictly adhered to, because variations produce changes in the amount of expansion, hence in the size of the casting. Where dimensional errors of a few hundredths of one per cent mean the difference between success and failure of a casting, all details must be observed carefully.

Mixing. Hand-spatulated and, to a lesser extent, mechanically mixed investments, usually contain some trapped air, which frequently accumulates on the surface of the wax model and will produce a protrusion on the casting. These imperfections are annoying and, if unobserved, may cause serious injury to the tooth. The most satisfactory procedure is to remove air by vacuum after the investment has been mixed, then to fill the ring and again evacuate the air. This can be done in one step, but requires a rather high extension on the ring to hold the investment during the violent boiling while air is being eliminated.

Vacuum equipment is not essential, and satisfactory results can be obtained when thorough mechanical spatulation is followed by painting the investment on the pattern with a fine sable-hair brush. If an oily separating medium has been used when making the pattern, a very thin coating of a wetting agent applied to the surface of the wax pattern will be found helpful in applying the investment. If the coating of wetting agent is allowed to dry, its usefulness will be lost.

Heating the Investment. The casting ring or flask must be lined with a layer of asbestos at least $\frac{1}{16}$ in. thick to permit the investment to expand since, during heating, the metal ring will expand only about half as much as the investment. Unless the investment can expand, the mold will be distorted and the casting will not fit properly.

Quartz silica investments, of which many are available, show a gradual expansion from room temperature to 600 C; thereafter, no significant dimensional change results from further heating. These quartz investments are much alike in their behavior and provide a maximum expansion of approximately 1.0 to 1.1%. They should be heated to about 700 C in order to get somewhat above the critical temperature of 600 C. When the ring is removed from the heating chamber, some heat is lost before the cast is made, and if the temperature were just above 600 C, contraction might occur before the cast was made.

A cristobalite investment expands very rapidly over the range from 200 to 300 C and should be heated more slowly than a quartz investment through this temperature range in order to avoid danger from cracking and checking. Thermal expansion of cristobalite investment is about 1.2% from room temperature to 400 C and 1.4% to 700 C.

With the availability of investments to provide almost any desired expansion, with great accuracy and reliability, it remains only for the dentist to study his wax pattern, to decide what expansion will be required, and to use an investment with that expansion.

Melting. For small castings the alloy can ordinarily be melted with little difficulty by means of the usual dental equipment, consisting of a gas-and-air blowpipe. Careless manipulation of the blowpipe may result in selective oxidation of components of the alloy or may produce subsequent general porosity in the casting. During melting, the metal should be covered at all times with the reducing part of the flame, and as soon as the metal begins to melt, it should be covered with a reducing flux. After the metal has been melted and has formed into a ball, heating should be continued, carrying the temperature well above the upper limit of the melting range to ensure rapid and complete filling of the mold or casting.

Finishing. After the inlay has been cast, the sprue is removed and the outer surface is polished, except at margins, with fine garnet, cuttlefish disks, pumice in water and whiting or rouge. Then the inlay is tried in the cavity. Contacts with adjacent and occluding teeth are tested and adjusted. All margins are tested with a sharp explorer point, are finished on the tooth with fine stones and disks, and are finally polished with pumice and whiting.

Finally the cavity is dried and the restoration is cemented in place with a mixture composed chiefly of zinc oxide and orthophosphoric acid. The purpose of the cement is to seal out oral fluids and bacteria and is not to hold the inlay in the tooth.

Properties. For information concerning the compositions and mechanical properties of cast dental alloys, see page 1120.

The Working of Platinum Metals

By C. S. Sivil*

PLATINUM, PALLADIUM, and platinum and palladium alloys are usually given their first reduction by hot forging or rolling. Although it is not essential with high-quality metal, except for some of the harder alloys, hot working reduces the time of working. Hot working temperatures vary from 800 to 1300 C; the harder alloys require the higher temperatures. Although platinum and palladium will weld at high temperatures, hot working will not weld internal cavities, which must be avoided by proper melting and casting procedures.

Further working is done cold with reductions of 5 to 10% per pass. Reductions between anneals range from 50% for the harder alloys to 95% for soft alloys in strip form, and to as high as 99% for fine wire made of pure platinum. Wire may be reduced by rolling or swaging. Odd shapes are produced by special rolls, either driven or passive; the passive rolls, generally called Turk's-head rolls, are actuated by pulling the wire through. Further reductions are carried out by drawing the wire through dies made of sintered carbide or diamond. For drawing fine wire, diamond dies are essential.

Palm oil, soap powder, or one of the softer wire-drawing soaps may be used as a lubricant for drawing on the block, while emulsions of oil, soap, and water are employed on the continuous multiple-die machines used for the finer sizes. For extremely fine sizes, some of the natural fish oils are effective. In presswork, a fluid green soap is satisfactory. The fact that the platinum metals

* Metallurgical Department, Baker & Co., Newark, N. J.

do not react with the usual lubricants makes effective lubrication somewhat difficult, and lubricants that contain metal may be employed, or supplementary coatings of silver or copper can be used. The usual objection is that such lubricants are hard to remove before annealing.

It is essential to pickle high-purity platinum in hot 10 to 20% HCl before annealing, in order to remove traces of iron or other base metals that would otherwise diffuse into the platinum during the anneal. Platinum and most platinum alloys are annealed in a moderately oxidizing atmosphere. Palladium and palladium alloys are often annealed in a similar atmosphere and cooled by quenching, but nitrogen or steam should be used in the early anneals and is preferable for all anneals.

Rhodium and iridium are best worked from small ingots not more than ½ to ¾ in. thick. Iridium must be worked hot (1200 to 1400 C at the start is a satisfactory range) and high-purity metal must be used. Even then it is difficult to work iridium into thin sections.

Rhodium requires an initial hot reduction at about 1100 C, but after the metal has been worked down to a thickness of approximately 0.1 in., it can be cold rolled. Annealing is required after each 30 to 40% reduction. Too high anneals should be avoided since thoroughly recrystallized metal of the usual purity is brittle.

At the start, wire is drawn at 1100 C, but the temperature is allowed to decrease during processing, so that it is about 700 C for 0.020-in. wire. Further reduction is done cold, with anneals after each 50 to 75% reduction in area. As in rolling, the anneals must be at comparatively low temperature; 750 to 800 C is suitable. In general, the working behavior of rhodium and iridium considerably resembles that of tungsten or molybdenum, but the temperature level is somewhat lower.

The Forming and Cutting of Gold Alloys

By H. R. Stegeman*

THIS ARTICLE is a brief discussion of the forming and cutting of carat gold alloys, including gold-filled parts.

Forming. Hard rolled strip may be blanked, and the blanks may be bright annealed for approximately an hour at about 650 C, or the strip can be annealed before blanking. Blanking dies are usually made of a "nondeforming" oil-hardening tool steel. Use of the high-carbon high-chromium type of steel may be justified if extremely long runs are anticipated. Cupping and drawing dies of SAE 3140 steel are preferred and are used with a lubricant consisting of paraffin oil plus 22 oz of vaseline per gallon. Drawn parts are bright annealed in a furnace with a controlled atmosphere for 20 to 25 min at 650 C.

Forming dies of carbon steel containing 0.90 to 0.95% C are used for both preliminary forming and final forming. The parts are bright annealed between these operations, are scratch-brushed, using water and soapbark, and are then dried before the final forming or coining, which is done dry.

* Wadsworth Watch Case Co., Dayton, Ky.

Cutting. When possible, gold alloys are machined after moderate cold reduction; 20 to 30% is suitable. Castor oil is the preferred lubricant. Sulfurized lubricants would bring in many complications and therefore are avoided. Facing cuts on the lathe are made at a speed of 350 ft per min with carbide-tipped tools. Grooving is done at 115 ft per min with a high speed steel tool. For drilling, carbon steel drills are used, and a speed of 5000 rpm is typical for a drill 0.040 in. in diam.

Mill facing is carried out at 470 ft per min with a spiral high speed steel milling cutter. Spot facing is done at speeds of 200 to 400 ft per min with carbide-tipped cutters. Chromium-plated cutters have somewhat longer life than uncoated high speed steel cutters. Small high speed steel saws are operated at 400 ft per min.

In machining gold-filled parts, most of the cutting may be in the core metal, and the choice of cutters thus depends partly on the nature of the base metal. With nickel silver cores, carbide tools are satisfactory for light cuts, as in lathe and spot facing, while high speed steel is better for pure nickel cores.

Joining and Cladding Precious Metals

IN THIS article the joining of precious metals is discussed under the following headings: resistance welding of precious metals, joining of platinum and palladium, brazing of sterling silver articles, resistance brazing of gold alloys, dental gold solders, cladding with gold and silver and their alloys, cladding with platinum and palladium and their alloys, and induction heating for cladding.

Resistance Welding of Precious Metals

By E. F. Holt*

In industries that produce jewelry, dental mountings, electrical contacts, optical aids and such, many of the precious metals and alloys are successfully joined by resistance welding. Binary alloys of gold and copper, ranging from 14 to 24 carats, and many of the ternary alloys of gold with copper, silver and nickel, are resistance welded for assemblies of watchcase and strap, nose bridges for eyeglasses, costume jewelry and dental mountings.

In general, welding is done by means of small, bench-type resistance-welding machines, ranging from ½ to 5 kva, depending on the size and shape of the work parts. Welding pressures range from 2 oz to 6 lb. Small synchronous timers for controlling the duration of the welding current are recommended for this type of work. The recommended weld time is usually from ½ to 2 cycles.

* Metallurgical Research Department, P. R. Mallory & Co., Inc., Indianapolis

Gold-filled materials are rarely resistance welded because of difficulty in avoiding exposure of the base metal. Instead, soldering and brazing are usually employed for joining gold-filled materials.

Hard Alloys. Extremely hard alloys of osmium and ruthenium, generally plus other platinum metals, are frequently used for tipping fountain pen nibs. Small pieces of the alloys are resistance welded to 14-carat gold pen nibs to provide the wearing surface. The resistance-welding equipment for welding pen nibs is generally automatic, but the welding conditions are similar to those described for welding gold alloys.

Silver Alloys. Fine silver and silver-base alloys are used extensively for electrical make-and-break contacts and are resistance welded to many types of base-metal switch and relay parts. Solid fine silver and silver alloys are difficult to join together by resistance welding because of their relatively low resistivity. However, the materials are readily welded to many base metals that have higher resistivity and that alloy readily with silver. For example, fine silver contacts, coined or headed with a welding projection on one side, may be readily welded to contact arms made of such materials as nickel silver, phosphor bronze, copper-nickel, beryllium copper, yellow brass and similar metals. A typical electrode arrangement for such applications is shown in Fig. 1.

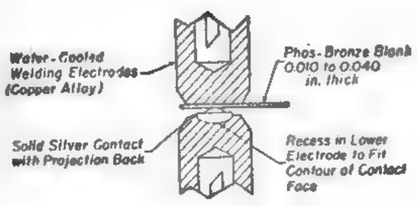

Fig. 1

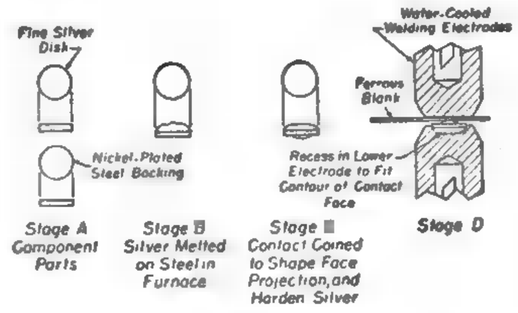

Fig. 2

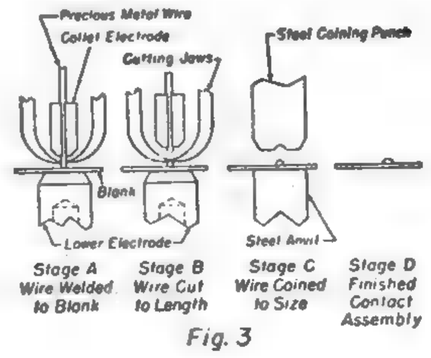

Fig. 3

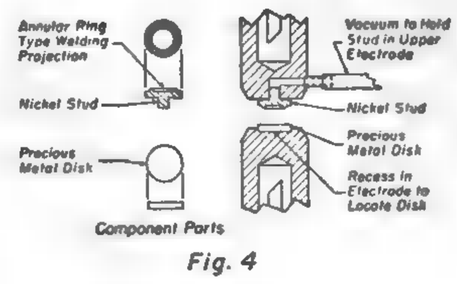

Fig. 4

Fig. 1 Resistance welding solid silver contacts to bronze blanks. Fig. 2 Fabricating and resistance welding silver-faced steel-backed contacts. Fig. 3 Resistance welding precious-metal contact assemblies. Fig. 4 Resistance welding precious-metal contact disks to nickel studs.

The welding conditions required for a silver contact ¼ in. in diam with a projection back are: duration of welding, 10 cycles; electrode force, 150 lb; and welding current, about 6000 amp.

Electrode arrangements similar to that shown in Fig. 1 may be used to weld any of the precious metals and alloys that are capable of being coined or headed to raise the required welding projection. Pure platinum and palladium are examples of other precious metals capable of being worked to provide a welding projection.

In welding silver contacts to ferrous metals, it is desirable first to attach the fine silver contact to a steel backing, which may be made with a welding projection. The precious-metal facing may be attached to the steel backing (generally nickel-plated) by furnace brazing with silver solder, or by melting the precious metal on the steel. A patented process used for producing bimetal contacts for resistance-welding applications is shown in Fig. 2. The backing may also be made of such metals as monel, nickel and the like, where greater resistance to corrosion is desired.

Many contact assemblies are resistance welded; for this purpose silver, platinum, palladium and their alloys are used in wire form. First the end of the wire is welded to the blank; then the wire is cut off close to the blank, and the welded wire is coined to the proper contact dimensions.

In Fig. 3 is shown the sequence of operations that an automatic welding machine performs in one cycle. The welding conditions are usually: duration of welding, 1 to 6 cycles; force, 1 to 2 lb; welding current, 1000 to 2500 amp.

Platinum and Palladium. Platinum, palladium and their alloys containing iridium or ruthenium are frequently resistance welded to nickel and nickel alloys by the projection method. The nickel blank is generally headed from wire; a welding projection is thrown up during the heading operation. A typical assembly is shown in Fig. 4, which also presents a welding electrode arrangement. Welding conditions for such an assembly, using a precious-metal contact disk about ¼ in. in diam and 0.040 in. thick, would be: duration of welding, 6 to 12 cycles; electrode force, 250 lb; and welding current, 6000 to 8000 amp. Platinum wire is resistance welded to platinum-rhodium alloy for thermocouples using small condenser-discharge welding controls. Platinum wire mesh is fabricated by cross-wire welding with similar equipment. Peak welding currents of 1000 to 3000 amp are required for welding platinum wires of small diameter; the duration of the discharge is from 2 to 10 milliseconds. A force of a few ounces is frequently used.

Joining Platinum and Palladium

By R. H. Atkinson*

Platinum and palladium can be joined by hammer welding at about 1200 C; by welding just short of fusion, with or without a small amount of solder that melts at about 1600 C; by complete fusion, as in joining thermocouples; by electrical resistance welding; or by soldering. In soldering, pure gold is used for uniting platinum-clad chemical equipment; while for platinum jewelry, solders are used that contain approximately 60 to 70% Au, with the remainder largely platinum metals in order to make the solders white and to provide a sufficiently high melting point. Solders that melt within the range from 1300 to 1500 C are most popular for platinum jewelry. Parts are first assembled by welding or by soldering with solder that melts at 1500 C, while subsequent soldering is done with a solder that melts about 100 C lower than that used previously. Solders melting at 1400 C or lower are used with palladium. For repair work, solders are available that melt as low as 1000 C.

Strict cleanliness and freedom from grease are required in all welding or soldering operations that involve the noble metals. The parts to be united may be filed lightly with a clean file and then fixed in proper relation to each other. Very small pieces of the appropriate solder are placed at the joint with the aid of a small camel's-hair brush moistened in a solution of borax. The joint is then heated, slowly at first, by a small flame of city gas mixed with oxygen or by an oxyacetylene flame, until proper fusion occurs; overheating must be avoided. For palladium, the oxyacetylene flame is decidedly advantageous* and should be oxidizing. Under this condition, palladium maintains a good surface that is easily polished. Reducing flames are undesirable for palladium, since a reducing flame of city gas mixed with oxygen will embrittle the surface. The temperature of the acetylene flame is high, and for soldering jewelry it is desirable to use a tip with a diameter of 0.4 mm across the orifice. This small hot flame has the added advantage of localizing the heat at the joint to be soldered, without disturbing joints previously made.

Difficulties in soldering may be caused by the following factors: dirt, excessively wide joints, excessive heating, insufficient flux (particularly with the lower-melting solders), or the stressing of the solder while it is near the melting point.

Brazing of Sterling Silver Articles

By Henry B. Smith*

Preparation and Cleaning. The removal of oil, grease, dirt and scale is essential. This can be accomplished by using hot alkaline cleaners or by degreasing with suitable oil solvents and pickling in acid if oxides are present. Cyanide solution is also useful in removing tarnish films.

The surface is prepared ordinarily by mechanical means, such as shaving, turning, filing and scraping. As with other metals, a closely fitted mechanical joint is superior to one with larger seams and openings.

Flux. Solutions of borax or boric acid, sometimes plus sodium fluoride, are used with or without a wetting agent. After application of wet flux, the article should be dried before soldering. A reducing gas, used advantageously in furnace brazing, permits a minimum use or, with some kinds of work material, a total absence of flux, and maintains a clean bright surface on the brazed article, so that no subsequent cleaning operation is required. The gas does not need to be strongly reducing; a content of 2 or 3% hydrogen is enough to prevent the occurrence of "fire" in the silver article. (Fire is oxidation of the copper in the sterling

* R. H. Atkinson and G. P. Gladis, A Study of the Behavior of Rutheniopalladium in Torch Flames, with the Object of Improving Soldering Techniques, Trans AIME, 166, 426, (1946)

* R. Wallace & Sons Mfg. Co., Wallingford, Conn.

silver.) Boric acid is useful also for coating the work piece away from the joint to protect it from oxidation during torch soldering.

Methyl borate is sometimes used as a flux and is introduced in the gas line to the torch. It will protect the surface on which the flame impinges, imparting a green color to the flame.

Solder. ASTM solders 3, 4, 5 and 6 (*see* page 80) are used, as well as a lower-melting solder in which some of the zinc has been replaced by cadmium.

Form of Solder. Solder is often used in granular or wire form, but in furnace brazing, strips or stampings in the form of washers or gaskets may be employed. A gasket fitted to a closely machined joint will give the best results, and incidentally use less solder.

Supporting the Work. Jigs or fixtures are sometimes used to support the article while it travels through the furnace. These should be as light as possible to keep the dead load at a minimum. Supports of this kind can be made from heat-resisting alloys, stainless steel, or nickel alloys.

In torch soldering, turntables are used to hold the articles so that flame can be played over all parts with more or less uniformity.

Component parts of an assembly can be held or stitched together satisfactorily by a putter welder, which holds the parts in alignment for the actual brazing operation.

Torch. Torches using city gas and air provide a suitable means of heating. The flame should be slightly reducing for the best results and large enough to cover the articles satisfactorily.

Bottled gas, such as propane or butane, can be used if provided with suitable torches. If oxidation occurs in the sterling silver, it is ordinarily necessary to remove a film of metal containing copper oxide. This is done by immersing the oxidized area for a definite period, usually less than one minute, in a warm solution of one part nitric acid and two parts water, at approximately 54 C.

Furnaces. Gas-heated or electrically heated furnaces are the types ordinarily used. They are of either the batch type or the conveyer type, according to the amount of production that is needed. The batch type is more economical as far as atmosphere gas is concerned, but has a smaller capacity for a given size of hearth than the conveyer type.

The conveyer type of furnace usually gives a very uniform product, since the temperature is controlled automatically. If the capacity of the furnace is not exceeded, a markedly uniform product can be secured. The duration of cooling should be long enough for the sterling piece to reach a point between 70 and 150 C before exposure to the air; otherwise a slight discoloration is likely to occur.

Resistance Brazing of Gold Alloys

By Carl Samans*

In joining small parts, as in the manufacture of spectacle frames and some types of jewelry, resistance heating by direct passage of a low-voltage current through the joint is used and the parts are held in suitable clamps. Through proper design and location of the clamps and the surfaces of contact, the process can be closely controlled to liberate the heat exactly where it is needed. Copper (both OFHC and free-cutting), silver, tungsten and Elkonite have all been used for the contact surfaces. For this work on a small scale, 500 to 600 watts is required; and 200 to 300 amp at 1 to 3 volts is normal for soldering a section about 0.07 in. in diam.

The brazing alloy in wire form is fed through an insulated pencil to the articles, which are preassembled and held in place by the contacting jaws. The heating continues as long as desired, and is subject to constant control by the brazing wire, which can be used as a make-and-break contact switch. By this method, such widely different parts as gold-filled iron or stainless steel, solid 10-carat gold, and gold-filled nickel or 10% nickel silver have been brazed together successfully. Staining can be kept at a minimum by use of the proper fluxes—ordinarily borates or phosphates, often containing a small amount of a fluoride.

Dental Gold Solders

By Walter S. Crowell*

Dental gold solders are alloys of gold, silver, copper, tin and zinc. Small quantities of active deoxidizers, such as phosphorus, may be added to improve resistance to oxidation. Copper is replaced by nickel to produce solders approximately matching white or platinum-colored plate and wire. Copper and silver are varied to control color and working characteristics.

The precious-metal alloys on which gold solders are used have a high precious metal content and are confined to a relatively limited range of composition. Dental alloys are almost always soldered in an open flame. The solders are formulated for desirable properties under these conditions.

Applications. In dentistry there are two broad classes of applications for gold solder—orthodontia and crown and bridge work. In orthodontia the high-strength wires of precious metal described on page 1120 of this Handbook are joined. In crown and bridge work, parts made of 22-carat gold plate and the high-strength wires are assembled. In many instances the solder not only serves to join the parts but is also used in bulk as part of the structure itself. Complicated appliances may require assembly in steps by successive soldering operations, making it necessary to use a series of solders with graded melting points.

Composition. The gold content of dental solders varies between 40% and 85%. Most of the solder used contains between 58% and 65% Au. When solders contain less than 58% Au (about 14 carats), resistance to corrosion and tarnish decreases rapidly; consequently, appliances joined by such solders are unfit to remain continuously in the mouth. For repairing soldered structures, it is usual to employ lower-carat solders because of their lower melting temperatures. Lower-carat solders are often preferred for orthodontic soldering, since high temperatures tend to affect adversely the physical properties of the wires used in constructing appliances. Tarnish and corrosion are not serious factors, because these orthodontic appliances are not worn for extended periods. High-melting, usually high-carat, solders are required where stepwise assembly is practiced. High-carat solders are useful also where close matching of the color of high-carat plate is considered necessary.

Typical compositions and characteristics of solders are given in the table below. Hardness data represent averages of the class. Melting ranges are extreme limits.

Class	Composition, percentage[a] Gold	Silver	Copper	Bhn (as cast)	Melting Range, deg Cent
Low-carat	45	30–35	15–20	140	816–691
General-purpose	60	12–22	12–22	110	835–724
High-carat	80	3–8	8–12	80	871–746

(a) All three solders contain from 2 to 3% Sn and from 2 to 4% Zn.

When gold, tin and zinc contents are constant and copper and silver are varied, significant differences in working characteristics are obtained with only a small change in melting point (liquidus); also changes in color are produced. High-copper alloys have a rich goldlike color, while high-silver alloys are lighter and less goldlike.

Melting Range. The melting range of high-silver alloys is relatively shorter than that of high-copper alloys. When flowed on high-carat gold plate, the sharp-melting solders spread freely with a minimum of attack on the plate itself. The high-copper alloys, which have a longer melting range, attach themselves to the plate before they are entirely melted. On continued heating, they do not spread over the plate, but alloy with it and finally "burn through".

Flowing and Burning Through. These phenomena of flowing and burning through occur when the usual dental wrought plate and wire alloys are soldered. Variations in melting range are not the only cause of the observed behavior. An important consideration is the melting point of the alloy that is formed when the solder diffuses into the part being soldered. When the high-carat wrought gold dental alloys are used, the resulting alloy melts at a higher

* Supervising Chemical Engineer, S. S. White Dental Mfg. Co., Philadelphia

temperature than the high-silver solders, and at a lower temperature than the high-copper solders. This is probably the factor that determines whether the solder flows out over the parts or "burns through".

The free spread or flow of the high-silver solders and their slow rate of attack on the pieces that are being joined, are characteristics that recommend them for use when parts are well fitted, and when it is important to retain as far as possible the original properties of the pieces.

The high-copper solders are useful when it is necessary to add material to a part that is deficient in size because of wear, accident or design. A skillful operator can build up this type of solder, layer by layer, until a considerable bulk of metal is obtained. Such a practice is followed in the construction of soldered bridgework, where fitting surfaces are made of wrought plate and the remainder of the piece is built up of solder.

In the general-purpose solders, the composition is chosen so that neither "build-up" nor "flow" is overemphasized, and a material is obtained that incorporates a useful compromise in these properties.

Process. A discussion of the process of soldering with gold solder would be a repetition of what has been said in the article in this Handbook on silver brazing (page 78). The same principles apply to both procedures. Surfaces must be clean and well fluxed. (Borax glass is an excellent flux.) Parts must fit together closely and reducing flame must be applied.

Gold solders are used principally in the jewelry industry and in dentistry, and to a small extent in electronics.

Cladding With Gold and Silver

By Ermand H. Davignon*

The bonding of gold and silver and their alloys to base metals is a process that is being developed increasingly. Many physical and mechanical properties of base metals, highly desirable for certain applications, cannot be duplicated in the gold or silver alloys alone; but when these base metals are combined permanently with gold or silver alloys by cladding, new applications can be developed.

It is sometimes difficult to obtain the desired color and composition in a gold alloy and at the same time have the physical and mechanical properties that are optimum for the intended use. In many instances the cladding of a desirable base metal with a gold alloy of a definite carat and color, in the correct proportions, will give necessary mechanical properties unobtainable in the gold alloy alone.

The composite of fine silver (or suitable silver alloy) clad on the proper base metal has desirable spring qualities, greater hardness, and the ability to be spot welded. In addition, the silver can be clad with a predetermined thickness of solder for subsequent joining in subassemblies.

Methods. On flat sheet stock, the gold alloy to be bonded is proportioned in thickness to the base metal, in order to provide the specified ratio by weight for a composite article. For example, 1/10 12-carat "gold filled" would require a sheet of 12-carat gold (50.0% Au) approximately 0.056 in. thick, to be bonded onto a base-metal bar approximately 0.750 in. thick. The exact thickness of the 12-carat gold is determined by careful weighing so that the gold alloy will equal 10% of the composite assembly.

Some methods by which gold, silver and their alloys have been clad are described here:

Dry Bonding. By this method two or more surfaces can be bonded together without solder, by the application of heat and pressure. The temperature should never be allowed to exceed the solidus point of either metal. Dry bonding is sometimes referred to as "sweating".

Moist Bonding. This method makes use of a solder that has a wide plastic range before its melting point is reached. The liquid present in the solder is utilized while other phases are still solid.

Wet Bonding. This method joins metals with a solder that is completely liquid at the time of bonding.

Welded Bonding. Two metal surfaces are joined together without solder, in this method, while the temperature remains in the plastic range of one or both of the metals to be joined, never reaching the liquidus temperature before completion of the bond. The liquid of the joined metals is used to form the bond.

Puddled Bonding. This is the melting of one metal onto the surface of another that has a higher melting point.

Conditions of Operation. In cladding gold, silver and their alloys on base metals, four major requisites are necessary in order to insure results that will meet high standards.

1 The surfaces of the metals to be joined must be thoroughly cleaned.

2 The cleaned surfaces must be kept free from oxidation during the heating cycle, either by a flux or by suitable control of atmosphere.

3 The mode of heating and its control should be such that the temperature of the entire bar is uniform at the end of the heating cycle, and has the correct value for proper bonding.

4 Pressure should be applied during the heating cycle or at the termination of the cycle and should be held constant until a strong bond has been developed over the entire surface. Pressure is secondary to temperature in the bonding of metals, provided *complete* contact is effected at the proper time. The pressure necessary to produce a bond of high quality depends on several factors, such as the composition of the metals, the area of the surface, the thickness of the base metal, the temperature employed to effect the bond, and the method used for bonding. For example, if a base metal of 90% Cu, 10% Zn is to be clad with a gold or silver alloy, pressures would be as follows, on a bar one inch thick:

Dry bond	3000 to 4000 psi
Moist bond	1000 to 2000 psi
Wet bond	500 to 1000 psi
Welded bond	2000 to 3000 psi
Puddled bond	None

These pressures should be lower for metals that are less malleable at the temperature of bonding, such as tin bronzes, 70–30 brass, and gilding metal; and should be higher for metals such as Inconel, steel and pure nickel.

Solders used in cladding precious metals to base metals should be free from cadmium and low in zinc content. These two metals, having comparatively low boiling points, are undesirable in a solder to be used for cladding, since they frequently cause trouble by distillation, which may result in future blisters under certain conditions. Solders should be ductile enough to allow the clad metal to be rolled without danger of the bond becoming brittle. The melting point of the solder used must be high enough to allow for subsequent annealing and soldering of the finished composite metal without damage to the original bond. Metals to be clad are wired, clamped, or wrapped with sheet metal, steel plates and sheet asbestos before bonding. Furnaces that bond clad metals successfully are of the open-box gas-heated, salt bath, closed-box (electric-resistance or gas-heated) and bell types. Also, as a recent trend, high-frequency electric heating is being used for cladding precious metals.

* Metals & Controls Corp., Attleboro, Mass.

Cladding With Platinum and Palladium

By F. E. Carter *

Platinum, palladium and their ductile alloys can be welded or brazed to silver or to base metals by the same general procedures employed in cladding with gold or silver. However, welding is ordinarily preferred for the platinum metals, since it permits the use of higher annealing temperatures with minimum damage by diffusion, and permits the use of pure gold or related high-melting solders for final assembly. In any event, the possible melting of the alloys that are developed at interfaces must be avoided. The minimum melting point in the palladium-nickel system is 1240 C; in the platinum-nickel system, 1400 C. Cladding is most easily done on nickel cores, and less easily on silver, copper, and molybdenum. Molybdenum is very difficult to clad.

* Baker & Co., Newark, N. J.

The plates of platinum and base metal may have a ratio of thickness between 1 to 1 and 1 to 100. After bonding, the composite block is cold rolled to the thickness required for utilization as sheet, or blanks may be cut from the stock, to be pressed and drawn into seamless tubing. The cladding may be applied to one or both surfaces of the base metal; consequently, seamless tubing is available clad on the inside, on the outside or on both surfaces. Similarly, rod and wire with outside cladding are fabricated from platinum tubing welded to silver and base-metal cores. From these elemental forms, a large variety of chemical and electronic equipment may be constructed. Strip that is clad with palladium or platinum is used for electrical contacts, and platinum-clad molybdenum and molybdenum-nickel wire are used for grids in VHF (very high frequency) electronic tubes.

Applications. The development of clad equipment for heat exchangers has been most successful. Heating and cooling coils, bayonet and candle heaters, and evaporators have been built with the tubes and tube sheets. Platinum-clad anodes are being used increasingly as insoluble anodes in electroplating processes, and often as supplementary anodes in the electrodeposition of nickel on intricate shapes, to secure uniform deposition despite the irregularities. Long experience has indicated that the platinum thickness should not be less than 0.004 in. where plant equipment is concerned. Usually a thickness of 0.005 in. is recommended as the minimum; 0.010 in. is desirable. Before installation, all clad materials can be thoroughly tested with acids for continuity of the platinum surface, and methods are available for repairing minute punctures in the cladding.

If clad material is to be used at temperatures higher than about 700 C, the rate of diffusion of the base metal into the platinum and of platinum into the base metal must be considered, and if the composite is to be used in atmospheres that would oxidize the core material, the rate of diffusion of oxygen through the platinum is important, because oxygen, reacting at the metal-to-metal interface, will oxidize the base metal and ultimately damage the cladding. The duration of usefulness increases rapidly in length with an increase in the thickness of cladding. Fortunately, the diffusion rate of nickel and copper into platinum is rather low; at 800 C, for instance, the diffusion rate for low concentrations of nickel into platinum is 1/600 of the rate of diffusion of nickel into gold at the same temperature.*

Platinum-clad silver has been used at temperatures as high as 750 C; this is considered a maximum for silver core material. Platinum-clad copper has been used at temperatures as high as 800 C, and platinum-clad nickel or steel at slightly higher temperatures. In any event, equipment operating at high temperatures requires individual consideration. Under some circumstances, a thin platinum tube may be inserted into a preoxidized nickel-chromium or stainless steel tube, or ceramic supports can be used.

Induction Heating for Cladding

By Carl Samans*

In the cladding process for the manufacture of 12-carat gold-filled wire, a core, generally of nickel or bronze, 1.3 in. in diam and 12 in. long, is slipped into a shell of gold alloy that weighs one-tenth of the total. A sheet of silver solder, 0.002 in. or 0.003 in. thick, and a trace of flux are interposed between the core and the shell; then the shell is drawn down to a snug fit. The assembly is placed within a cooled solenoid, fed by a 6-kva, 35,000-cycle tube converter, and is rotated slowly until the solder melts and effects a good bond.

In the manufacture of flat stock, arrangements have been developed so that external pressure can be applied simultaneously with the heating, which may be accomplished with a low-frequency (60-cycle) supply; about 75 kva is required.

A number of features involved in the above process were developed by W. J. Wrighton and T. C. Jarrett (U. S. Patents 2,273,609; 2,284,504; and 2,360,185).

Electroplating With Precious Metals

GOLD, silver, platinum, palladium and rhodium are electrodeposited on various base metals in order to obtain a surface that is pleasing in appearance, resistant to corrosion or oxidation, or high in reflectivity. Often one precious metal is plated on another precious metal as a finish. The more important plating solutions and conditions of operation are described here, and brief remarks are included concerning the usefulness of the electrodeposited coatings.

Gold and Gold Alloy Plating

By Louis Weisberg*

GOLD and gold alloy electrodeposits are generally produced in cyanide solutions, except in gold refining, where the chloride solution is used. A distinction is sometimes made between flashing or coloring (which involves very thin deposits, seldom much more than 0.00001 in.) and heavy gold plating. The only important difference lies in the degree of control and the amount of care required. Coloring is subject to precise control but, in practice, is usually judged by eye.

Color is a dominant consideration in many applications. A pure gold deposit normally has an orange cast. The color may be influenced to some extent by choice of temperature, current density and other variables, but most colors are obtained by plating gold alloys. Addition of copper makes pink or red gold; silver or cadmium makes green; nickel or zinc, white. So-called "white gold" deposits, at best, are hardly white enough to pass as such and are usually covered with a rhodium flash. A wide range of gold colors can be obtained; one color that cannot be matched by any of these alloy deposits, however, is the rich orange yellow of 24-carat gold.

* Louis Weisberg, Inc., New York

Table I. Composition of Gold Plating Solutions

Material	Grams per liter				
	24-carat	Red	Green	Yellow	White
Gold	1.5	1.5	1.5	1.5	1.5
Copper	...	1	...	0.8	...
Silver	...	...	0.1	0.15	...
Nickel	...	...	...	...	5
Zinc	...	...	...	...	0.5
Free potassium cyanide	8	8	8	0.2	3
Potassium carbonate	15	15	15	15	15

Combinations of three or even four metals may be employed to obtain the properties desired in the deposit. Some typical gold plating solutions are shown in Table I.

The compositions of some typical gold deposits are shown in Table II.

It is clear from comparison of Tables I and II that the proportions in which various metals are present are by no means the same in the deposit and in the solution.

Current density, temperature, and the content of free cyanide are just as important as the metal composition in the operation of gold plating solutions. In most gold

Table II. Composition of Gold Deposits

Material	Composition, percentage				
	24-carat	Red	Green	Yellow	White
Gold	100	94	97	75	85
Copper	...	6	...	8	...
Silver	...	...	3	17	...
Nickel	...	...	...	...	■
Zinc	...	...	...	...	10

plating, the temperature of the solution ranges from about 110 to 150 F. The middle of the range is preferable. High current efficiency is favored by high metal content, low current density, high temperature and moderate amounts of free cyanide. High content of carbonate decreases current efficiency. Increased free cyanide content raises the conductivity and improves the throwing power of the solution.

Cathode current density for ordinary gold plating should not exceed 5 or 10 amp per sq ft. If the solution is agitated vigorously or if there is rapid motion of the work material relative to the solution, the current density can be increased far beyond these values without much, if any, drop in current efficiency.

Anodes of gold or of a suitable gold alloy may be employed. Since these do not always dissolve at the same rate as that at which metal is deposited at the cathode, supplementary insoluble anodes are used occasionally. Some platers prefer to use only insoluble anodes and to replenish the solution by adding salts. Either method is satisfactory if adequate control is provided.

An ampere-hour meter facilitates control, especially if it is adjusted to signal when additions should be made. For this purpose, it is important to know the weight of metal deposited per ampere-hour as well as the composition of the deposit. With 24-carat deposits, the weight laid down per ampere-hour may approach 7.3 g; with alloy deposits, the weight per ampere-hour is likely to be about 2.5 to 3.5 g.

Thick deposits of alloy are sometimes brittle and require heat treatment to produce satisfactory physical properties. Heat treatment of such deposits often causes a change of color, on account of diffusion between the gold layer and the underlying metal. Where the underlying metal may be softened too much by the heat treatment, use can be made of an age hardening base metal chosen so that the same heat treatment is applicable to the base metal and to the gold coating.

Success in depositing gold alloys requires the maintenance of uniform operating conditions. Replenishment of the solution depends on the principle that what goes in must equal what comes out. Allowance must be made for loss of solution by drag-out as well as for the composition of the deposit. Uniform distribution of deposit, and deposition of the proper amount of gold on each piece are factors that rank in importance with the maintenance of color and physical properties.

Silver Plating

BY N. E. PROMISEL*

SILVER can be plated from a variety of baths, but except in special instances, the cyanide type of bath is the one used commercially. The basic constituents of this bath are silver, sodium or potassium cyanide to dissolve the silver as a complex salt, plus an excess quantity of cyanide (called "free cyanide") and either sodium or potassium carbonate. Generally the potassium salts are preferred, though they are somewhat more expensive. Potassium nitrate is sometimes used to replace the carbonate. To obtain semibright rather than matte white deposits, very small amounts of carbon disulfide, or in certain instances other brighteners, are added.

Most silver plating is done by using two baths in succession. (When steel is to be silver plated, it is given a copper "flash" or treated as indicated under Strike Solution, below.) The first bath, called the "strike" solution, has a low concentration of silver and a high cyanide content. This solution serves several functions, primarily promoting good adhesion and improving covering power and throwing power. The strike solution is used to produce only the initial flash coating and is rarely used longer than a minute or two. This "flashing" is then followed by silver plating in the second or "plating" solution, in order to build up the deposit to the desired thickness. In all instances the work pieces must have been cleaned well previously, pickled, and immersed in a cyanide dip.

* Bureau of Aeronautics, Navy Dept., Washington

The anodes used for silver plating should be the purest obtainable, in general not less than 999.5 fine. This is important because very small traces of certain impurities may cause "black anodes", that is, the covering of the anode by a blackish scum that interferes with corrosion of the anode and the composition of the bath, and may cause rough deposits. A high content of free cyanide minimizes this danger, especially at the higher current densities. The content of free cyanide should always be ample to ensure good corrosion of the anode. The ratio of anode to cathode areas should not be less than one to one.

For general purposes, the formulas of Tables III and IV have been used successfully; many modifications are possible.

Table III. Strike Solution for Silver Plating

Material	Range	Recommended
Silver cyanide[a]	0.25 to 0.87 troy oz/gal	0.62 troy oz/gal
(Metallic silver equivalent to above)	0.2 to 0.7 troy oz/gal	0.5 troy oz/gal
Sodium cyanide (free)	8 to 14 avdp oz/gal	10 avdp oz/gal
Temperature	.....	22 to 30 C, preferably 26 C
Current density	.....	15 to 25 amp/sq ft
Voltage	.....	Usually about 6 volts

(a) In plating directly on steel, a preliminary strike is used, containing about one-third as much silver. Fractions of 1 oz of copper cyanide per gallon may also be added, if necessary, to improve adhesion.

For the potassium cyanide and carbonate in the above plating solution, the cheaper sodium cyanide and carbonate may be substituted, in quantities of 2.5 to 5.0 oz avdp per gal and 3 to 10 oz avdp per gal, respectively. In instances when, for reasons of economy, 15 to 20 oz avdp of potassium nitrate per gallon is added to the "sodium" solution, the quantities of the other constituents are held to the lower part of the range. Agitation of the work material is nearly always desirable.

For contact with the solution, iron is a convenient and satisfactory material for tanks, anode racks and cathode racks, especially if its original tight black scale has not been removed. However, care should be taken not to contaminate the solution with chlorides. Ceramic material and glass may also be used where practicable, and several

Table IV. Solutions for Silver Plating

Material	Range	Recommended
Silver cyanide	2.5 to 4.3 troy oz/gal	3.7 troy oz/gal
(Metallic silver equivalent to above)	2.0 to 3.5 troy oz/gal	3.0 troy oz/gal
Potassium cyanide (free)	4 to 7 avdp oz/gal	5.5 avdp oz gal
Potassium carbonate	5 to 15 avdp oz/ gal	6.0 avdp oz/gal
Brightener (carbon disulfide dissolved in a cyanide solution)	.....	As needed (avoid excess)
Temperature	22 to 26 C	preferably 26 C
Current density	8 to 20 amp/sq ft	
Voltage	Generally not more than 1 volt, depending on the plating conditions and geometry of the setup	

synthetic plastics have been successful, such as phenol-formaldehyde and some polyvinyl types.

If proper attention is paid to minimizing drag-out and if enough anodes are used, the silver content of the bath will be maintained automatically at the desired value. If silver is needed, the best addition is a silver cyanide. While the bath is standing, as well as while it is in use, the free cyanide content will gradually decrease and must be replenished. The brightener disappears also, even when the bath is not in operation. It is better to add small quantities of brightener often than to add large quantities at one time. Impurities and dirt should be kept out of the solution, but few of the common impurities (except sometimes iron) give trouble. The carbonate content of the bath increases gradually. When more than 12 oz of carbonate per gallon is present in a "sodium" solution, and more than 15 oz per gal in a "potassium" solution, the excess should be removed either by adding gypsum and filtering or by lowering the temperature to very low values to precipitate the sodium carbonate.

For special applications, it may be advantageous to modify the plating conditions. For example, in plating bearings, higher temperatures, greater agitation, special racking, more concentrated solutions, and additions of potassium hydroxide, permit much higher current densities and give good, heavy deposits expeditiously.

Platinum and Rhodium Plating

By K. Schumpelt*

PLATINUM and palladium have long been electrodeposited, and the commercial deposition of rhodium, although more recent, has advanced rapidly. These metals can be deposited directly on precious metals as well as on copper and nickel and on copper and nickel alloys. When base metals and their alloys are to be electroplated, a nickel underplate is desirable, and is essential for plating on tin, zinc, and tin or zinc alloys.

Electrodeposits of platinum and rhodium are used for ornamental or decorative finishes and also for finishes that are to perform a definite function; for instance, as a permanent reflector, as protection against oxidation and finger stains, or as an oxide-free, hard, gall-resisting surface on sliding electrical contacts. Many essential parts in radar and other electronic equipment have been rhodium-plated.

Complex phosphate baths have long been used for depositing platinum; two such compositions are given below:

	A	B
Ammonium phosphate $(NH_4)_2HPO_4$	20 g	43 g
Sodium phosphate $Na_2HPO_4 . 12H_2O$	100 g	120 g
Pt as $H_2PtCl_6 . 6H_2O$	4 g	6.6 g
Water	1000 ml	1000 ml

Operating temperature, 90 C; current density, about 1 amp per sq dm; 3 to 4 v, with insoluble platinum anodes.

The above formulas give bright flash deposits at a pH of about 7. For building up heavier deposits, the bath should be made strongly ammoniacal. The rate of deposition is rather slow, about 8 mg Pt per amp-min.

The solution, which originally has an orange color, should be boiled until it becomes pale yellow. During this boiling, the platinic chloride is transformed into a complex ammino phosphate. Since the bath is operated with insoluble platinum anodes, the metal content must be replenished by additions of platinic chloride; after each such addition, the boiling should be repeated. Chlorides gradually accumulate in the bath to a point where good deposits can no longer be obtained.

To permit replenishment without accumulating chlorides, an ammino nitrite of platinum, called platinum "P" salt, containing 61% Pt, was devised. One bath based on the use of this salt has the following composition:*

Ammonium nitrate	100 g
Sodium nitrite	10 g
Platinum as diammino nitrite	10 g
Ammonia	50 ml
Water	1000 ml

Operating temperature, 95 C; current density, 6 to 13 amp per sq dm; 4 to 5 v.

This solution covers quickly and has rather good throwing power. For the building up of heavy deposits, a voltage of 2.5 and a current density of 6 amp per sq dm are recommended. The bath is replenished with platinum "P" salt, dissolved in ammonia.

Rhodium† is generally employed for producing rather thin, very white, highly reflective plates, that can be secured from either the sulfate or complex phosphate baths. In either instance the rhodium is generally supplied in the form of a concentrated solution.

Baths for rhodium plating are:*

	A	B
Sulfuric acid	20 ml	.....
Phosphoric acid	.....	10 to 40 ml
Rhodium (in prepared solution)	2 g	2 to 4 g
Water	1000 ml	1000 ml

Optimum operating temperature, 40 to 45 C; current density 1 to 8 amp per sq dm; 2.5 to 5 v.

Insoluble platinum anodes are used, and the bath is replenished with the concentrated solution of rhodium supplied by the manufacturer. The rate of deposition varies from 2 to [illegible] mg per amp-min for different types of solutions.

Where rhodium or one of the other platinum metals is to be applied to Invar, Kovar or stainless or ordinary steel, special treatment of the base metal is required to secure an adherent nickel plate. For outdoor exposure or at high humidity, the nickel plate should be 0.002 or 0.003 in. thick, since the surface is very noble, and if pores are present, rapid attack on the underlying metal can occur. For many purposes, rhodium deposits 0.000006 to 0.00001 in. thick are sufficient, but where heavier plates up to 0.001 in. are required, special sulfate solutions are employed.

* Baker & Co., Newark, N. J.

* Keitel and Zschiegner, U. S. Patent 1,779,436

† Editor's Note. For further discussion of the engineering properties and uses of rhodium electrodeposits, the reader may refer to an article by L. B. Hunt in Met Ind (London), 71, 339 (1947).

Palladium Plating

By R. H. Atkinson*

PALLADIUM in its use for thin decorative platings has been overshadowed by rhodium, which is harder and has higher reflectivity (80%, compared with 60%), but palladium is superior for thick deposits (0.0001 in. and thicker). The following bath[1] is suitable for thin decorative and protective plates:

Palladium (as dinitro-diammino palladium)	10 g per liter
Ammonium nitrate	100 g per liter
Sodium nitrite	10 g per liter
Ammonia (sp gr 0.880)	50 ml
Temperature	40 C
Anode (insoluble)	Pd or Pt
Current density	0.1 amp per sq dm

Another bath[2] has been developed for heavy deposits required in electroforming:

Palladium (as chloride)	50 g per liter
Hydrochloric acid	18 g per liter
Ammonium chloride	20 g per liter
pH	0.4
Temperature	70 C
Anode (soluble)	Very pure palladium
Current density	1 amp per sq dm

The ammonium chloride refines the grain size of the deposit, but since it makes deposits likely to blister when heated, it should be omitted or replaced by sodium chloride if the plated articles are to be heated subsequently. The palladium chloride and the palladium anodes must be extremely pure to yield ductile, heavy plates. Base metals that are attacked by hydrochloric acid should be plated first in the dinitro-diammino bath, or with gold.

In addition to the foregoing, other baths[3] have been found suitable for both thin and thick deposits.

Polishing Precious Metals

By H. K. Stegeman*

THROUGH all rolling and forming operations on articles made of precious metals, great care is used in maintaining the high quality of the surface; however, several additional finishing operations are necessary for producing the excellent quality of surface generally required. These operations include the removal of sufficient metal to develop an essentially smooth surface, and then buffing to develop the maximum specular reflectivity; or controlled, fairly coarse abrasion, to produce the "butler" finish. Scratch brushing also is sometimes used for producing a final finish, and is ordinarily employed as a cleaning operation before the last press operation, when the work is coined in highly polished dies.

Where the objects have sharp corners that must be preserved, or where they have rather large, essentially flat areas, lapping is the best surfacing method. In this operation the work piece may be brought into contact with either the end, side or circumference of the hard felt lap.

Lapping

1 Felt wheels, from ¼ to 10 in. in diam
2 Spindle speed, from 2000 to 3450 rpm
3 Compound, tripoli or a mixture of 600-grit aloxite and stearic acid

Lapping may be followed by a cutting buffing, or the buffing may be used instead of lapping on objects that have rounded contours.

Buffing

1 Cotton buffs, 64 by 68-weave and from 6 to 8 in. in diam
2 Spindle speed, from 2000 to 3450 rpm
3 Compound, tripoli

Brushing is used where the objects are very irregular or where decorations have appreciable depth.

Brushing

1 China hog-bristle brushes, 3½ in. in diam
2 Spindle speed, 3450 rpm
3 Compound, red rouge (greasy type)

* Wadsworth Watch Case Co., Dayton, Ky.

Following the lapping or cutting buffing, buffing with greasy rouge and color buffing with dry rouge are suitable for the usual gold alloys and silver, and provide the final specular finish desired.

Rouge and Color Buffing

1 Cotton buffs, 64 by 68-weave and from 4 to 8 in. in diam
2 Spindle speed, 3450 rpm
3 Compound, red rouge (grease or dry type as required)

For platinum and palladium, separate wheels are required in order to avoid transferring particles of gold to these metals, and thus causing a slight yellow cast. A cutting buff charged with tripoli is used and should be followed by cleaning in hot water that contains ammonia and soap. After this cleaning, white rouge is applied with the type of cotton buff described above, and the metal is cleaned with hot water, ammonia and soap as before. Red rouge is not desirable on the platinum metals.

Alternatively, a "butler" finish may be used as the final finish. It can be produced by the wheel method or by abrasion with a sharp cutting material such as 240 or 320-grit emery cloth.

Butler Finishing

Wheel Method.
1 Cotton buffs, 64 by 68-weave and from 6 to 8 in. in diam
2 Spindle speed, 1750 rpm
3 Compound, No. 240 grit greaseless

Hand Method.
1 Either 240 or 320-grit emery cloth
2 Abrading performed by hand

Scratch Brushing Carat Gold Alloys and Sterling Silver

1 Brushes
(*a*) German silver, 2½ in. in diam by ⅜ in. wide with wires ¾ in. long
(*b*) Brass, 1½ in. in diam by ⅛ in. wide with wires ¼ in. long
(*c*) Brass, 2½ in. in diam by ⅛ in. wide with wires $\frac{5}{16}$ in. long
2 Spindle speed, 1800 rpm
3 Lubricant, warm water or soapbark solution for press cleaning

The Metallography of Precious Metals

By E. M. Wise*

MOST SAMPLES of precious metals are small and require mounting before they can be examined microscopically. Because it is transparent, methyl methacrylate is generally preferred to bakelite as a mounting material. Where electrolytic etching is to be employed, small samples should be wrapped with a connecting wire before being mounted. This is unnecessary for large samples, since contact can be made with the face of the specimen in a region not to be examined.

Polishing. In polishing the precious metals it is extremely important to avoid surface flow, because shallow etches will be employed, and some of these metals have a marked tendency to pit during continued etching.

Grinding successively on 180, 240, 320 and graphited 400-grit silicon carbide papers is generally satisfactory. After the sample has been washed carefully, it may be polished on two 6-in. diam disks covered with unweighted flat silk crepe. The first disk runs at 300 to 500 rpm and is wet with a suspension of A. O. M303 or Fisher 12–300–3 abrasive, diluted 1 to 5. Four or five minutes on this wheel may be required for developing a good surface on the specimen. After the sample and the hands of the operator have been washed, further polishing is done on a disk wet with Rite Tonerde No. 3, diluted 1 to 2. This step may require two minutes, at 600 rpm.

* The International Nickel Company, Inc., New York

Etching. The most widely used nonelectrolytic etch is a mixture of equal volumes of 10% ammonium persulfate in water with 10% KCN in water.* Although the separate solutions are stable in air, the mixture must be used within a few minutes after being made. Since this solution and the fumes from it are poisonous, it should be used under a hood. The fumes also make tobacco smoke taste very unpleasant, but aside from these disadvantages, the mixture is excellent. When swabbed on specimens of the usual gold alloys and palladium alloys, the mixture acts rapidly and smoothly. It may be used also on silver and certain nickel alloys. For the more resistant alloys, 20% solutions may be employed.

These same metals can be etched when made the anode in a 5% KCN solution, but this is not effective for platinum and the usual platinum alloys, which are best etched with alternating current in a 5% NaCN solution at a current density of 0.5 to 1.5 amp per sq cm. Only one or two minutes is required for etching pure platinum at this current density. The cathode in this etching solution is platinum, and the voltage is from 1 to 5, preferably delivered from a low-voltage transformer fed from a small Variac. This etchant can be used also with palladium and gold alloys.

Another etchant widely used with the a-c etching pro-

* Adapted to metallography by E. M. Wise, from the work of M. C. Jewett, who developed this reagent for a somewhat different purpose.

cess, is a 20% solution of hydrochloric acid in water saturated with sodium chloride.[1] This can be used with most of the platinum metals, but rhodium is best etched with 20% H_2SO_4 in water, using alternating current.

Sterling silver and fine silver are usually etched by swabbing with a modified chromic-sulfuric mixture.* A concentrated stock solution is made, containing 100 ml saturated solution of potassium dichromate in water, ▮ ml saturated solution of sodium chloride in water, and 10 ml concentrated sulfuric acid, added slowly. One volume of this solution is added to 9 volumes of water before use.

Various etches are available for special purposes; for instance, pure palladium may be etched with concentrated cp nitric acid to which a trace of chloride has been added in the form of a drop of tap water per 20 ml of nitric acid.* For darkening certain precipitates in 14-carat Au-Cu-Ag alloys without attacking the matrix, a 25% solution of ferric chloride in water has been employed after adding it to an equal volume of a water solution that contains 3% H_2O_2.[2] Dilute aqua regia and various molten chloride mixtures containing oxidizing agents have been employed for etching platinum alloys, but the use of a-c etching has virtually eliminated interest in these.

PROPERTIES OF PRECIOUS METALS

SILVER AND SILVER ALLOYS

Silver

COMPILED BY E. M. WISE*

B *1 Important uses.* The photosensitivity of silver halide salts, particularly in sulfidized areas, and the ease with which silver can be reduced, are the basis of photography. Silver offers advantage over copper for electrical purposes, principally because of resistance to oxidation; it is used both solid and as an electroplate for contacts in electrical devices, and performs best where sufficient arcing and wear occur to keep the contact clean, and where the contact pressure, current and voltage are not too low. Other industrial uses are based on corrosion resistance, catalytic activity, ease of electrodeposition and, particularly in brazing alloys, on the moderately low melting point and good mechanical properties of many of the silver alloys. Uses in bearings also are important (*see* page 754). The high and uniform reflectivity in the visible region and the ease of deposition are responsible for use in reflectors and in silverware and jewelry. Resistance to corrosion by foods and organic acids is a factor in these latter uses. The first use of silver alloys for coinage probably resulted from appearance and moderate scarcity.

C *1 Density* at 20 C (68 F). 10.49 ▮ per cu cm (0.379 lb per cu in.).[2] 10.50 ▮ per cu cm computed from lattice parameter and atomic weight.[3] Density is lowered by cold work and probably by oxygen.

Solid, at 960 C (1760 F). 9.85 ▮ per cu cm (calculated from linear expansion data)

Liquid, at 960 C (1760 F). 9.3 g per cu cm
at 1100 C (2012 F). 9.18 g per cu cm
at 1200 C (2192 F). 9.1 ▮ per cu cm[14,15]

D *1 Melting point.* 960.5 C (1760.9 F) for *oxygen-free* silver. Freezing point in approximate equilibrium with the oxygen in the atmosphere (partial pressure of oxygen 149 mm Hg) is about 950 C (1740 F).[4,5] Freezing point is not lowered by carbon.

4 Vapor pressure of liquid silver.[7,8,9]

Temperature, deg Cent....	1190	1360	1580	1870	2212
Vapor pressure, mm Hg....	0.1	1	10	100	760

The rate of volatilization is quite high at high temperatures and is greater under oxidizing gases than under reducing gases.[6]

at 100 C (212 F).[16] 0.0568 cal per ▮
0 to 800 C (32 to 1472 F).[16]

$C_p = 0.055401 + 0.14414 \times 10^{-4}t - 0.16216 \times 10^{-8}t^2$

At 39.8 K, 0.00187 cal per g. Between 3 and 4 K, the value drops to 0.1% of that at 39.8 K

13 Latent heat of fusion.[3] 25 cal per g approx

15 Latent heat of vaporization.[2] 556 cal per ▮ approx

16 Thermal conductivity at 0 C (32 F). 1.0 cgs. This is about 8% higher than for copper, and shows only a small temperature dependence. Values of 1.018 cgs at minus 183 C (minus 297 F) and 0.85 cgs at 450 C (840 F) have been reported.[2]

19 Recrystallization temperature. Probably about room temperature, under extreme conditions.

E *1 Volume conductivity* referred to standard copper. 108.4% for extremely pure silver (105% referred to very pure copper)

2 Electrical resistivity at 20 C (68 F). 1.59 microhm-cm for extremely pure silver, melted and annealed in vacuo. This is 94.5% of that of equally pure copper.[19] 1.47 microhm-cm has been calculated for 0 C (32 F) from the temperature coefficient and the resistivity at 20 C.[20]

5 Temperature coefficient of electrical resistivity 0 to 100 C (32 to 212 F).[20] 0.0041 per °C. The temperature coefficient for minus 192 to 500 C[20] and from 500 C to above the melting point[21] is shown in Fig. 1.

At 20.4 K, R_t/R_o is about 0.01 and at 1.3 K, 0.0068.[22] Cold working silver increases its resistivity considerably, an increase of 5% for 90% reduction has been observed.[23] Annealing silver of commercial purity, successively in air and hydrogen, disrupts the grain boundaries and also increases the resistance.

Hydrostatic pressure reduces the resistivity slightly; 12,000 kg per sq cm causes a 4% reduction.[24] Tension also reduces the resistance slightly.

9 *Thermal emf versus platinum* (cold junction 0 C, hot junction at 100 C)[2] is plus 0.74 mv

F 1 *Reflectivity.* This value for clean silver is high in the visible and infrared, but shows a sharp valley in the near ultraviolet. The curve of Fig. 2 is from the work of several investigators,[27,28] whose data are in fair agreement in overlapping areas. As a result of the high and fairly uniform reflectivity in the visible range, silver is considered white, but if human eyes were sensitive to a slightly shorter wave length region, silver would be colored.

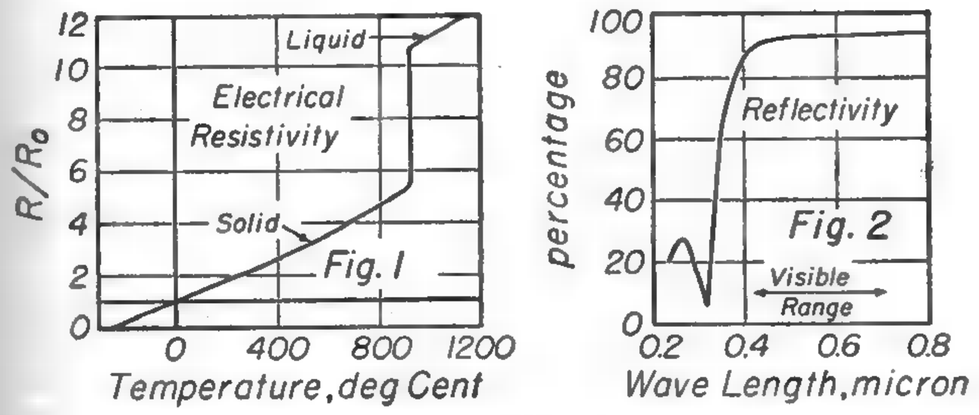

Fig. 1 and 2 Resistivity and reflectivity of silver

5 *Emissivity.* The emissivity of silver at 0.65 microns is extremely low and not known accurately, but values of 0.044 at 940 C (1724 F) and 0.072 at 980 C (1796 F) have been observed for liquid silver.[25] Other experiments on the relative emissivity of silver and a black body show no discontinuity at the melting point of silver, the emissivity being about 0.055 at about 700 C (1292 F) and increasing only slightly at 1800 C (3272 F).[26]

G 2 *Mass magnetic susceptibility.*[33] Minus 0.020 × 10^{-6} cgs

I 2 *Resistance to specific agents.*

Silver is resistant to acetic acid and has been used for condensers handling this acid. It is also resistant to various other organic acids and foods that are free from sulfur. It shows good resistance to phenol and to hydrofluoric and phosphoric acids. It is resistant to sodium and potassium hydroxides, is used in the laboratory for caustic fusions, and has also been considered for large equipment. It is attacked by moist bromine, iodine and chlorine and vigorously by HCl, HI and HBr. Alkaline cyanides, in the presence of air or other oxidizing agents, dissolve silver rapidly. Nitric acid that contains traces of nitrous acid attacks silver vigorously as does hot concentrated sulfuric acid. Hot dilute sulfuric acid also attacks silver. A more complete discussion is presented in the "Corrosion Handbook".[34]

Silver does not appear to oxidize at room temperature in air and thus differs from copper, but is attacked and blackened by ozone. Silver oxide however does exist and has extremely high resistivity. Sulfur attacks silver rapidly as it does copper, and the rate of tarnishing of silver in indoor atmospheres is determined by the supply of sulfur atoms, since the coating is nonprotective. This sulfide decreases the reflectivity of silver and also increases the electrical contact resistance, particularly at low currents, since it is nonohmic in character. The rate of sulfidation of silver indoors in a large city is of the order of 70 micrograms per sq dm per day.* Much work has been done searching for a tarnish-resistant high-silver alloy, but it appears that substantial additions of noble metals are required to achieve this goal, about 50% palladium[34]* or 70% gold being needed for complete resistance. Various protective plates have been used to protect silver from tarnishing. Of these, rhodium plate applied over a very thin nickel plate is the most successful and maintains a very pleasing appearance.

J 1 *Crystal structure.* Face-centered cubic; lattice parameter 4.0778 kX at 18 C (64 F).

K *Mechanical properties.*

Tensile strength and hardness. Considerable spread exists in values reported for both tensile strength and hardness of quite pure silver. An average of 18,200 psi for tensile strength has been reported[31] for 5-mm wire annealed at 600 C. Commercially pure silver (about 999 fine) annealed at 650 C had a tensile strength of 22,900 psi.[2] Work on the effect of oxygen on the hardness of annealed silver of various purities[32] indicates that oxidation of impurities during oxidizing anneals generally causes a substantial increase in surface hardness and restrains grain growth, effects that are absent in spectroscopically pure silver. Very pure silver had a Vickers hardness of 25 after a hydrogen anneal at 650 C, and 27 VPN after annealing in air at 650 C. 100 VPN was obtained on electrodeposited silver that had a higher electrical resistivity than wrought silver.*

Yield strength. 7900 psi (divider method) was reported for commercially pure silver.[2] The proportional limit for pure silver strained 5% and annealed 1 hr at 700 C is 670 psi. The 0.01% proof stress is 1100 psi.[29]

Elongation (over 20 mm) for 5-mm wire is 48%.[31] For commercially pure silver, 54% elongation.

Reduction of area for 5-mm wire.[31] 91%

Modulus of elasticity for silver strained 5%, then heated 0.5 hr at 350 C is 10,300,000 psi.[29] Another value from the same investigator is 11,300,000 psi.

Poisson's ratio for annealed silver is 0.37, and for hard drawn material is 0.39.[30]

N *Working data.* Because molten silver dissolves oxygen and evolves some of it on solidification, the oxygen content should be brought to a low level before the metal is poured. Where high electrical conductivity is required, purity must be maintained as with copper, but iron need not be guarded against. Sulfur is undesirable, as are many base metals. The solid solubility of oxygen in silver and the rate of diffusion of oxygen through hot silver are high; consequently silver of normal purity will be damaged if it is heated first under oxidizing conditions and then in hydrogen.[32,35]† Academically pure silver may not be damaged by this treatment.[32] The effect of heating first in hydrogen and then in air is probably negligible.[32]†

9 *Annealing temperature.* 300 C (572 F) is suitable for commercially pure silver, cold worked at least 50%.

11 *Suited to forming* by hot or cold methods, with high reductions, since the metal is extremely ductile.

Silver-Copper Alloys

By E. M. Wise*

THE SILVER-COPPER alloys have been used for thousands of years. These elements are reduced together in most refining operations. Traces of copper are likely to be present in commercial silver, and copper containing up to 30 oz Ag per ton is produced to provide a higher recrystallization temperature without impairing the conductivity of copper. Copper is effective in hardening silver, but lowers the melting point considerably and lowers the electrical and thermal conductivities appreciably.

Sterling silver must contain at least 92.5% Ag. The remainder is unrestricted but is normally copper since, in general, other metals have proved less desirable and are less effective hardeners. The 10% Cu, 90% Ag alloy is called "coin silver". The eutectic alloy contains 28.1% Cu.

Although sterling silver can be age hardened without difficulty, and part of the merit of this composition in providing acceptable properties after miscellaneous treatments, results from some hardening on cooling in air, the fact that this alloy can be age hardened escaped notice by metallurgists for more than 1000 years. Substantial hardening can be obtained by simple treatments, as was discovered in 1922 from tension tests on sterling silver quenched from 650 C, and also after annealing at 650 C and aging at 325 C for 30 min.[2] The quenched material had a tensile strength of 37,400 psi, and a yield strength of 19,700 psi, with 42% elongation, while the quenched and aged material showed a tensile strength of 43,400 psi, and a yield strength of 30,000 psi with 25% elongation. This was discovered independently by Fraenkel in 1926,[3] and in 1927 by Norbury,[4] who performed tension and hardness tests on sterling silver quenched and aged for ½ hr at a series of temperatures. Numerous investigations have since been made concerning the hardening process[5-8] and the correction of the equilibrium diagram.

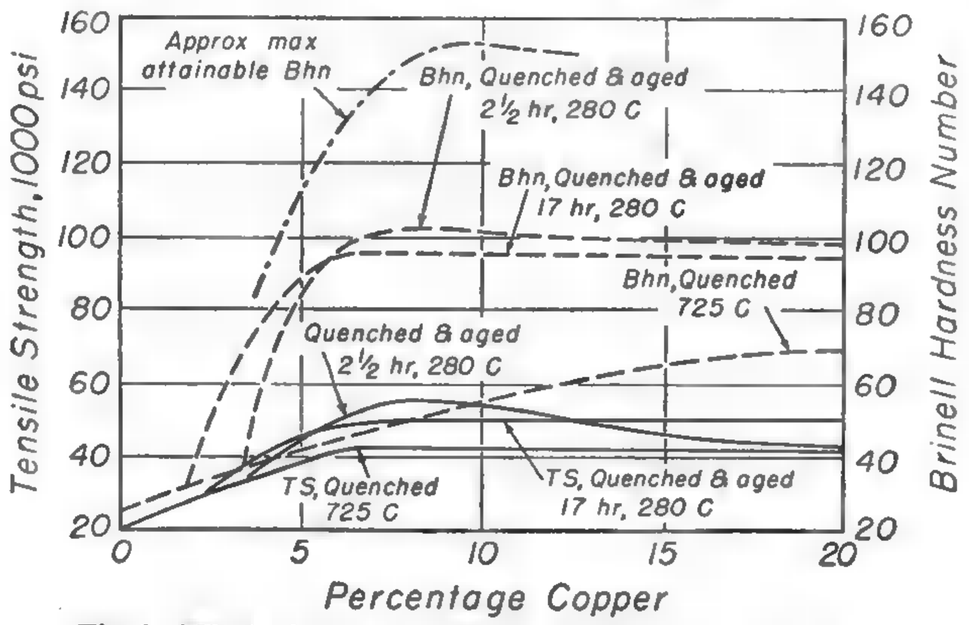

Fig. 1 Effect of copper content on the tensile strength and Brinell hardness number of silver-copper alloys

Leach and Chatfield[14] conducted tension and ductility tests on sterling silver variously annealed and air-cooled or quenched. These investigators demonstrated that material annealed above 650 C was harder when air-cooled than when quenched, and they showed particularly that for general use, where neither quenching nor age hardening is contemplated, annealing at 650 C is most suitable. Fraenkel and Schaller[5] determined the tensile strength, hardness and resistivity for alloys containing from 2 to 20% Cu quenched from 725 C and variously aged. Figures 1 and 2 are based principally on the work of these two men. Higher values for resistivity and for hardness after aging, can be secured in most of the alloys by the use of slightly higher quenching temperatures or somewhat different aging cycles. Approximate maximum values for hardness are shown in Fig. 1.

The solubility of copper in silver at 650 C is about 4%, and at 725 C about 6%, so sterling silver processed at these temperatures is duplex with small amounts of the copper-rich phase scattered through the silver-rich matrix. Aging treatments cause precipitation of the copper-rich phase and, if prolonged, increase the electrical conductivity considerably. Annealing for some time at 770 C produces a coarse-grained single-phase alloy that is somewhat harder, has lower conductivity, and perhaps is less ductile than material annealed at lower temperature, but is more responsive to age hardening.

Coin silver will remain duplex after any annealing treatment, and ages in much the same manner as the 7.5% Cu alloy. Both alloys respond to an aging treatment of 2 hr at about 280 C or 1 hr at 300 C. The mechanical properties of coin silver are virtually the same as those of copper sterling after the usual annealing treatments at about 650 C, since the composition of the silver-rich phase will be the same. Alloys containing 20 to 30% Cu have much more of the copper-rich phase, which does not age harden at the temperature suitable for the silver-rich alloy, and therefore the hardness of the higher-copper alloys is usually lower after aging.

Many articles made of sterling or coin silver are left in the cold worked condition and may be hard enough in that condition, but where hard soldering has been done and the cooling was rapid, a final aging treatment will greatly improve the article, increase its yield strength, and minimize denting. It is probable that the low-temperature aging treatment could be applied to advantage to many old articles.

Resistance to Corrosion and Oxidation. At ordinary temperatures, the presence of copper in solid solution in silver will have little effect on the resistance of the metal to corrosion. The presence of small areas of the slightly less noble copper-rich phase might be expected to cause difficulty because of electrolytic effects, but apparently the difference between the potentials is small enough for the duplex alloys to behave satisfactorily in their usual applications. In sea water, however, and in similar electrolytes, some selective attack may be anticipated.

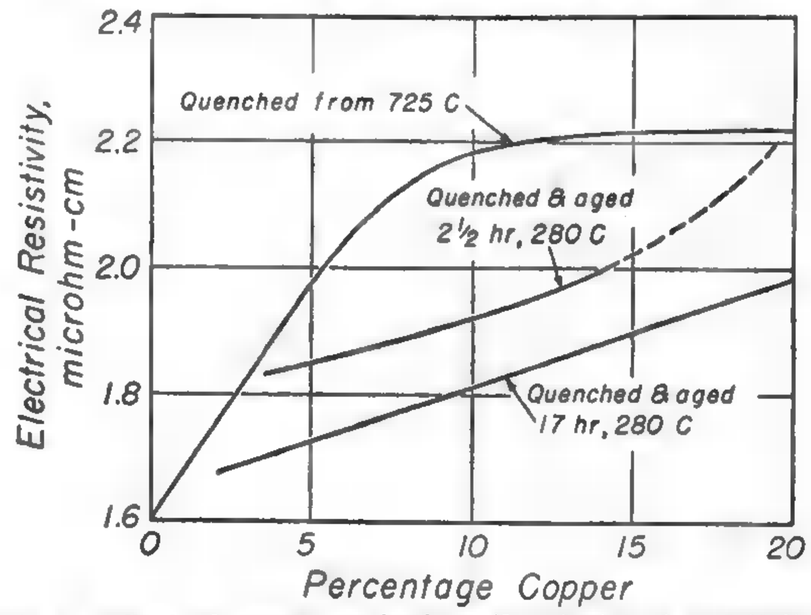

Fig. 2 Effect of copper content on the electrical resistivity of silver-copper alloys

At slightly elevated temperatures, copper oxidizes selectively. This behavior is of some consequence in electrical contacts, since it necessitates higher contact pressure. At approximately 600 C, oxidizing atmospheres will cause rapid oxidation of the copper and oxygen will diffuse to a considerable depth, forming a substance called "fire".[13,14] One hour of exposure to air at this temperature will oxidize the 7.5% Cu alloy to a depth of 0.003 in.[13] This was formerly very troublesome but with the production of well-deoxidized alloys and the use of nonoxidizing atmospheres, effects from the oxidation of copper have been minimized.

Because sulfur tarnishes the silver-copper alloys in about the same way as it tarnishes silver, sulfur must be excluded or the silver must be protected by appropriate

* The International Nickel Company, Inc., New York

coatings, such as rhodium over nickel. if appearance is to be maintained without polishing.

Processing. In the melting of the alloys, the oxygen content should be brought to a low level before pouring at 1050 to 1100 C.[13] Where the electrical conductivity is not important, final deoxidation with 0.05% P is convenient. Cadmium has been used as a partial deoxidizer; 0.5% or more is required. Melting the material under a cover of bone buttons and pouring the alloy through a reducing flame during casting, also gives good results. The alloy may be reduced approximately 60% in rolling, and short anneals are suitable at 650 to 740 C in a steam atmosphere or a salt bath. Where the higher temperature is used, quenching is required for producing full softness. Alternation of oxidizing and reducing atmospheres is very damaging. Where oxidation has occurred in annealing, pickling in a hot sulfuric acid solution (5 to 10%) is suitable. After soldering, dipping for *less than one minute* in a solution of one part HNO_3 and one part water is effective.

Uses. Sterling silver is used for flat and hollow tableware and various items of jewelry. Coin silver with 10% Cu and 90% Ag is used for U. S. silver coins and for electrical contacts operating under service conditions where pure silver is considered too soft and is more likely to pit. The 20% Cu alloy has no special properties, but the 28% Cu eutectic alloy finds some use as a brazing solder where an alloy is required that is free from zinc, cadmium and tin and will melt at 779 C (in the absence of oxygen).[15] Various modifications of the silver-copper alloys are made, and small amounts of nickel are added to some of the contact alloys. Sometimes 0.5% Cd or more is added for various reasons. Palladium has been added to the eutectic to provide a higher-melting, strong solder and age hardenable contact alloy. Zinc, cadmium, and sometimes tin or phosphorus, are added to the eutectic or lower-silver alloys to provide useful brazing alloys.

Silver-Copper-Zinc(-Cadmium-Tin) Brazing Alloys

By Robert H. Leach*

SILVER ALLOYS in this group, used principally for joining metals, have been known for many years as "silver solders". Recently the name "silver brazing alloys" has come into use, a term more accurately suggestive of their characteristics, particularly of the temperatures at which they are used and the strength of joint made with them.

The article on brazing methods (page 78) lists 15 alloys representing a range of composition of specific alloys in common use for joining both ferrous and nonferrous metals and alloys. Since the term "brazing" implies that there is no melting of the material being joined, the important thermal property of these alloys is the temperature at which they are molten and flow freely into a joint.

The silver-copper eutectic, which contains 72% Ag, 28% Cu, melts at 779 C (1434 F). Quaternary alloys having varying percentages of cadmium or tin, as well as silver, copper and zinc, have lower liquidus temperatures; the liquidus range of these alloys extends from approximately 620 C (1150 F) to 845 C (1550 F) or higher. The solidus temperatures range from about 0 to 65 C (150 F) below the liquidus temperatures.

The strongest joints are made with these alloys when the maximum joint clearance is only a few thousandths of an inch. When the alloys are in the form of thin castings of relatively small cross-sectional area, their physical properties are of interest in connection with their ultimate use. However, since the diffusion into the joint members varies with the type of metal or alloy being joined, and the time and temperature of heating, the factors of greatest importance are the strength, malleability and ductility of the finished joint. As a general guide, tests show that the alloys in common use have tensile strengths from approximately 40,000 to 60,000 psi in cast form. These alloys are malleable and ductile and can be fabricated into sheet and wire with 50% or greater reductions between anneals.

The mechanical properties of the joint vary with the type of joint and composition of the material being joined. Lap joints are preferred if the design permits. The length of the lap affects the shear strength of the joint with any given alloy, but a reasonable lap of a maximum of about two or three times the thickness of the metal to be joined, will produce a joint as strong or stronger than the metal. With many nonferrous metals and alloys, the strength of butt joints will equal or exceed the strength of the joint members. Tests have shown also that butt joints properly made on steel or iron exceed the yield strength and often show values that approximate the tensile strength of the material. Joint strength greater than that of the silver brazing alloy can be obtained with butt joints on materials that have strengths higher than the alloy. The malleability and ductility of butt joints with many materials, allow severe cold work to be done on the joint without causing failure.

Experimental data and service records show that joints made with silver brazing alloys offer high resistance to fatigue when subjected to repeated shock and vibration.

The strength of silver brazing alloys declines rapidly at elevated temperatures. Short-time tests indicate that the loss in strength at 400 to 450 F will approximate 20 to 30% of the strength at room temperature and 50% at 600 F. Service tests of longer duration indicate that 400 F (205 C) is about the limit for the use of silver brazing alloys, unless the type of joint allows for an unusually large factor of safety.

The electrical conductivity of silver brazing alloys varies from 15 to 80% of the conductivity of copper. Alloys with higher silver content and lower zinc content have the highest conductivity. The silver-copper eutectic (72% Ag, 28% Cu) has approximately 77% the conductivity of copper. The thickness of the silver brazing alloy in joints on electrical equipment is so small in comparison with the joint area that the conductivity is usually satisfactory for all requirements.

The corrosion resistance of silver brazing alloys compares favorably with that of most of the nonferrous alloys with which they are used. Alloys containing 50% Ag or more are suitable for joining corrosion-resistant base metals such as nickel, Monel, stainless steel and allied materials used in chemical equipment, where enough nobility in the brazing alloy is desirable to avoid the selective attack on it. The melting range of the silver brazing alloys is neither low enough nor high enough to prevent carbide precipitation in unstabilized stainless steels.

Silver Materials for Electrical Contacts

UNALLOYED SILVER can be used successfully for electrical contacts where some slight arcing and wear occur to keep them clean, and where the contact pressure, current and voltage are not too low. Under higher-current conditions certain silver alloys, or various aggregates of silver with metals or nonmetals, may be employed for greater serviceability, even though the addition of these other materials to silver increases the electrical resistivity considerably.

The following substances discussed here are added to silver in order to provide useful material for contacts: tungsten, molybdenum, nickel, graphite, cadmium oxide, and lead oxide. The methods of powder metallurgy—rather than melting—are used for compounding the alloy or aggregate of silver with each of these substances.

Silver-Tungsten and Silver-Molybdenum

By E. F. Swazy* and Lee S. Busch*

BECAUSE of lack of mutual solubility of the component metals, alloys of silver with tungsten or molybdenum cannot be made by the usual metallurgical methods; powder metallurgy is necessary. These materials are useful as arcing tips, current-carrying contacts, and in aircraft, where they are used in the voltage-regulator system. A silver-molybdenum material is particularly useful in household circuit breakers, which are now widely used to replace fuses. To function satisfactorily, the aggregates must be free from porosity.

The desirable properties of these materials are the result of the combination of the high electrical conductivity and corrosion resistance of silver with the hardness and resistance to arcing and abrasion of tungsten or molybdenum. Both tungsten and molybdenum form oxides, but these oxides are not adherent and are easily separated from the parent metal by the wiping action of the contact mechanism.

Figures 1 to 4 show relationships between silver content and tensile strength, density, electrical resistivity and hardness. The figures include data theoretically obtainable in the ranges of very high and very low silver contents, as well as from the commercial materials.

Silver-Nickel

By Gregory J. Comstock* and Fred Farnham†

NICKEL has a much higher melting point than copper or silver; also nickel is harder and much more resistant to tarnishing. A mixture of silver and nickel has characteristics desirable for electrical contacts. The mutual solubility of silver and nickel is so low that most compositions must be made by the powder method. The product is unusual in that both components are ductile at atmospheric temperature if sufficiently pure; consequently it is possible to cold work all the mixtures. These mixtures are not to be confused with nickel silvers, which are copper-base alloys containing nickel and zinc, but no silver.

The data shown in Fig. 5 relate to products made by the powder method. Tensile properties are shown for the annealed condition and after reducing the cross section 4 B&S numbers by rolling. These mixtures are sufficiently ductile to be cold headed, and annealed material may have an elongation of 10% or more. Contacts are made also by sintering to shape without appreciable subsequent working, but the properties of such articles differ from those in Fig. 5.

The addition of nickel to silver increases the hardness and decreases the mechanical and electrical wear without greatly reducing the electrical or thermal conductivities. For example, the 5% Ni mixture has an electrical conductivity approximately equal to that of copper. The electrical contact resistance of the higher-silver alloys is very low; that of the 15% Ni alloy is of the same order as the electrical contact resistance of fine silver. The low contact resistance of these mixtures makes them useful as contact surfaces. Mixtures containing approximately 15%

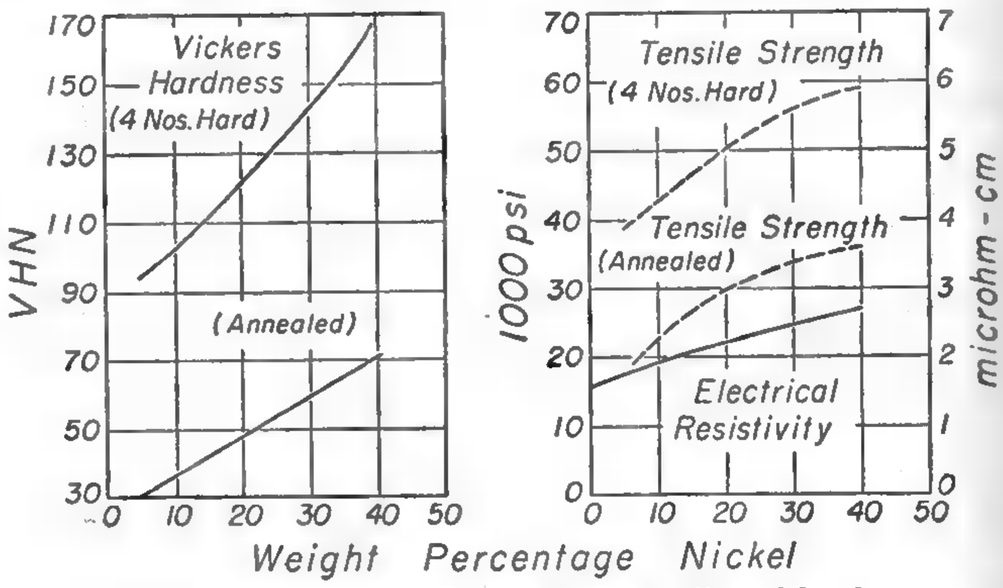

Fig. 5 Electrical resistivity, tensile strength and hardness of wrought silver-nickel alloys

Ni are useful for high-conductivity applications, while the mixture with higher nickel content is used where resistance to arcing is essential, as in medium-size circuit breakers.

Where maximum resistance to sticking is required, one contact of silver-nickel is used in conjunction with one of silver-graphite. In high-capacity circuit breakers, where arcing contacts are utilized to protect the main contacts, frequently the main current-carrying contacts are silver-nickel. Silver-molybdenum and silver-tungsten are used for the arcing contacts where ability to break high currents is required, and silver-tungsten is employed where maximum resistance to erosion by the electric arc is demanded.

Contacts of silver-nickel mixtures can be bonded to massive copper conductors. In large apparatus, this construction is commonly used and, for heavy service, offers an advantage over silver. Such applications include disconnect switches, transformer tap changers, and main contacts of large circuit breakers.

Silver-Graphite

By E. I. Shobert, II*

THE TECHNIQUES of powder metallurgy are used for making these materials when the volume of silver is greater than 50%, which corresponds to 15% graphite by weight. Less metallic mixtures, containing less than 50% metal by volume, employ carbonized binders or are made by impregnating a porous carbon with molten silver. The properties of the high-silver silver-graphite alloys are shown in Fig. 6.

Originally these materials were produced to minimize the welding of electrical contacts. The resistance to welding improves with the graphite content; however, the contact resistance also increases with the graphite content and is approximately doubled at 5% graphite. Consequently

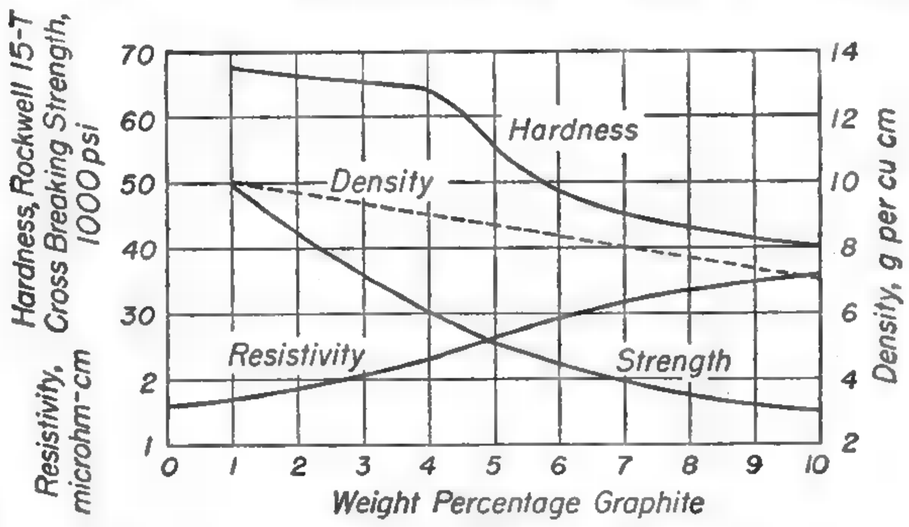

Fig. 6 Some properties of silver-graphite mixtures

some compromise is necessary in selecting the proportions of silver and graphite. These materials have found substantial use in contacts for circuit breakers, switches and the like where the frequency of operation is moderate, and also for various sliding contacts on instruments, variable resistors and low-voltage motors and generators. For these latter applications, materials with substantial amounts of graphite are employed, and it has been observed that during use, copper slip rings acquire a coating of silver that further reduces the contact drop.

Silver–Cadmium Oxide

By E. F. Swazy* and Lee S. Busch*

SILVER ALLOYS that contain small percentages of cadmium have good qualities as electrical contacts, although these contacts can be used only in circuits where the current is low. The presence of cadmium lowers the transfer of material to a minimum and permits longer use of the contact. However, larger amounts of cadmium lower the electrical properties to a point where the operating characteristics are inferior to those of fine silver.

If cadmium oxide and silver powders† are properly mixed, pressed and sintered, the properties of the resultant material are excellent for heavy-duty contacts. The amount of cadmium oxide determines the current rating at which the material has optimum performance within the limits of the design of the electrical circuit.

The fabrication is typical of powder metallurgy processes; that is, mix, press, sinter and re-press. By this method, finished electrical contacts are made that require no further finishing after they have been attached to their carrying member. The material may also be fabricated by hot pressing, but this method is not well suited to economical, high-speed production, except in special instances.

The cadmium oxide used is considered an additive and is ordinarily present in amounts less than 15% by weight.

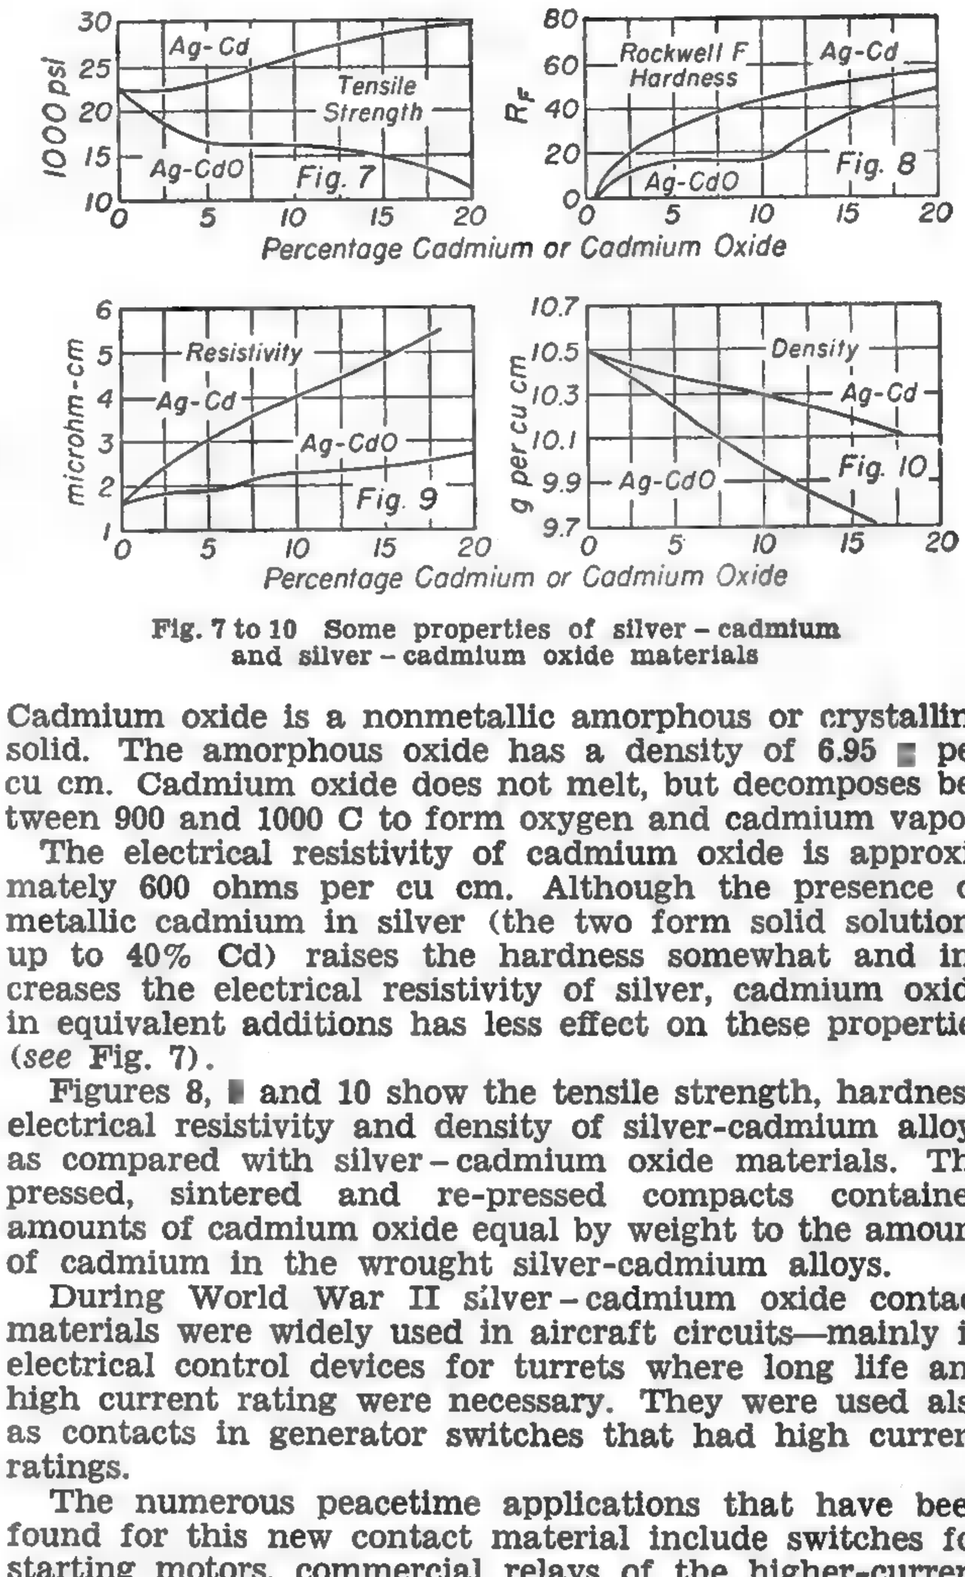

Fig. 7 to 10 Some properties of silver – cadmium and silver – cadmium oxide materials

Cadmium oxide is a nonmetallic amorphous or crystalline solid. The amorphous oxide has a density of 6.95 ■ per cu cm. Cadmium oxide does not melt, but decomposes between 900 and 1000 C to form oxygen and cadmium vapor.

The electrical resistivity of cadmium oxide is approximately 600 ohms per cu cm. Although the presence of metallic cadmium in silver (the two form solid solutions up to 40% Cd) raises the hardness somewhat and increases the electrical resistivity of silver, cadmium oxide in equivalent additions has less effect on these properties (*see* Fig. 7).

Figures 8, ■ and 10 show the tensile strength, hardness, electrical resistivity and density of silver-cadmium alloys as compared with silver – cadmium oxide materials. The pressed, sintered and re-pressed compacts contained amounts of cadmium oxide equal by weight to the amount of cadmium in the wrought silver-cadmium alloys.

During World War II silver – cadmium oxide contact materials were widely used in aircraft circuits—mainly in electrical control devices for turrets where long life and high current rating were necessary. They were used also as contacts in generator switches that had high current ratings.

The numerous peacetime applications that have been found for this new contact material include switches for starting motors, commercial relays of the higher-current class, and various alternating-current applications where fine silver is not a suitable electrical contact material.

Silver–Lead Oxide

By E. I. Shobert, II*

THIS MATERIAL is used principally for contacts in low-voltage electrical circuits where fairly heavy currents are to be controlled. It has been used also in vibrating contacts for direct current, including inductive loads where it may be used as the positive contact in combination with another material for the negative contact to minimize transfer. Although the resistivity of the material is increased considerably by the lead oxide, the contact resistance is increased only about 15%. Some pertinent properties are listed in Table I.

Table I. Some Properties of Silver – Lead Oxide

Composition, % Silver	Lead Oxide	Cross Breaking Strength, psi	Rockwell Superficial Hardness	Density, g per cu cm	Electrical Resistivity, microhm-cm

See Palladium and Palladium Alloys, pages 1128 and 1129.

33 Ag – 52 Hg – 12.5 Sn – 2 Cu – 0.5 Zn

COMPILED BY WILMER SOUDER*

A *1 Common name.* **Dental Amalgam,** "Silver" Filling
4 Government number. U-A-451a

B *1 Typical uses.* Restoring lost tooth structure
2 Precautions in use. Small amounts of moisture (from the hand or mixing equipment) added during amalgamation cause excessive expansion of the hardened alloy. Excess mercury, remaining in the alloy after packing, causes the alloy to expand and flow excessively. Excessive working of the alloy during amalgamation or packing reduces or eliminates the setting expansion. Incomplete amalgamation produces an alloy that corrodes readily. Improper condensation (packing) increases the rate of corrosion and decreases physical properties.

C *1 Density* at −3 C (+26 F). 11 g per cu cm (0.397 lb per cu in.)
5 Solidification shrinkage. Expands 8 ± 5 microns per cm during solidification

D *1 Liquidus temperature.* Begins to sweat mercury and to break down at about 75 C (167 F)
6 Thermal expansion at or near body temperature. 0.000022 to 0.000028 per °C

E *11 Electrolytic solution potential* versus gold in normal sodium chloride solution. minus 0.5 volt

F *4 Color.* Silvery white

I *1 General resistance to corrosion.* Tarnishes readily unless well polished. Electrolytic corrosion and pitting may result from contact with other metals, incomplete amalgamation or nonuniform mixing. The amalgam is attacked readily by inorganic acids.

K *Mechanical properties.* Compressive strength 40,000 to 50,000 psi after ▮ days; tensile strength ⅛ to $\frac{1}{10}$ of the compressive strength; rigidity, all amalgams flow when subjected to loading; loads of $\frac{1}{10}$ of the compressive strength may cause a flow amounting to 1% per 24 hr; flow 2 to 4% at 20 to 25 C in the first 24 hr for loads of $\frac{1}{10}$ the crushing strength applied 3 hr after amalgamation; modulus of elasticity 1,500,000 psi (very uncertain); indentation hardness (Knoop method) 90 after 5 days

M *Composition limits* (U-A-451a). For silver alloy used in the preparation of amalgam: 65% Ag min; 25% Sn min; 6% Cu max; 2% Zn max.

N *3 Alloying.* Usual composition is 5 parts silver alloy of above type to 8 parts of mercury mixed in a mortar. Approximately 3 parts of mercury is expressed during packing.
11 Suited to forming by packing from its plastic form.
12 Precautions in forming. Avoid over-trituration, excess mercury in finished material, and contamination with moisture during amalgamation and packing.
13 Compacting pressure. 1 to 3 kg per sq mm

GOLD AND GOLD ALLOYS

Gold (99.99+ Au)

COMPILED BY WM. F. ROESER*

B *1 Typical uses.* Gold of the highest purity, called "Proof Gold", contains more than 99.99% Au, and is a premium product used for standardizing purposes. The usual grade of refined gold contains from 99.95 to 99.98% Au and is suitable for most purposes, including dental and jewelry alloys. Metal that contains 99.5% Au is acceptable for international exchange and by the U. S. Mint without a refining penalty. Coin gold containing only copper as a hardener with 89.9 to 91.7% Au may also be acceptable.

Besides monetary uses, nearly pure gold is employed as beaten foil for decorative and dental uses, for electroplating and surfacing china and glass, for thermal limit fuses to protect electric furnaces, as a freezing-point standard, and occasionally as a high-melting noble solder and lining material for chemical equipment. Gold alloys are used for jewelry, dental, electrical and some chemical purposes.

2 Precautions in use. Unless you have a license, do not buy or sell gold without consulting the U. S. Bureau of the Mint. In melting avoid contamination with base metals, particularly lead, bismuth and the like. Keep atmosphere oxidizing during melting.

C *1 Density* at 20 C (68 F). 19.32 g per cu cm (0.698 lb per cu in.)

D *1 Melting point.* 1063.0 C (1945.4 F)
4 Boiling point. 2970 C (5380 F)
6 Thermal expansion at 20 C (68 F). 0.0000142 per °C ▮ to 950 C (32 to 1742 F)

60% reduction ...	32,000	30,000	4	58	11,500,000

7 *Hot working temperature range.* Gold can be worked at any temperature below the melting point.
9 *Annealing temperature.* Apparently no annealing is required.
11 *Suited to forming* by all methods so far as is known.
17 *Joining.*
Braze with silver solder; no flux; any flame.
Oxyacetylene welding with gold; no flux; any flame.
Resistance welding. Any method

Gold-Copper-Silver Alloys (Green, Yellow and Red Golds)

By E. M. Wise*

THE Au-Cu-Ag system is the base for the high-carat green, yellow and red gold alloys used in jewelry. Frequently the properties of these alloys are modified somewhat by additions of other elements, such as zinc and nickel. The pink golds contain sufficient nickel and zinc to yield appreciably different properties and colors. The white golds are Au-Cu-Ni-Zn alloys.

Ten-carat alloys, particularly the greenish types, generally contain considerable zinc and a little nickel, so they also must be considered apart from the ternary group. Many of the dental casting alloys are closely related to the high-carat Au-Cu-Ag alloys, but the higher-strength compositions contain sufficient palladium and platinum to alter their properties substantially. Although the Cu-Ag-Pd system is closely analogous, structurally, to the Cu-Ag-Au system, the melting points of Cu-Ag-Pd alloys are higher, with the result that a continuous series of useful alloys exists in which palladium replaces gold, atom for atom.

The liquidus and solidus and the hardness of alloys in the annealed condition are shown in Fig. 1, based essentially on the work of Sterner-Rainer.[1] Alloys containing a few per cent of zinc are slightly softer in the annealed condition than the basic ternary alloys. Copper hardens these alloys, not only by the usual solid-solution effect, but also by inducing in some of the alloys, the type of low-temperature atomic rearrangement termed "ordering", which causes substantial age hardening.

Copper lowers the melting temperature of the high-gold alloys to a minimum of 884 C in the liquidus of the binary copper-gold alloys, while a eutectic, melting at 779 C, forms between copper and silver. The solid solubility of copper in silver and silver in copper is limited and decreases with temperature, and the domain of heterogeneous alloys increases as the temperature decreases.[11] As a result of these phenomena, alloys containing about 25% Cu have nearly the minimum melting temperature, and alloys containing less than 50% Au (12-carat) may contain some eutectic.

The 10-carat alloys are generally limited to the high-copper side of the eutectic. Even alloys that contain more gold than this, also may precipitate phases of rather low nobility during slow cooling. Photomicrographs of these structures, as well as of structures associated with ordering, have been published.[2,3,4,5]

Age hardening can be induced in certain Au-Cu-Ag alloys by heating for ½ to 2 hr at 200 to 350 C[2,4,6] or by slow cooling,[7,8] depending on the alloy. The more complex alloys used in dentistry may require higher temperatures.[9] Maximum values for the hardness of aged ternary alloys are shown in Fig. 1 for 18- and 14-carat alloys, based principally on the work of Nowack.[6] If considerable ductility is required, less drastic hardening may be necessary. Low-carat alloys that contain considerable zinc plus a small amount of nickel, age harden very effectively,[2] as do various other commercial alloys.[2,5,7,9] A review of the age hardening of precious metal alloys is accessible.[10]

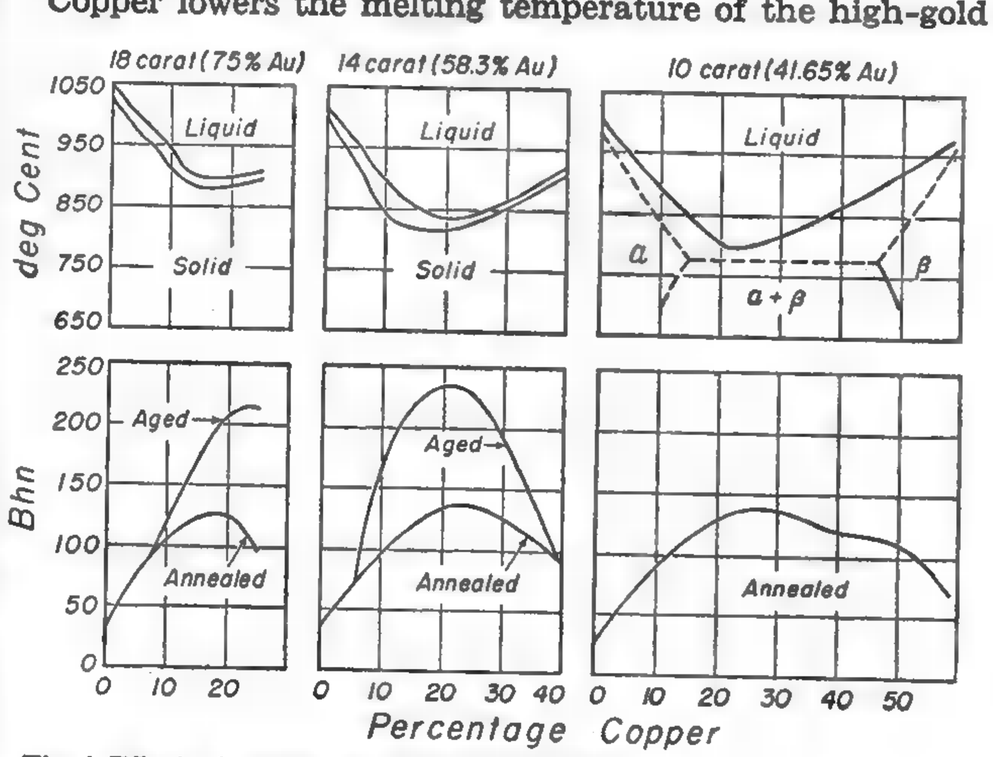

Fig. 1 Effect of copper on melting and hardness of Au-Cu-Ag alloys

Color. The addition of silver to gold apparently reduces the reflectivity in the extreme red, with the result that a 75% Au – 25% Ag (18-carat) alloy has quite a good green color. Replacing about half the silver with copper produces a yellow gold and a further increase produces a red gold. The 58.35% Au – 41.65% Ag (14-carat) alloy has an unattractive greenish white color, and also is too soft to be useful, but if 6 to 12% of the silver is replaced by copper, a fair green results (which is somewhat improved by the replacement of a certain amount of silver by zinc). If 20 to 30% Cu is present, yellow alloys are formed. A further increase in copper yields reddish alloys. The presence of a little nickel lightens the color and hardens the alloy; zinc lightens the color, adds a slight greenish cast and may soften the alloy. At 41.65% Au (10-carat) useful compositions are confined largely to the high-copper alloys with considerable zinc and often appreciable nickel added to yield greenish, yellow, red and pink golds. (Pink golds are described on page 1119.)

Working. The melting and casting of these alloys is described on page 1096. All of them are cold worked; reductions of 50% or more are usual. Annealing for 15 to 30 min at 650 to 700 C is normal, and reducing atmospheres are desirable in order to avoid the oxidation of copper and any other base metals present. Such oxidation, which can

* The International Nickel Company, Inc., New York

extend to an appreciable depth, is called "fire", and to remove it is more difficult than to prevent it. When reducing atmospheres cannot be used, coatings of boric acid, ochre and the like are applied, and when flame heating is employed, methyl borate introduced into the combustible gas has a protective effect.* The age hardenable alloys should be cooled rapidly, but water quenching is not always possible because some of the alloys may crack.

Resistance to Corrosion. The 18-carat alloys contain 75% Au by weight, corresponding to about 50 to 60 atomic % Au, and are very resistant to tarnishing in indoor atmospheres, although probably not to outdoor urban exposures. They resist nitric, sulfuric, and hydrochloric acids and ferric chloride, but are attacked rapidly by mixtures of nitric and hydrochloric acids (aqua regia) and slowly by solutions of alkali cyanides plus air or other oxidizing agent. They are attacked when made anode in hydrochloric acid or cyanide solutions. Fourteen-carat alloys contain 58.33% Au by weight, or about 30 to 40 atomic % Au, and thus approach the region where the nobility decreases rapidly. They tarnish slowly in air but because of the color this is not very obvious. If free from stress, they are quite resistant to nitric acid or ferric chloride, but if highly stressed, these alloys may be cracked by various corrosives or may crack even in the apparent absence of a corrosive. Mercury is also likely to crack 14-carat alloys when they are under stress. Decreasing the gold content still further to 12 and 10 carats (about 20 atomic % Au) results in a rather sharp decrease in resistance to acids and an increase in the susceptibility to tarnish and sensitivity to stress-corrosion cracking. The resistance to corrosion of some of the alloys may be lowered or occasionally raised by aging.[5,10] Some aspects of this problem as it concerns a 10-carat light yellow gold have been considered.[5]

Uses. These alloys are used mostly in jewelry, pen nibs and the like, where they are employed in the form of castings, or in products made from rolled or drawn stock, or from clad material comprising a layer of gold on one or both sides of a core made of nickel silver, pure nickel, brass or bronze. Certain of these alloys can be electrodeposited, and sometimes coatings are produced by electrodeposition followed by heating to cause diffusion with the underlying metal. The closely related dental alloys are described on page 1120 in this Handbook.

Gold-Nickel-Copper-Zinc Alloys (White Gold)

By E. M. Wise*

When first offered as substitutes for platinum in jewelry these alloys contained about 80% Au. Later 18-, 14-, and 10-carat alloys were developed for use in solid and clad forms in the same manner as yellow and green golds, although the hardness and tendency to fire crack make white golds more troublesome to work. Faintly greenish whites are normally considered the whitest, but are the most difficult to handle. The optical industry makes considerable use of 12-carat alloys, white and pink, or "suntan", as described on page 1119. In recent years palladium has often been used instead of white gold, particularly in rings and gem mountings where maximum reliability is required. The white precious metal alloys used in dentistry are very different; they contain gold, platinum, palladium, silver and copper, as described in the articles on cast dental alloys and wrought dental alloys.

Composition and Constitution. The gold-nickel system just escapes being eutectiferous, since nickel and gold have limited mutual solubility at low temperatures,[1,2,3] although they form a continuous solid solution just below the solidus. As a result, an 18-carat (75%) gold-nickel alloy, oil-quenched from 850 C, is homogeneous and hard, though somewhat ductile, and is white in color and resistant to nitric acid. After very slow cooling, the same alloy becomes heterogeneous, is yellowish white in color, and is readily attacked by nitric acid. Various transformations occur in the gold-copper system, and only portions of the several binary systems involving zinc are face-centered cubic, so the constitution and transformations in the commercial alloys are complex—particularly in the high-carat alloys. However, the usual alloys are face-centered cubic solid solutions at high temperatures. Unfortunately the low-temperature transformations in these materials have been studied little in recent years.

The compositions employed for a given carat are the result of a compromise between color and working properties, and are quite critical—especially in the higher-carat alloys. For instance, the introduction of 1 or 2% Cu in the 19.2-carat alloy improved the elongation and largely eliminated edge cracking during rolling, without changing the color much. Further study and the use of very pure metals led to development of a whole series of lower-carat white alloys.[4] Compositions of the base metals to be alloyed with appropriate amounts of gold for providing alloys of good color, are shown in Fig. 1. The annealing curve for 14- and 18-carat alloys is shown in Fig. 2.[2] Alloys outside this band are made, but generally the appearance is somewhat inferior. The tensile properties for fully annealed and air-cooled alloys in this band, ranging from 10 to 19 carats, will be of the order of 95,000 to 105,000 psi, 30 to 50% elongation in 2 in. Published values scatter considerably, in part from the use of partial anneals, so fine details in the hardness-composition relation cannot be indicated. When the high-carat alloys are cooled slowly, extreme brittleness and some hardening result; for example, a decrease in elongation from 47 to 2% is noted in an 18-carat white

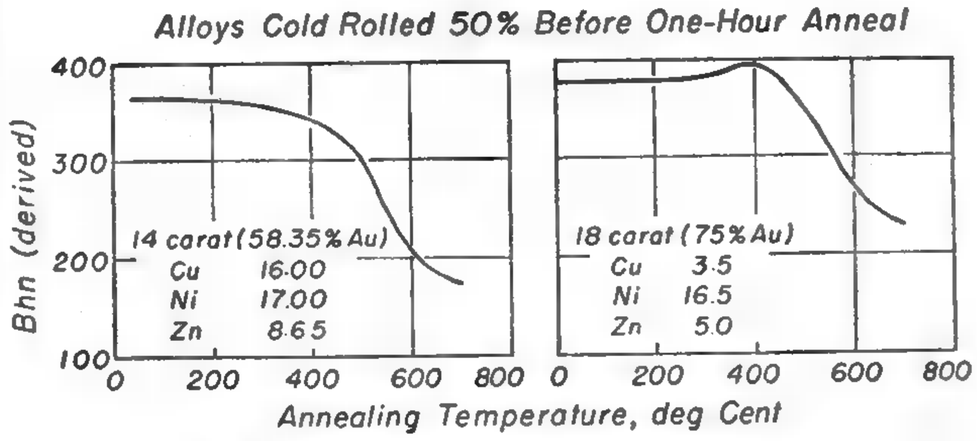

Fig. 2 Hardness of two white golds after annealing

gold. Though some of the lower-carat alloys also age harden on heating at 400 to 500 C, the alloys are usually harder than desired without such treatment, and aging may lower the corrosion resistance in certain of them.

Limitations and Precautions in Use. Cracking is the most serious limitation to the production and use of the whiter alloys and may have any of several different causes. "Fire cracking" (the most troublesome type in 14-carat and higher-carat alloys) develops during the heating of stressed material. Slow heating is not a remedy, since some alloys become extremely brittle at 200 to 300 C and crack before the release of stress by creep. Therefore it is necessary to adjust the working operations to minimize the stress in the parts before annealing. Good pinches are essential, as well as fairly high reductions (50% or more) between anneals in rolling; and side walls should be reduced adequately in shell drawing, sometimes followed by turning to remove rough edges before annealing. These precautions minimize fire cracking. Corrosion cracking is sometimes a problem with the lower-carat alloys, and even a small amount of cold work, before pickling or exposure to other corrosives, may result in cracking. Annealing prior to such exposures is desirable where possible. In general, white golds resist tarnish somewhat better than colored golds of the same carat, but the resistance of white golds to general corrosion is probably less, largely because the atomic percentage of gold in the white golds is lower for a given carat.

Gold-Silver-Copper-Nickel-Zinc Alloys (Pink or Suntan Golds)

By Carl Samans*

SOME physical and mechanical properties of several gold alloys of the pink or suntan types are listed in Table I. These alloys contain either 58.35% Au (14 carat), 50.0% Au (12 carat) or 41.65% Au (10 carat).

Tensile strengths range from 60,000 to 90,000 psi in annealed alloys, depending on the composition, with yield strengths 50 to 60% of the tensile strength, which is high for nonferrous alloys. After 50% cold work, the tensile strength will be 110,000 to 120,000 psi, with yield strength 90% or more of the tensile strength.

Thermal expansivities cover a considerable range, but are approximately 14×10^{-6} per °C at room temperature. Some of the alloys show abnormally high coefficients of the order of 25×10^{-6} at 300 C, but values of about 22×10^{-6} per °C at 700 C are fairly typical.

The mechanical properties and age hardening of a 10-carat alloy of this type were studied by Wise,[1] and recently the effects of a variety of mechanical and thermal treatments on essentially the same alloy were reported by Patterson and Iannone.[2] Not all the commercial alloys age harden, and this treatment is not always applied to those that are responsive. Jarrett[3,4,5] studied the effect of varying the individual components of 10-, 12- and 14-carat alloys, and a number of his alloys fall in the category of pink or suntan golds. The two latter investigators have included data on the rate of attack by nitric acid; this rate is considerable in the lower-carat alloys. These investigators also indicate the behavior of the alloys toward mixtures presumed to simulate perspiration.

Resistance to Corrosion. Many of the 10- and 12-carat gold alloys are known to be susceptible to stress-corrosion cracking[6] under certain conditions. This might be anticipated from the relatively high yield strength of the alloys even in the annealed condition. Immersion in 10% ferric chloride solution is effective in testing this tendency, although it is a severe test. Drying under stress in an artificial perspiration solution, is probably a closer approximation to actual conditions, and is known to cause cracking, although failures in actual service are not common. In general, alloys free from zinc seem to be somewhat less susceptible to stress-corrosion cracking than alloys that contain zinc.

The pink golds are by no means stainless and they may darken appreciably when exposed to sulfidizing and oxidizing conditions, such as some types of urban atmospheres, or to perspiration. Two artificial approximations of perspiration are commonly used for testing—a solution containing 1% acetic acid and 1% salt, and a solution containing 5% acetic acid and 5% salt. The two concentrations differ appreciably in their action, depending on the test conditions and the composition of the material tested. Lactic acid, rather than acetic acid, is present in perspiration, and the pH of perspiration changes with time so that care must be taken in conducting such tests and in correlating them with service behavior.

Uses. Certain of these alloys have been used for jewelry,

but in recent years they have been used principally for eyeglass frames and they are particularly well suited for this purpose. The alloys are employed in solid form or are clad upon a core of nickel, nickel silver or bronze. The methods of melting, casting and processing are similar to those employed with other golds, as described elsewhere in this section of the Handbook.

Gold Alloys in Dentistry

THREE principal types of gold alloy products are used in dentistry: castings, wires, and solders. The cast gold dental alloys and high-strength precious metal wires are described in this article. Information concerning the composition and use of dental gold solder is included in the article entitled "Joining Precious Metals" (*see* page 1104). The process of casting dental alloys is discussed in the article on page 1100.

High-Strength Precious Metal Wires

By N. O. Taylor*

THE PRECIOUS METAL wires used in dentistry are considerably stronger than might be anticipated from a superficial consideration of the properties of the constituent metals, which are all relatively soft.

Dental applications require high strength and elasticity in wires, as well as adequate resistance to corrosion by mouth fluids. The precious metal alloys that meet dental requirements are age hardenable and, when properly heat treated, wires of these alloys have high strength and, at the same time, relatively low moduli of elasticity (14,000,000 to 17,000,000 psi). The nature of these alloys and their response to heat treatment have been considered by R. L. Coleman,[1] Wise, Crowell and Eash,[2,3] and others.

(a) Fractional percentages of iridium, indium and rhodium are omitted here.

The high intrinsic value of the alloys, coupled with the fact that manufacturing lots are small, makes it impractical to test samples comparable in size with those used for most metals. Manufacturers of dental alloys publish data obtained from their alloys by test methods adopted by the Gold Division of the American Dental Trade Association.[4]

These methods are somewhat different from methods outlined in the American Dental Association Specification 7 for Wrought Gold Wires, yet differences in data from the two types of tests are minor except for values of percentage elongation. The manufacturers' methods are based on 8-in. gage lengths and the American Dental Association's methods on 2-in. gage lengths.

The high-strength wires used in dentistry may be classified into eight fairly well-defined groups. The data in Tables I and II were supplied by the members of the Dental Gold Institute as representing current products.

Cast Gold Dental Alloys

By E. M. Wise*

DENTAL ALLOYS must have good casting properties. Such alloys are generally melted with a gas-air torch, yet they must have a solidus temperature high enough to permit the use of gold solders. Also the metal must have adequate nobility and a desirable yellow or white color, coupled with the mechanical properties required for the inlay, bridge or partial denture involved. The necessary mechanical properties can be found in three or possibly four alloys, ranging from those having a Brinell hardness number as low as 40, suitable only for inlays not subject to stress, to progressively harder alloys from 100 to 130 Bhn, required for inlays subject to considerable stress and for bridge abutments and crowns. Alloys harder than 200 Bhn and having a high elastic limit are required for partial dentures.

The harder alloys are also responsive to age hardening, and when maximum elastic properties are required, the alloys should be suitably heat treated. If extensive shaping or leveling is necessary, castings should be softened by quenching from between 700 and 750 C. Some alloys are hardened by remaining in the investment while cooling from the casting temperature to about 350 C, before being quenched. Castings made of other alloys must first be quenched from between 700 and 750 C, and then hardened by heating to between 250 and 450 C and cooling slowly, or by aging for a suitable time at a temperature appropriate to the specific alloy. Most dental castings are irregular in shape and close dimensional accuracy is re-

quired; therefore warping caused by quenching from high temperatures is likely to be serious, especially in the larger castings. Pickling in a hot solution of 50% sulfuric acid, 50% water, is generally desirable for cleaning the surface of the cast alloy.

The American Dental Association has provided specifications for several types of cast dental golds and parallel Federal specifications have been established for several classes. Many of the commercial dental alloys fit into these classifications, but many other alloys have been designed to meet special requirements.

The alloys in use are the results of much research and the specific compositions adopted by individual manufacturers differ considerably in some instances. The general compositions of the widely useful alloys are shown in Table III. Table IV presents typical mechanical properties as determined on cast bars about 0.090 in. in diam and several inches long—a shape that is obviously difficult to cast at normal casting temperatures.

PLATINUM AND PLATINUM ALLOYS

Platinum

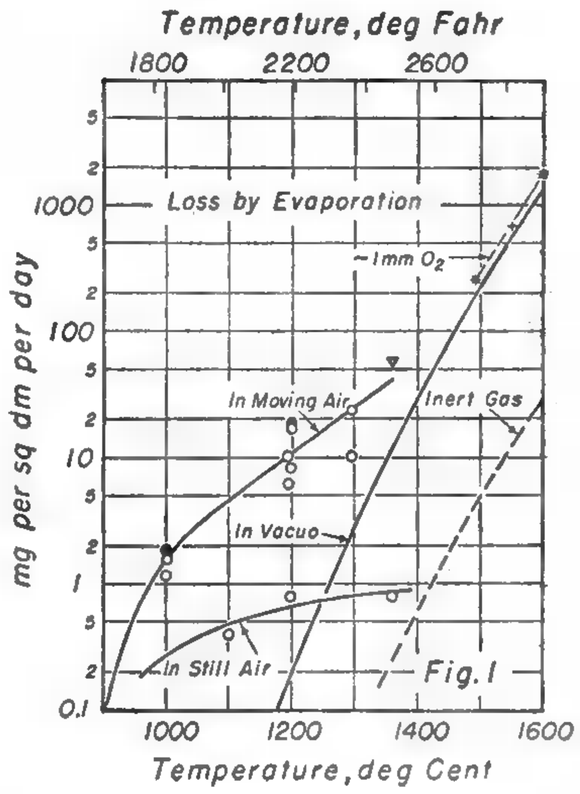
COMPILED BY E. M. WISE*

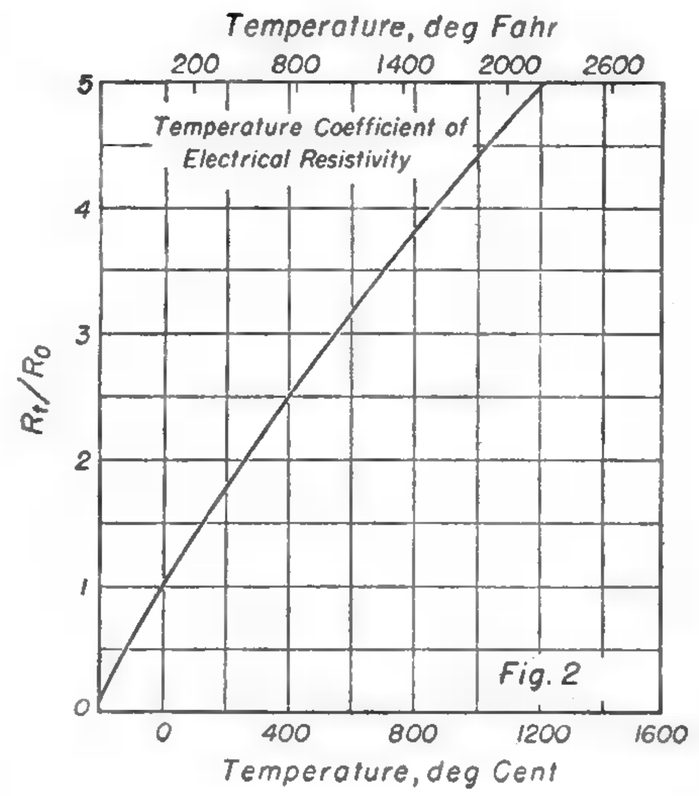
B *1 Typical uses.* Platinum is the best known and least rare of the platinum group metals, and has the widest range of uses because of its general corrosion resistance, high melting point, appearance, and ductility. Platinum of the highest purity (sometimes called "physically pure") is required for resistance thermometers and thermocouples. In addition, various alloying elements, such as ruthenium, iridium and, for special purposes, other hardeners are employed to develop higher mechanical properties or to withstand peculiar corrosive conditions better. Platinum is used for electrical contacts, chemical production, and laboratory equipment including spinnerets, anodes in both solid and clad form, for jewelry, and as leaf for decorative purposes. It is also used for producing high-purity optical glass and glass fiber. Platinum is an outstanding catalyst, both for oxidation, as in production of H_2SO_4 and HNO_3, and for hydrogenation in production of vitamins and other chemicals.

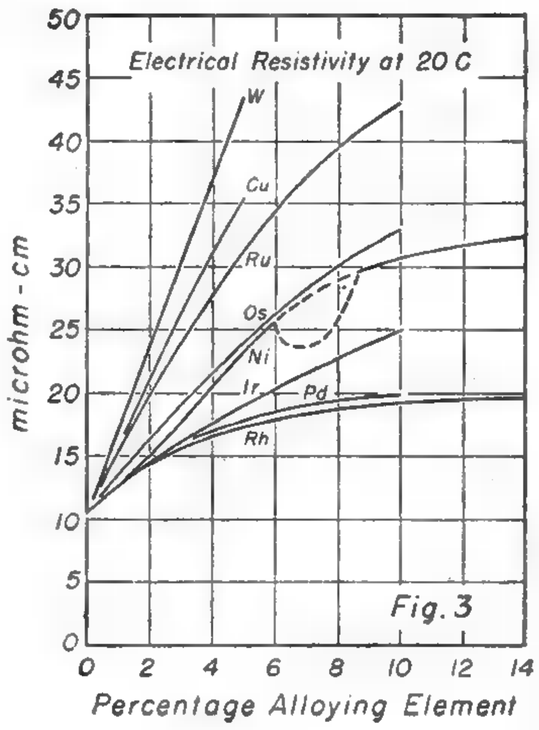
C *1 Density* at 20 C (68 F).[2] 21.45 g per cu cm (0.775 lb per cu in.)

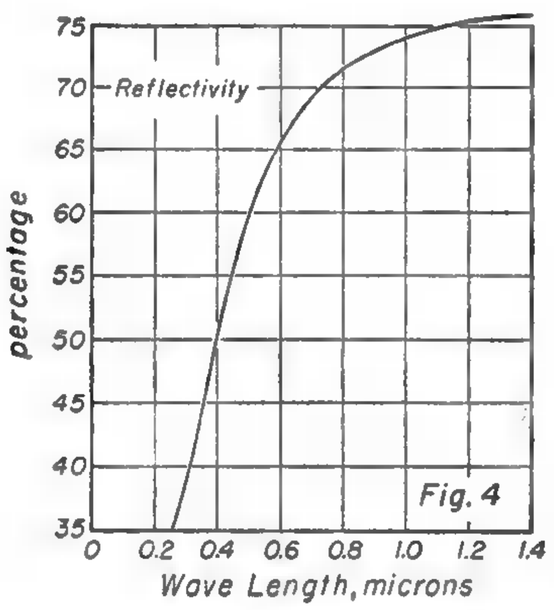
D *1 Melting point.*[4] 1773.5 C (3223.8 F)
4 Boiling point.[5] Approximately 4530 C (8185 F) calculated from thermodynamic data.[9] 4407 C (7965 F)
5 Vapor pressure
at 1000 C (1832 F). 1.1×10^{-12} mm of Hg
at 1500 C (2732 F). 1.1×10^{-6} mm of Hg
at 1773 C (3223 F). 1.3×10^{-4} mm of Hg

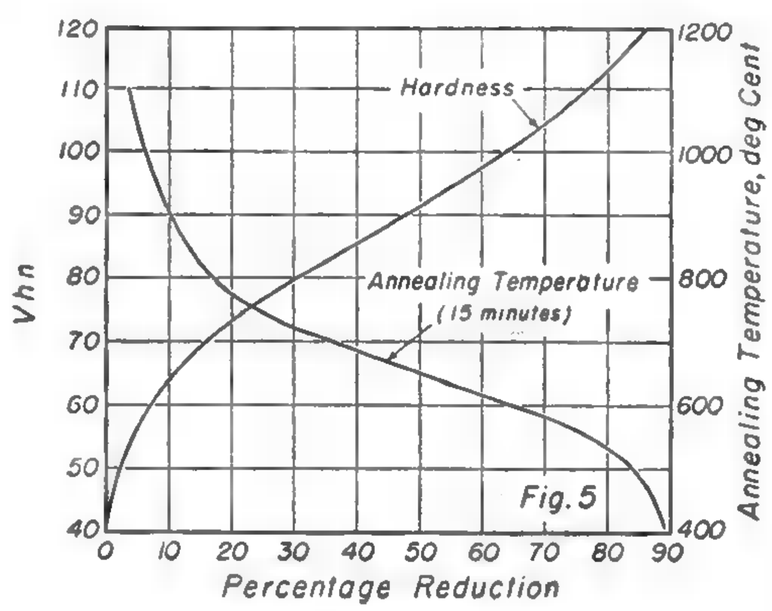
* The International Nickel Company, Inc., New York

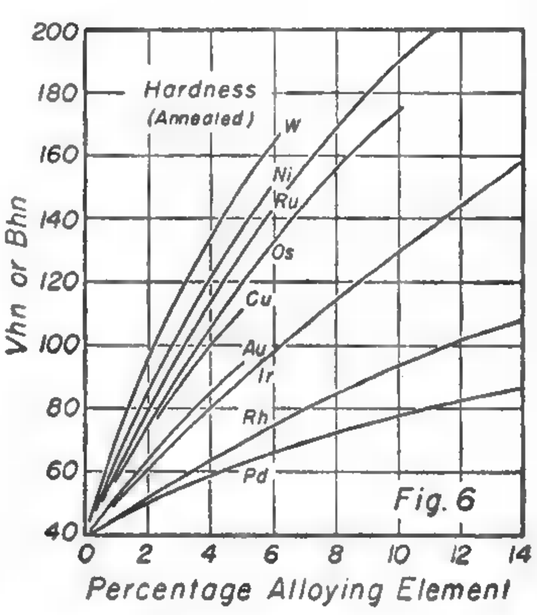












6 *Thermal expansion* at 20 C (68 F). 0.0000089 per °C
References 11 and 12 develop the equations for length versus temperature. Reference 12 is preferred for temperatures between minus 188 and plus 95 C. See reference 13 for equation for higher temperatures.

11 *Specific heat* at 0 C (32 F),[14] 0.0314 cal per g

13 *Latent heat of fusion.*[14] 26.9 cal per g

16 *Thermal conductivity*
at 17 C (63 F). 0.165 cal/sq cm/cm/°C/sec
at 100 C (212 F). 0.173 cal/sq cm/cm/°C/sec

20 *Rate of evaporation* in vacuo[5] and in low-pressure oxygen or air, based on the results of several experiments[6,7,8] and on unpublished data communicated by F. E. Carter, has been summarized in Fig. 1.[15]

E 2 *Electrical resistivity* at 0 C (32 F). 9.83 microhm-cm
at 20 C (68 F). 10.6 microhm-cm

5 *Temperature coefficient of electrical resistivity** 0.003925 per °C (0 to 100 C). The resistivity over a wide range of temperature corresponds closely to the formula:[2]

$$R_t = R_0 (1 + 3.9788 \times 10^{-3}t - 5.88 \times 10^{-7}t^2)$$

The ratio of resistivity at various temperatures to that at 0 C is shown in Fig. 2.[16] The change in resistivity with temperature is fundamental to accurate resistance thermometry and also is useful in estimating the purity of platinum, since the temperature coefficient is sensitive to traces of impurities, as is the thermal emf. For effects of alloying, see Fig. 3.[2]

9 *Thermoelectric force.* Very pure platinum is often the reference electrode in comparing the thermoelectric behavior of individual metals and alloys. Measurements of the thermal emf of samples of platinum (with the hot end at 1200 C and the cold end at 0 C) against platinum of extreme purity are useful for estimating the purity of different lots of platinum, as small amounts of impurities (except gold) in solid solution in platinum make the slightly impure platinum thermoelectrically positive to strictly pure platinum. Iron is perhaps the most troublesome element in this respect. Data on these matters, assembled from various sources, are included in reference 2.

F 1 *Reflectivity.** 67.3% in white light. *See* also Fig. 4.[18,19,20]

5 *Emissivity* with red filter.[16] Solid, 0.30 at $\lambda = 0.65$ μ (used in optical pyrometry). Liquid, 0.38

G 2 *Magnetic susceptibility* at 18 C (64 F).[17] 1.1×10^{-6} mass units

I 1 *General resistance to corrosion.* A detailed summary of the corrosion of the platinum metals is given in reference 15.

2 *Resistance to specific agents.* Platinum is resistant to reducing or oxidizing acids at room temperature, but is attacked by a mixture of nitric and hydrochloric acids, known as aqua regia, and somewhat slowly by hydrochloric acid plus other oxidizing agents. Platinum is resistant to ferric chloride at room temperature. Hydrobromic acid plus bromine attacks it at room temperature. All the free halogens attack platinum at elevated temperatures, but hydrochloric acid in the absence of oxidizing agents does not attack it, and platinum is useful against this normally active gas up to 1100 C. Sulfur dioxide does not attack platinum, even at 1000 or 1100 C.[27]

As an anode, platinum is outstanding and is used commercially in sulfuric and persulfuric acids, various sulfate-chloride plating electrolytes, and in chlorates, with very little corrosion. If electrolyzed with alternating current, chlorides may attack it and use is made of this fact in etching platinum and platinum alloys.

Platinum is quite resistant to acid potassium sulfate, sodium carbonate, potassium nitrate at moderate temperatures and to sodium carbonate at 800 to 900 C under nonoxidizing conditions, although it is attacked vigorously by molten alkali cyanides and polysulfides, but it is quite resistant to the normal sulfides plus alkali. Certain phosphates attack it at high temperatures, and care must be taken to avoid reducing conditions, particularly when compounds of arsenic, phosphorus, tin, lead, or iron, are present. Platinum is resistant to molten glasses, especially to those low in lead and arsenic.

Platinum, even in the form of thin leaf, is resistant to corrosion and tarnishing on atmospheric exposure, including urban sulfur-bearing atmospheres.

* W. F. Roeser, private communication

* F. L. Jones, private communication

J *1 Crystal structure.*[3] Face-centered cubic; lattice parameter at 20 C (68 F) 3.9158 kX

K *Mechanical Properties.*

Annealed: tensile strength 17,000 to 19,000 psi; proportional limit less than 2000 psi; elongation 25 to 40%; Vickers pyramid hardness 38 to 40; modulus of elasticity (for small cyclic strains) 21,300,000 psi* and also 24,600,000 psi[23] (which seems high); Poisson's ratio[24] 0.39.

Hard drawn: Modulus of elasticity 22,600,000 psi

Electrodeposited:[26] Vickers hardness, approx 600

The effect of cold rolling on the hardness after annealing for 15 min at various temperatures, for a sample about 99.99% pure[24] is shown in Fig. 5. The grain size after annealing this type of platinum is determined almost entirely by the prior reduction; virtually no grain growth occurs on the usual short anneals. It is probable, however, that platinum, free from oxygen in solution, will show grain growth after recrystallization and may possess a still lower annealing temperature. The effects of alloying elements on the hardness are shown in Fig. 6.

High-temperature properties. The short-time tensile strength of annealed, quite pure platinum was 20,700 psi at room temperature; at 400 C it was 13,000 psi; at 800 C, 8000 psi; and at 1000 C, 4000 psi.[27] The elongation increased with the temperature and exceeded 25% in all tests. The strengths of the alloyed platinums generally are higher than these values. The "time to fracture" of platinum and some platinum alloy wires at 1100 C has been studied.[22]

6 Creep behavior between 850 and 1000 C (1560 to 1830 F) is discussed in reference 21.

N *6 Precautions in working.* Melting procedures are described on page 1097. The maintenance of oxidizing conditions throughout processing is essential to avoid contamination in the high-purity materials. Pickling in hot hydrochloric acid, after rolling and before annealing, to remove iron, likewise is essential for high-purity wire and sheet.

15 Heat treatment. Hot reducing atmospheres, particularly where silica, iron or manganese are in the vicinity, are almost certain to result in contamination.

Commercial Types of Platinum

By F. E. Carter*

THE FOUR generally recognized grades of wrought platinum that contain at least 99% Pt are known commercially as types A, B, C and D.

Type A, which is at least 99.99% pure, is used for thermocouples and resistance thermometers. This grade is sometimes called "physically pure" because estimation of purity is based on determinations of the thermal emf and the temperature coefficient of resistivity, in addition to spectroscopic and chemical analyses. The properties of this type of material have been summarized in the data sheet on pure platinum.

Type B contains 99.9% Pt and is often called "chemically pure", "special pure" or "specially refined platinum". It is used for the preparation of pure salts and for making platinum-rhodium catalysts and the like.

Type C contains 99.5% Pt or more and is very low in iron and other base metals. It is called "crucible grade" and is used for general laboratory purposes and for anodes.

Type D, containing 99.0% Pt or more, is known as "commercial platinum" and is used for jewelry, electrical contacts and the like.

The resistance to corrosion at ordinary temperatures is the same for all these types, but at very high temperatures, under oxidizing conditions, some slight differences may be found. The electrical resistivity, temperature coefficient of electrical resistivity, and thermal emf differ among these grades, and the mechanical strength and annealing temperatures increase as the purity decreases. Platinum should not be heated under reducing conditions or with elements that will diffuse into the metal.

Typical values for the properties that would be expected to differ appreciably are listed in Table I.

* Baker & Company, Newark, N. J.

Table I. Some Physical and Mechanical Properties of Commercial Platinum

Property	Types A	B	C	D

Platinum Alloys Containing from 3.5 to 20% Rhodium

BY F. E. CARTER*

SOME physical and mechanical properties of platinum-rhodium alloys are listed in Table I and Fig. 1 and 2.

Working. The alloys that contain up to about 20% Rh can be worked hot or cold; alloys richer in rhodium require considerable hot work before they can be cold worked satisfactorily. The working range is from 900 to 1200 C and the annealing temperature is from 900 to 1000 C. Reductions up to 90% between anneals are satisfactory.

Uses. Rhodium is the preferred addition to platinum for most applications at high temperatures under oxidizing conditions since, in contrast with most other hardeners, rhodium is not selectively volatilized. The 10% Rh alloy is the most important of the series and finds major use as the catalyst for the oxidation of ammonia by air, in the production of nitric acid. This same alloy, but with composition controlled precisely, is the positive element in the standard thermocouple (Pt–10% Rh versus platinum) that is widely used in laboratories and in industrial control. Some use is made of the Pt–13% Rh versus platinum thermocouple in instruments that are calibrated for it.

Table I. Some Properties of Platinum-Rhodium Alloys

Rhodium content	3.5%	5%	10%	20%
Density, ▮ per cu cm	20.9	20.65	19.97	18.74
Electrical resistivity at 20 C, microhm-cm	16.6	17.5	19.2	20.8
Temp coeff of elec resistivity, 20 to 100 C	0.0022	0.0020	0.0017	0.0014
Tensile strength (annealed), psi	25,000	30,000	45,000	70,000
Elongation (annealed), %	....	....	35	40
Bhn (annealed)	60	70	90	120
Tensile strength (hard), psi	60,000	70,000	90,000	130,000
Elongation (hard), %	....	....	2	2
Bhn (hard)	120	130	165	210

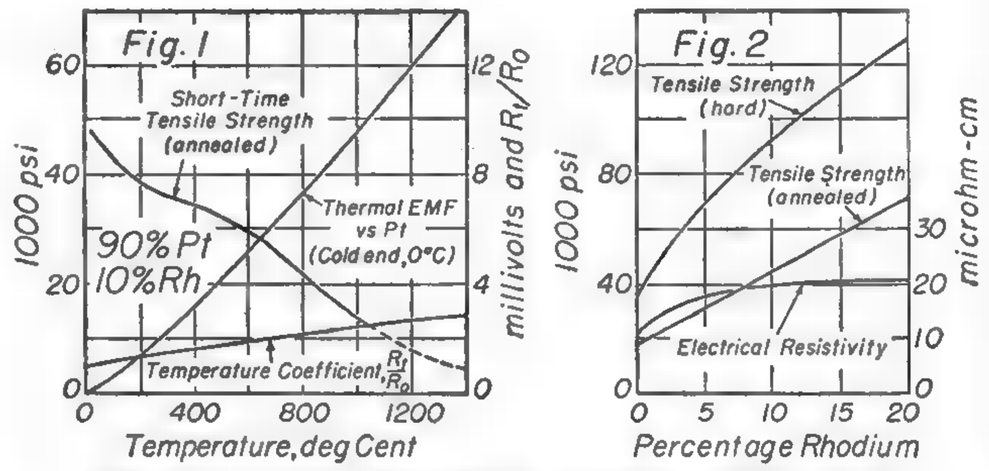

Fig. 1 and 2 Some properties of platinum-rhodium alloys

The 3.5% Rh alloy, used for crucibles, serves well and shows very little loss in weight at high temperatures. Platinum-rhodium alloys are useful in contact with molten glass; the 10% Rh alloy, in particular, is used for glass feeder dies and the like, and is especially desirable for handling the glasses of higher melting point.

The 10% Rh alloy is used for rayon spinnerets.

Both 10 and 20% Rh platinum make excellent windings for high-temperature electric furnaces that operate under oxidizing conditions. These are the preferred platinum alloys for this purpose.

Resistance to Corrosion. The resistance of the platinum-rhodium alloys to corrosion is as good as, or better than, that of pure platinum at ordinary temperatures, and at high temperatures is usually better than the resistance of pure platinum, except under sulfidizing conditions.

Platinum Alloys Containing from 5 to 30% Iridium

BY F. E. CARTER*

SOME physical and mechanical properties of four grades of platinum-iridium alloys are listed in Table I and the effect of iridium content is shown in Fig. 1.

Working. The alloys that contain from 5 to 10% Ir can be hot worked between 1000 and 1200 C. Temperatures between 1000 and 1300 C are suitable for the 25% alloy. In cold working, reductions of 75% between anneals are suitable for the 5 and 10% Ir alloys, and of 50% for the 25% Ir alloy. Annealing temperatures are about 1100 C for the lower alloys and 1200 C for alloys with 25-30% Ir.

Uses. Alloys that contain from 5 to 25% Ir are in general use. The 5 and 10% Ir alloys, also known as "medium hard" and "hard platinum", are widely used for jewelry; the 10% Ir and particularly the 25% Ir alloys are used for electrical contacts. The 25 and 30% alloys are used for tubing for pens and hypodermic needles, for spring elements and other articles in which maximum hardness and high annealing temperature plus ductility are required. The 10% Ir alloy is also used for anodes in electrolysis. Various platinum-iridium alloys are used in equipment for chemical plants and to some extent in dentistry.

Table I. Some Properties of Platinum-Iridium Alloys

Iridium content	5%	10%	25%
Trade designation	Medium Hard	Hard	....
Density, g per cu cm	21.49	21.53	21.66
Electrical resistivity at 20 C, microhm-cm	19	25	33(a)
Temp coeff, 0 to 100 C	0.0020	0.0013	0.00065(a)
Thermal cond at 17 C	....	0.074 cgs	....
Tensile strength (annealed), psi	40,000	55,000	125,000
Bhn (annealed)	90 (33R_B)	130 (62 R_B)	240 (18.5 R_c)
Tensile strength (hard), psi	70,000	90,000	170,000
Bhn (hard)	140 (79 R_B)	185 (91 R_B)	310 (31.5 R_c)

NOTE. For the 10% Ir alloy the thermal expansivity at 20 C is 8.89 × 10^{-6} per °C. The effect of temperature on the length of this alloy between 0 and 1000 C is

$$L = L_0 10^{-6} (1 + 8.841\ t + 0.0013\ t^2)$$

(a) With an iridium content of 30%, the resistivity is 35 microhm-cm and the temperature coefficient is 0.0006 between 0 and 100 C.

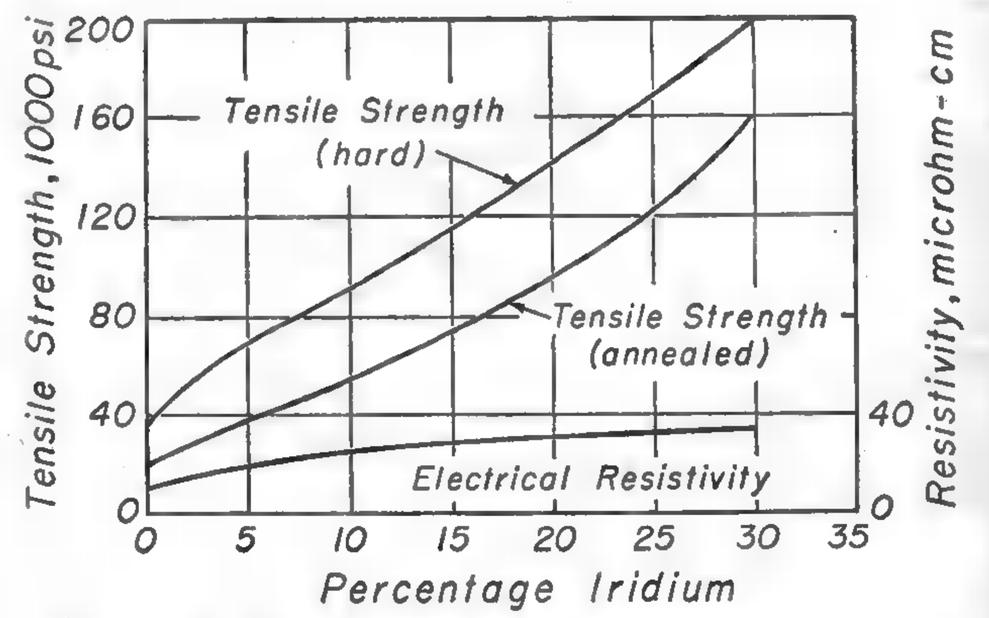

Fig. 1 Effect of iridium content in platinum-iridium alloys

Resistance to Corrosion. In general, the resistance to aqueous solutions of halogens is increased by the presence of iridium, particularly when 20 to 25% Ir is present, but for high-temperature service in air, alloys that contain more than about 1% Ir are seldom used, since iridium is lost through oxidation and volatilization.

* Baker & Company, Newark, N. J.

Platinum Alloys Containing 5 and 10% Ruthenium

By F. E. Carter*

PERTINENT physical and mechanical properties of two grades of platinum-ruthenium alloy are listed in Table I and the effect of ruthenium content is shown in Fig. 1.

Working. The 5% Ru alloy is hot worked between 900 and 1200 C and the 10% Ru alloy, between 1000 and 1300 C. Annealing temperature for the 5% alloy is about 1000 C and for the 10% alloy, 1100 C. Maximum reduction between anneals should not exceed 90% for the 5% alloy, or 75% for the 10% alloy. The atmosphere for high-temperature anneals should be only slightly oxidizing, since excessively oxidizing atmospheres cause loss of ruthenium in the same general manner as with iridium alloys.

Uses. The alloy that contains 5% Ru is used in jewelry, since it has properties essentially the same as the 10% Ir alloy—the so-called "hard platinum" of the jewelry trade. The same alloy is also used for laboratory electrode stems and for certain other chemical equipment, but it is not completely suitable for service at high temperatures under strongly oxidizing conditions. Platinum-ruthenium alloys are frequently employed as electrical contacts—the 5% Ru alloy in the medium-duty field and the 10% alloy in aircraft magnetos. Complex platinum-base alloys that contain 4 to 5% Ru are being used to some extent for spark plug electrodes in aircraft.

Table I. Some Physical and Mechanical Properties of 95 Pt–5 Ru and 90 Pt–10 Ru Alloys

Property	Hard Jewelry Grade	Contact Grade
Ruthenium content, %	5	10
Density, g per cu cm	20.67	19.94
Electrical resistivity, microhm-cm	31.5	43.0
Temperature coefficient, 0 to 1000 C	0.0009	0.0008
Tensile strength (annealed), psi	60,000	85,000
Elongation (annealed), %	34	31
Hardness (annealed), Bhn	130 (70 R_B)	190 (86 R_B)
Tensile strength (hard), psi	115,000	150,000
Elongation (hard), %	2	2
Hardness (hard), Bhn	210 (94 R_B)	280

Platinum Alloys Containing from 1 to 5% Nickel

By E. M. Wise*

SOME physical and mechanical properties of platinum alloys that contain 1, 2 and 5% Ni are listed in Table I and Fig. 1 and 2.

Uses. This type of alloy has long been used because of good strength at high temperature. The 5% Ni alloy has been used in a vacuum as the base for long-life oxide-coated thermionic cathodes.[1] Alloys that contain up to 2% Ni are used for spinnerets and associated equipment in producing fiber glass.[2]

Resistance to Corrosion. Selective oxidation of nickel will occur when these alloys are heated to high temperatures under strongly oxidizing conditions. For this reason an alloy containing 5% Ni will gain rather than lose in weight while heating below 1500 C in air, but in the alloys that contain less than 2% Ni, this effect is reduced and such alloys are satisfactory for handling molten glass.[2]

Table I. Some Physical and Mechanical Properties of Platinum-Nickel Alloys

Nickel content	1%	2%	5%
Density, g per cu cm	21.1	20.8	20.0

Platinum-Palladium-Silver Alloys

See Properties of Palladium Alloys, page 1129.

84 Pt – 10 Pd – 6 Ru

COMPILED BY E. M. WISE*

B *1 Typical uses.* This alloy was developed specifically for electrodes in spark plugs in high-duty aircraft engines, where maximum resistance to highly leaded fuels is required. Under combustion conditions some lead from the fuel is reduced, and in alloys in which lead is virtually insoluble it tends to penetrate along grain boundaries. Damage from this cause is reduced if the alloy is in the cold worked, unrecrystallized condition.[1] With pure platinum and the platinum-palladium alloys lead is absorbed in the surface layers and shows less tendency toward the more damaging intercrystalline attack, apparently because of some solid solubility of lead in the alloy. However, these materials are too soft to resist erosion and mechanical stresses, so a small amount of ruthenium is added to harden them.[2] For the best results this alloy should be used in the drastically cold worked condition. Although designed especially for spark plug electrodes, this alloy, as well as the 10 to 12% Pd platinum alloy, is useful for electrical contacts in magnetos and the like.

96 Pt – 4 W

COMPILED BY E. M. WISE*

B *1 Typical uses.* This alloy was developed initially for spark plug electrodes in aircraft engines, but was shortly adopted for grids in radar tubes where reduced electron emission was required. It performs outstandingly in both situations. For spark plugs it is employed in the drastically hard drawn condition because it is more resistant to lead in that state. For radar use, slightly softer wire is preferred since it is more easily handled. Because of the selective oxidation of tungsten, this alloy is not recommended for service at very high temperatures under oxidizing conditions where platinum or rhodium platinum would be suitable.

PALLADIUM AND PALLADIUM ALLOYS

Palladium

COMPILED BY E. M. WISE*

B *1 Typical uses.* Palladium resembles platinum in many respects including appearance, high ductility, and strength, and follows it in importance and abundance. Palladium is used for contacts in electrical relays, as an alloying element in complex wrought and cast dental alloys, in jewelry, and as an industrial catalyst in the manufacture of synthetic organic products, such as vitamins and ethylene, and also in the manufacture and purification of hydrogen. Some use is also made of the rapid and selective diffusion of hydrogen through palladium to prepare chemically pure hydrogen. Sometimes this effect is used to act as a valve that will admit hydrogen to vacuum systems when the palladium is warmed.

C *1 Density* at 20 C (68 F).[2] 12.02 g per cu cm (0.4343 lb per cu in.)

5 *Emissivity*[20] with a mean wave length of 0.65 μ: (solid) 0.33; (liquid) 0.37.

G 2 *Magnetic susceptibility*[17] at 18 C (64 F). Approx 5.8×10^{-6} mass units

I 1 *General resistance to corrosion.* At room temperature palladium is resistant to corrosion by hydrofluoric, perchloric, phosphoric and acetic acids. It is attacked slightly by sulfuric, hydrochloric and hydrobromic acids, especially in the presence of air; and it is attacked readily by slightly impure nitric acid, ferric chloride, hypochlorites, and moist chlorine, bromine and iodine. In ordinary atmospheres palladium is resistant to tarnish, but some discoloration may occur during exposure to moist industrial atmospheres that contain sulfur dioxide. Adding palladium to gold or silver alloys improves the tarnish resistance.

J 1 *Crystal structure.* Face-centered cubic; lattice parameter, 3.8825 kX at 20 C.[4]

K *Mechanical properties.*

Modulus of elasticity. 16,000,000 psi;[21,22] 17,500,000 psi.[23]

Strength and hardness. The hardness of pure, rolled and annealed palladium is about 37 to 39 Vickers, almost the same as that of platinum, and when tested as 0.050-in. wire after annealing at a high temperature, the metal may show a tensile strength as low as 21,000 psi with about 24% elongation. Similar wire annealed at 800 C will have a tensile strength of about 25,000 psi with 30% elongation. Such material work hardens slowly and will show a tensile strength of about 37,000 psi after 75% reduction by drawing. The effect of cold working upon the Vickers hardness of pure palladium, wrought from pure sponge melted in a lime block furnace, is shown in Fig. 5,* along with data on the tensile properties for cold drawn wire. Data on the hardness of commercial palladium are also shown in Fig. 5. This commercial palladium was also very pure (approx 99.9%), but differences in the method of melting and the presence of traces of deoxidizing elements increased its hardness and strength. Such material has a tensile strength from 25,000 to 30,000 psi as annealed, and about 47,000 psi after cold drawing 50%. The tensile properties of commercial palladium, initially reduced 50% by cold drawing and annealed for 5 min at various temperatures are shown in Fig. 6.[19] The optimum anneal for this material is about 800 C (1472 F). Electrodeposited palladium, much harder than the wrought materials, ranges from 190 VPN for metal from the chloride bath to about 400 VPN for deposits from complex nitrite baths. The types of palladium employed for jewelry and in some other articles generally contain ruthenium and are considerably harder than the pure metal. The relative effects of various additions on the hardness of annealed material are summarized in Fig. 7.[12]

High temperature properties. The short-time tensile strength of commercial palladium initially annealed at 1100 C was 28,000 psi at room temperature, 18,100 psi at 400 C, 8300 psi at 800 C, and 3800 psi at 1000 C.[3]

N 6 *Precautions in working.* Procedures for melting have been described on page 1097. Nitrogen is a good annealing atmosphere, and temperatures of about 800 C 1470 F) for five minutes give good combinations of properties in the commercially pure material, while 1000 to 1100 C (1832 to 2012 F) is required for some of the harder alloys.

17 *Joining.* In soldering palladium, an oxyacetylene torch is desirable, and platinum solders melting from 1100 to 1300 C (2000 to 2375 F) should be used.

* R. H. Atkinson

60 Pd – 40 Ag

COMPILED BY R. F. VINES*

B *1 Typical uses.* For electrical contacts at low currents and as a nontarnishing electrical resistor of low temperature coefficient. This alloy contains sufficient palladium to be nontarnishing in indoor atmospheres and, where resistance to nitric acid is desired, 5 to 10% Pt can be added at the expense of palladium. The alloy, solid or as cladding, is suitable for jewelry.

C *1 Density.* 11.3 g per cu cm (0.408 lb per cu in.)

D *1 Liquidus temperature.* 1390 C (2534 F)
2 Solidus temperature. 1330 C (2426 F)

E *2 Electrical resistivity* at 20 C (68 F). 42 microhm-cm
5 Temperature coefficient of electrical resistivity 20 to 100 C (68 to 212 F). 0.00002 per °C
Coefficient of strain resistivity. $(dR/R)/(dL/L) = 0.88$

K *Mechanical properties. Annealed:* tensile strength 51,000 psi; elongation in 2 in. 47%; VHN 100.
50% reduction: tensile strength 94,000 psi; elongation in ▮ in. 4.5%

* Dentists' Supply Company, York, Pa.

60 Pd – 40 Cu

COMPILED BY H. T. REEVE*

B *1 Typical uses.* This alloy was devised for electrical contacts in the milliampere range, in circuits containing sufficient capacity so that a considerable rush of current occurs on closure. It is also used where a hard material is required for slip rings running against brushes of the same material, and is generally given a final heat treatment to convert it to the ordered, highly conducting condition. This conversion is accelerated greatly by cold work or by the presence of hydrogen in solution.

C *1 Density* at 20 C (68 F). 10.6 g per cu cm (0.383 lb per cu in.)

D *1 Liquidus temperature.* Approx 1225 C (2235 F)
2 Solidus temperature. Approx 1195 C (2185 F)

E *2 Electricial resistivity.* 35 microhm-cm, annealed and quenched; 3.5 microhm-cm, ordered, which is best produced by heating cold worked material at about 300 C.
5 Temperature coefficient of electrical resistivity 20 to 100 C (68 to 212 F). 0.00032 per °C, annealed; 0.00224 per °C, ordered.

K *Mechanical properties.* Tensile strength 75,000 psi, annealed; 193,000 psi, hard drawn

* Bell Telephone Laboratories, Murray Hill, N. J.

Palladium-Silver-Copper Alloys

BY E. M. WISE*

PALLADIUM increases the liquidus and solidus temperatures of silver-copper alloys and increases the mutual solubility of silver and copper. At high temperatures most of the ternary alloys are solid solutions, and all are workable after quenching. At lower temperatures there are ordered phases based on PdCu and $PdCu_3$. In the low-palladium alloys, copper-rich and silver-rich phases may be precipitated.

Many of the alloys are age hardenable. The maximum hardnesses are shown in Fig. 1. It will be noted that values in excess of 450 Vickers or about Rockwell C 49 are attainable in alloys that contain approximately 30% Cu, 30% Ag, 40% Pd. This hardness is unusually high for an alloy that is readily workable in the quenched condition.

Alloys that contain less than 5% Cu or more than about 65% Pd (slightly more than 50 atomic % Pd) do not age harden and have properties intermediate between the silver-palladium and copper-palladium alloys.

Melting and Working. The alloys must be melted in such a manner that oxygen, silicon and sulfur are low in the metal when it is cast. Final deoxidation with a few hundredths per cent of calcium or calcium boride often is useful. Annealing in nitrogen at about 800 C is suitable for most of the alloys, and the age hardenable ones should be cooled fairly rapidly to ensure full softness. If much zinc is present, oil quenching may be required to prevent partial hardening during cooling. Treatment for ¼ to 5 hr between 400 and 450 C hardens many alloys effectively.

Resistance to Tarnishing. The silver-palladium alloys that contain 50 to 60 weight or atomic % Pd, have good resistance to tarnishing but that of the corresponding copper-palladium alloys is not quite so good. If substantial age hardening is required, the palladium content should not exceed about 45%, but small amounts of gold or platinum can be added without impairing the hardening, and may actually increase it along with the resistance to tarnishing. As a result, a whole series of useful quaternary alloys exists between Cu-Ag-Pd and Cu-Ag-Au systems.

Uses. Alloys that contain about 45% Pd with sufficient copper to age harden to the desired level are used in dentistry, as are variants that contain a small percentage of platinum or gold. These alloys are used also for electrical contacts subjected to sliding wear or for applications that require good spring properties. About 1% Zn may be present, and this as well as platinum appears to accelerate the age hardening. The alloys containing 10 to 15% Pd have been considered for silver solders of unusually high strength.

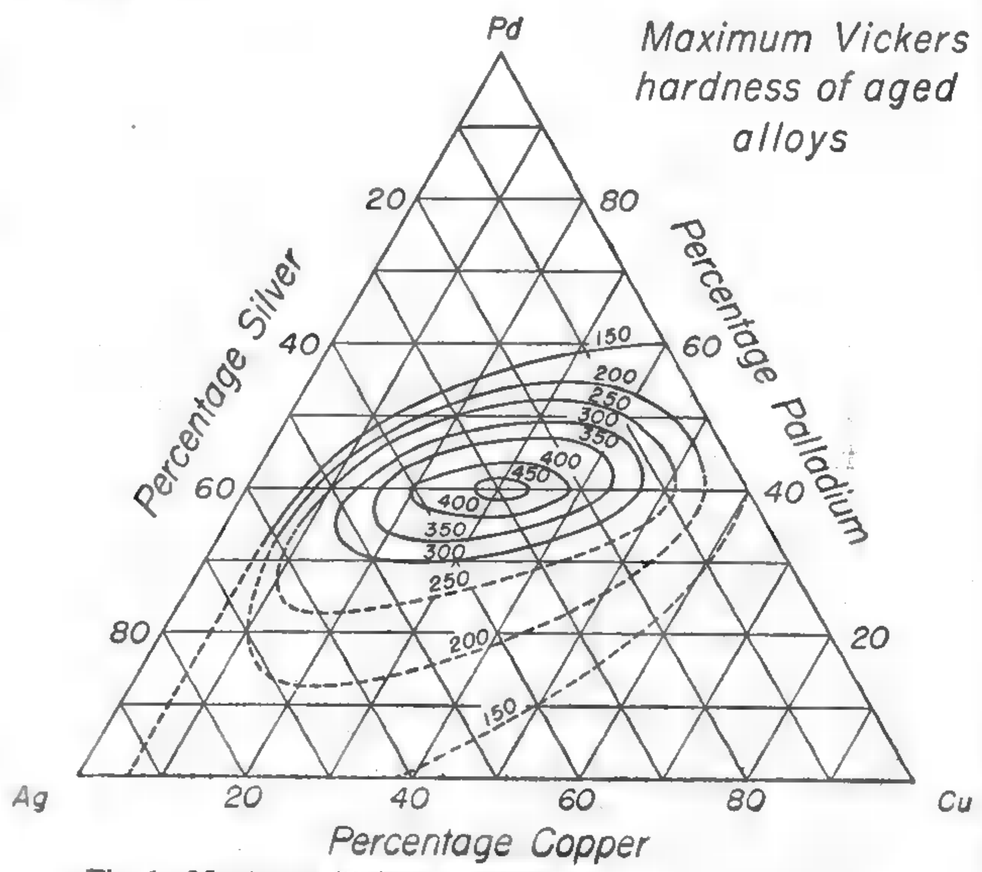

Fig. 1 Maximum Vickers hardness of aged Pd-Ag-Cu alloys

* The International Nickel Company, Inc., New York

Palladium-Gold-Silver Alloys

By E. M. Wise*

SOLID Pd-Au-Ag alloys are probably free from transformations, as are all the binary alloys of these metals. The solidus and liquidus temperatures are higher than for most gold alloys, and throughout the system, the melting range is narrow. The hardness of annealed alloys is shown in Fig. 1.

Working Properties. Precautions are required to secure low oxygen, sulfur and silicon contents in the cast alloys. The best annealing temperatures are higher than required for the usual gold alloys. Steam or nitrogen are probably the best annealing atmospheres. Alternately oxidizing and reducing atmospheres should always be avoided, since they cause damage to the surface of most of the alloys. The working properties of high-purity alloys are excellent; both solid and clad materials can be fabricated by cold working and in some instances by hot working.

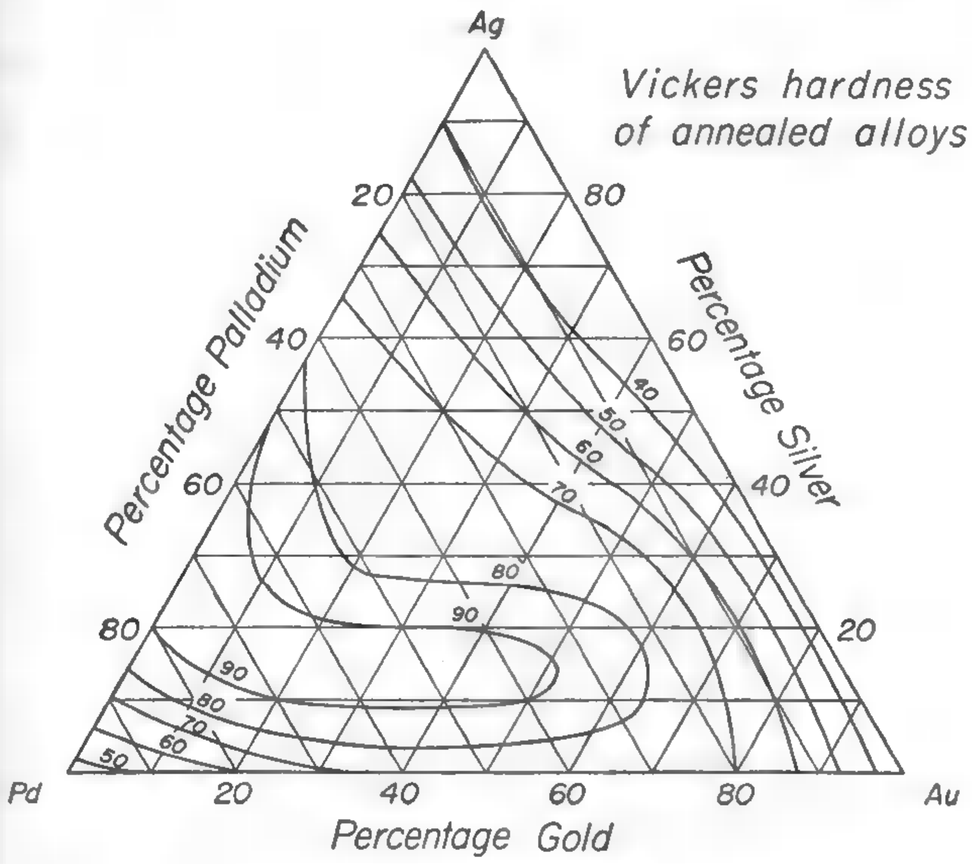

Fig. 1 Vickers hardness of annealed Pd-Au-Ag alloys

* The International Nickel Company, Inc., New York

Corrosion Properties. In general the resistance to tarnishing of the ternary alloys increases with the sum of the percentages of gold plus palladium, but palladium is somewhat more effective. The resistance to tarnishing becomes very good at 50 to 60% Pd or at about 70% Au. The addition of 20% Au to palladium or about 60% Au to silver, results in substantial resistance to nitric acid, and the ternary alloys from these points to the gold corner are very resistant to nitric acid. Although these alloys do not oxidize at high temperatures, they do dissolve some oxygen if heated in air; then if the alloys are heated later in a hydrogenous gas, hydrogen will diffuse into the metal, will react with the oxygen in solid solution, and will produce small surface blisters. This effect is greater in the silver-rich and the silver-palladium-rich alloys.

Uses. Gold-palladium alloys that contain 15 to 20% Pd are essentially white in color and are tarnishproof. The gold-silver alloys that contain about 50% Ag also are white, but will tarnish. The ternary alloys extending from these points to the palladium corner are white, and those that contain sufficient palladium plus gold are sometimes used where a somewhat subdued white color is desired, as in certain soft and ductile dental alloys and some high-melting solders. These alloys, however, should not be confused with the Au-Ni-Cu-Zn alloys, which are also white but much harder and more difficult to fabricate.

The addition of copper to Pd-Au-Ag alloys provides metals that are responsive to age hardening and are the basis for many of the cast and wrought high-strength dental materials.

Palladium-Platinum-Silver Alloys

By R. F. Vines*

THE WIDE spread between the liquidus and solidus temperatures of the silver-platinum alloys and the transformations that occur in the binary alloys generally have limited the interest to alloys containing a few per cent of platinum. The addition of palladium, which forms simple solid solutions with both platinum and silver, avoids both troubles and gives rise to a wide field of readily fabricated single-phase alloys.

The hardness of rolled and annealed alloys is approximately as shown in Fig. 1. Some of the ternary alloys can be age hardened appreciably, but the solid solution alloys are of most interest. If higher hardness is desired, supplementary hardeners may be added—for example, a few per cent of nickel.

Palladium-silver alloys that contain 50 to 60% Ag possess adequate resistance to tarnishing to be suitable for jewelry and optical uses, but sometimes resistance to nitric acid is considered necessary also, in order to conform to the customs of the industry, and experiment shows that this resistance can be secured by the addition of a small amount of platinum. Typical alloys, comparable with the usual carat gold alloys in cost, would contain 40% Pd, 10% Pt, 50% Ag or 50% Pd, 7.5% Pt, 42.5% Ag, sometimes with 2% Ni replacing silver where higher hardness is desired.

Alloys that contain about 25% Pt, 25% Ag, 50% Pd, offer a good base for high-melting, corrosion-resistant dental alloys. These alloys, like those lower in platinum and palladium, can be hardened further by small additions of certain other metals.

* The Dentists' Supply Company, York, Pa.

Considerable use has been made of a silver-rich alloy containing 3% Pt, particularly for instrument slip rings, where something harder than pure silver is desired. This amount of platinum would, of course, have little effect on the resistance to tarnishing. Aside from this

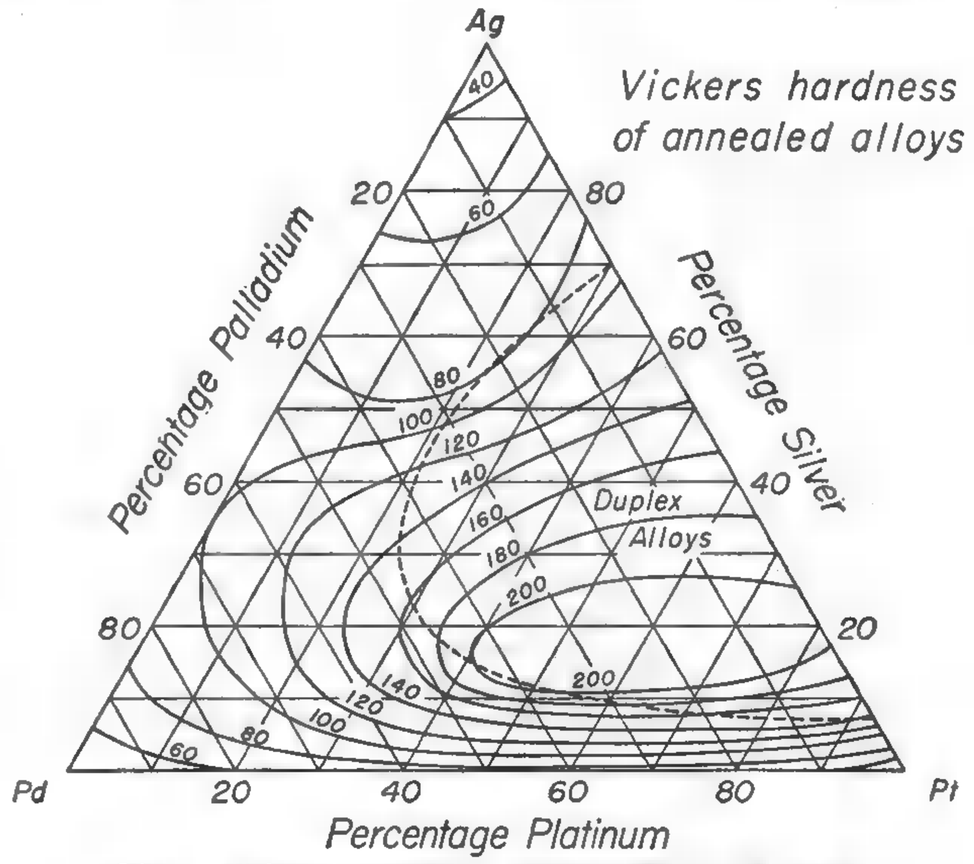

Fig. 1 Vickers hardness of annealed Pd-Pt-Ag alloys

application, the silver-rich alloys of this series have been used little; however, the 40% Ag, 60% Pd alloy, and related alloys in which a little palladium is replaced by platinum, are useful for electrical contacts, particularly where resistance to tarnishing is essential.

The alloys high in palladium or platinum can be melted best in a high-frequency furnace with final deoxidation by a trace of calcium boride. Annealing is desirable at 800 to 1000 C in a neutral atmosphere such as nitrogen. Rolling of the single-phase alloys involves no special problems. The heterogeneous alloys are troublesome to fabricate but thus far have been used very little.

95.5 Pd – 4.5 Ru and 95 Pd – 4 Ru – 1 Rh

COMPILED BY R. H. ATKINSON*

B *1 Typical uses.* Ruthenium, alone or with a small percentage of rhodium, is the principal hardener employed with palladium. The resulting alloy is designed primarily for jewelry; it can also be used for electrical contacts. The alloy is used principally in wrought form; production by casting is anticipated.

C *1 Density* at 20 C (68 F). 12.0 g per cu cm (0.434 lb per cu in.)

E *2 Electrical resistivity* at 20 C (68 F). 23.5 microhm-cm for the 4.5% Ru alloy

F *1 Reflectivity.* See Fig. 4 on page 1127.

K *Mechanical Properties. See* Table I.

N *9 Annealing. See* Fig. 1, the annealing curve for 95 Pd – 4 Ru – 1 Rh, which indicates that temperatures between 1000 and 1100 C are suitable. Annealing in nitrogen is desirable for high-quality jewelry.

17 Joining. Soldering with an oxyacetylene torch and melting with this torch or electrically without contamination with silicon, oxygen or sulfur, are highly desirable.

Table I. Mechanical Properties of Pd-Ru and Pd-Ru-Rh

Condition	Tensile Strength, 1000 psi	Elongation, percentage	Vickers Hardness Number
95.5 Pd – 4.5 Ru			
Annealed	....	....	80 to 90
Annealed and furnace cooled	....	....	100 to 130

IRIDIUM, OSMIUM, RHODIUM AND RUTHENIUM

Iridium

COMPILED BY R. F. VINES*

B *1 Typical uses.* Small crucibles have been made of iridium for studying high-temperature reactions. Iridium has been used for extrusion dies for very-high-melting glasses.* Iridium is not wet by mercury and this phenomenon has been used in certain electrical devices. The major use is as an alloying element in platinum; occasionally iridium is added to other metals of the platinum group. This addition increases the resistance to aqueous corrosives and reduces the rate of attack in aqua regia. More than about 1% Ir in platinum is usually not desirable if the alloy is to be used at high temperatures under oxidizing conditions, since iridium is oxidized and volatilized. Platinum-iridium alloys, which are used for jewelry, electrical contacts and elsewhere, are discussed in the article on page 1124.

C *1 Density* at 20 C (68 F). 22.5 ▮ per cu cm (0.813 lb per cu in.)

D *1 Melting point.*[3, 4] 2454 ± 3 C (4449 ± 5 F)

4 Boiling point.[5] Approximately 5300 C (9570 F)

6 Thermal expansion[6] at 20 C (68 F). 0.0000068 per °C

11 Specific heat[7] at 20 C (68 F). 0.0307 cal per g

16 Thermal conductivity.[8] 0.14 cal/sq cm/cm/°C/sec

E *2 Electrical resistivity* at 0 C (32 F). 4.9 microhm-cm at 20 C (68 F). 5.3 microhm-cm[9]

5 Temperature coefficient of electrical resistivity.[10] 0.003925 per °C (0 to 100 C)

6 Thermal emf versus platinum[11] 0 to 100 C (32 to 212 F). + 0.65 mv

F *1 Reflectivity.*[12] 64% at $\lambda = 0.45\ \mu$
70% at $\lambda = 0.55\ \mu$
78% at $\lambda = 0.75\ \mu$

Iridium is intermediate between palladium and rhodium in reflectivity and color.

5 Emissivity at 0.65μ. 0.30 for solid unoxidized metal[13]

G *2 Mass magnetic susceptibility* at 18 C (64 F).[14] 0.15×10^{-6} cgs

I *1 General resistance to corrosion.*[17] Iridium is the most corrosion-resistant element. It is not affected by

* Research Laboratory, Dentists' Supply Co., York, Pa.

* J. C. Chaston, private communication

common acids, including hot sulfuric acid. It is slightly attacked by sodium hypochlorite solutions but not by aqua regia at ordinary temperatures. However, at elevated temperatures and pressures aqua regia does attack iridium, and this method may be used for dissolving iridium and its refractory alloys for analysis. Iridium is virtually insoluble in lead even at high temperatures and use is often made of this fact in preliminary steps in chemical analysis.

K *Mechanical properties.* The Vickers hardness[15] of annealed iridium is approximately 170 and that of hard rolled material, 350.

The modulus of elasticity[16] is extremely high, perhaps as high as 76,000,000 psi.

N *Working data.* Iridium can be melted in a high-frequency furnace in a thoria crucible and can be forged with some difficulty at temperatures ranging from 1200 to 1500 C (2190 to 2730 F). Hot rolling is possible. In general, the workability of iridium is between that of ruthenium and rhodium.

Osmium

COMPILED BY E. M. WISE*

B *1 Typical uses.* Osmium is the rarest of the platinum metals and is the hardest and has the highest melting point. It is completely unworkable. The hardness, resistance to wear and to corrosion of high-osmium and related alloys in which osmium and ruthenium are present account for their use for tips of fountain pen nibs, long-life phonograph needles and instrument pivots. The best quality alloys often contain 60% or more of osmium, plus ruthenium, the remainder platinum metals, sometimes plus a little tungsten or other metal. The hardness of these alloys is approximately 700 to 800 VPN. For instance, the 25 Pt–75 Os alloy has a VPN of 800; the 50 Pt–50 Os alloy, a hardness of 720 VPN.[10] The resistance to rubbing wear is perhaps the most important characteristic of the high-osmium alloys but is not solely the result of high hardness; other alloys as hard or harder are inferior. The low magnetic permeability, hardness and corrosion resistance of the osmium alloys makes them useful for certain instrument pivots. In certain types of vibrating electrical contacts where the movement is small, an alloy containing 66 to 70% Os, balance rhodium, made by fusion or by sintering, has been employed for the positive contact with 10% Ru platinum for the negative. This combination minimizes metal transfer and results in smooth wear.

C *1 Density* at 18 C (64 F). 22.61 g per cu cm (0.82 lb per cu in.) from X-ray data;[2] 22.48 g per cu cm (0.812 lb per cu in.) has been obtained by direct measurement. The difficulty of securing completely sound specimens renders the measurement uncertain.

D *1 Melting point.* Probably about 2700 C (4890 F)

4 Boiling point.[4] Probably about 5500 C (9950 F)

Vapor pressure. Probably lowest of platinum metals. The rate of evaporation in vacuo or in an inert gas is correspondingly low, but in the presence of appreciable oxygen, oxidation occurs, resulting in rapid volatilization through the formation of the volatile and toxic OsO_4 (boiling point, 130 C); consequently osmium and osmium alloys are not used at elevated temperatures under oxidizing conditions.

7 Thermal expansion at 50 C (122 F) parallel to *c*-axis. 0.0000058 per °C

8 Thermal expansion at 50 C (122 F) perpendicular to *c*-axis. 0.000004 per °C

11 Specific heat at 0 C (32 F).[6] 0.0309 cal per g
at 100 C (212 F). 0.0314 cal per g
at 1600 C (2912 F). 0.0385 cal per g

E *2 Electrical resistivity* at 20 C (68 F).[7] Approx 9.5 microhm-cm

5 Temperature coefficient of electrical resistivity 0 to 100 C (32 to 212 F).[8] 0.0042 per °C

G *2 Mass magnetic susceptibility.*[9] Approx 0.074×10^{-6} cgs

I *2 Resistance to specific agents.** The rapid oxidation of osmium in air at elevated temperatures must be recognized in considering uses and processing. Osmium is resistant to sulfuric, hydrofluoric, hydrobromic and hydrochloric acids at room temperature. Finely divided osmium is attacked by nitric acid, but the fused metal is quite resistant to this acid, although reasonably well sintered samples are attacked appreciably by nitric acid and by aqua regia. The alkaline hypochlorites also attack the sintered metal. The usual high-osmium alloys are, however, extremely resistant to corrosion by inks even when subject to simultaneous rubbing on paper, although this combination is quite corrosive to some alloys that will withstand ink alone.

J *1 Crystal structure.*[3] Close-packed hexagonal; $a = 2.7304$ kX; $c/a = 1.5785$ at 18 C (64 F).

K *Mechanical properties.* Vickers hardness about 400; values of 350 and 438 have been observed.† Variations in the porosity of the sample and differences in purity probably account for the spread in observed values. Modulus of elasticity has been estimated to be as high as 81,000,000 psi,[11] highest of all elements.

N *Working data.* Osmium is completely unworkable. No ductility is apparent, so that osmium and osmium alloys must be produced by melting or sintering, followed by grinding to produce the final shapes required. Care must be taken to avoid oxidation during high-temperature operations and particularly in the recovery of the metal from grindings and other scrap.

Rhodium

COMPILED BY C. S. SIVIL*

B *1 Typical uses.** The pure metal is used principally where maintained high and uniform reflectivity is essential. This includes mirrors, principally those made by electrodeposition of rhodium on metal, plus some made by subliming rhodium on glass. Various types of light filters can be made by applying very thin coatings by subliming. A substantial amount of rhodium is electrodeposited as a nontarnishing finishing plate on jewelry articles, including white gold, silver, and other metals, as described in the article on Plating Precious Metals. Some use is also made of rhodium for the plating of sliding electrical contact surfaces; for this purpose rhodium is sometimes applied over a heavier plate of palladium. Some pure wrought rhodium is used but rhodium is most important as an alloying element with platinum, since these materials find much use at elevated temperatures for crucibles, furnace windings, glass working equipment, thermocouples, and particularly for catalysts.

C *1 Density* at 20 C (68 F). 12.44 g per cu cm (0.447 lb per cu in.)

D *1 Melting point.*[2] 1966 C (3571 F)
4 Boiling point.[3] Probably about 4500 C (8130 F).

G *2 Magnetic susceptibility*[10,11] at 18 C. 1.14×10^{-6} cgs

I *1 General resistance to corrosion.* Rhodium remains bright and untarnished during atmospheric exposure, and its general resistance to corrosion is exceptionally high. It is resistant even to boiling aqua regia. However, rhodium is attacked somewhat by hydrobromic acid, particularly when hot; by moist iodine, and by sodium hypochlorite. Hot sulfuric acid also attacks it, and sufficient corrosion occurs on electrolysis with alternating current in sulfuric acid to make this a useful metallographic etch.

Ruthenium

COMPILED BY R. H. ATKINSON*

B *1 Typical uses.* As a hardener for platinum and palladium for jewelry and other applications, including 10 to 11% Ru platinum for aircraft magneto contacts and similar contacts. Hard, complex high-ruthenium alloys are also used for pen tipping and the like. Some of these alloys also contain osmium.

C *1 Density* at 20 C (68 F). 12.2 ■ per cu cm (0.441 lb per cu in.) 12.45 g per cu cm at 18 C (64 F) computed from lattice constants.

D *1 Melting point.* 2500 ± 100 C (4530 ± 180 F)
4 Boiling point. Probably about 4900 C (8850 F)
6 Thermal expansion at 20 C (68 F). 0.0000091 per °C
11 Specific heat at 0 C (32 F). 0.057 cal per g

E *2 Electrical resistivity* at 0 C (32 F). 7.6 microhm-cm
10 Electrochemical equivalent (valence 2). 0.527 mg per coulomb
16 Supraconductive at 2.04 K

F *1 Reflectivity* in the visible range. 63% avg

G *2 Magnetic susceptibility.* 0.895×10^{-6} mass units

I *1 General resistance to corrosion.* The general resistance of ruthenium to corrosion approaches that of iridium. It is unaffected by common acids, including aqua regia, at temperatures up to 100 C, or by sulfuric acid up to 300 C. It is moderately attacked by aqueous solutions of alkaline hypochlorites.

J *1 Crystal structure.* Close-packed hexagonal; $a = 2.6987$ kX; $c = 4.2728$ kX.

K *Mechanical properties.* Vickers hardness 220 as cast; 390 for metal forged above 1500 C; modulus of elasticity, approx 60,000,000 psi

L *1 Metallography.* Etching: Use a-c electrolytic.

N *6 Precautions in melting.* Use inert atmosphere for induction melting. For torch melting, compress ruthenium powder to bar and use lime hearth and neutral oxyacetylene flame; work in hood with good draft to remove ruthenium tetroxide fumes.
7 Hot working temperature. 1500 to 2400 C (2730 to 4350 F)
11 Forming. Very difficult to work, but with care it can be forged at temperatures above 1500 C (2730 F).
13 Compacting pressure. 40,000 psi

* The International Nickel Company, Inc., Bayonne, N. J.

Antimony

COMPILED BY K. C. LI*

B *1 Typical uses.* Alloyed with lead for batteries. Alloyed with tin or lead for bearings and type metal. In the form of an oxide (Sb_2O_3) in enamels, pigments, and in fire-proofing materials.
C *1 Density* at 20 C (68 F). 6.62 g per cu cm (0.239 lb per cu in.)
D *1 Melting point.* 630.5 C (1166.9 F)
4 Boiling point. 1440 C (2620 F)
6 Thermal expansion 20 to 60 C (68 to 140 F). 0.0000085 to 0.0000108 per °C, the value depending on the crystal orientation in the polycrystalline material.
11 Specific heat at 20 C (68 F). 0.049 cal per g
13 Latent heat of fusion. 38.3 cal per ■
15 Latent heat of vaporization. 320 cal per ■
16 Thermal conductivity. 0.045 cal/sq cm/cm/°C/sec
E *2 Electrical resistivity* at 0 C (32 F). 39.0 microhm-cm
F *1 Reflectivity.* 70% at $\lambda = 5890$ A
G *2 Mass magnetic susceptibility.* minus 0.87 cgs
I *2 Resistance to specific agents.* See Table I.
J *1 Crystal structure.* Rhombohedral; lattice constant at 20 C, 4.4974 kX; axial angle, 57° 6.5′.

Table I. Resistance of Antimony to Corrosion

Corrosive Agent	Resistance	Remarks
Acid hydrochloric	Resistant	.....
Acid hydrochloric	Moderate attack	In presence of air
Acid hydrofluoric	Resistant	.....
Aqua regia	Severe general attack	.....
Acid nitric	Severe general attack	.....
Acid sulfuric	Severe general attack	Warm, concentrated
Acid sulfuric	Resistant	Cold or dilute
Ammonia	Resistant	.....
Carbon dioxide	Resistant	.....
Chlorine	Severe general attack	.....
Alkalies and alkali salts	General attack	.....
Air	Resistant	When dry
Air	Moderate general attack	When moist and in presence of light

5 Minimum interatomic distance. 2.898 kX
K *Mechanical properties.*
Brinell hardness number. 30 to 58
Ultimate tensile strength. 1560 psi (1.1 kg per sq mm)
Modulus of elasticity. 11,300,00 psi
Torsion modulus. 2,800,000 psi

* Chairman, Wah Chang Trading Corporation, New York

Arsenic

COMPILED BY A. C. VAUGHAN*

A *1 Common name.* Black Crystalline Arsenic
5 Other designations. There are two other forms of arsenic—black amorphous (density 3.70) and yellow cubic arsenic (density 2.0)
B *1 Typical uses.* Alloyed with lead to facilitate forming more perfect spheres in making lead shot. Alloyed with copper to increase corrosion resistance and to raise the recrystallization temperature. Added to lead-base babbitt and solder alloys to improve properties.
C *1 Density* at 15 C (59 F). 5.73 g per cu cm (0.207 lb per cu in.)
D *1 Melting point.* 814 C (1497 F) at 36 atmospheres
4 Boiling point. Arsenic sublimes at 610 C (1130 F)
6 Thermal expansion at 20 C (68 F). 0.0000047 per °C
11 Specific heat 0 to 100 C (32 to 212 F). 0.082 cal per g
15 Latent heat of vaporization. 444 cal per g
E *1 Volume conductivity* referred to standard copper. 4.9%
2 Electrical resistivity at 0 C (32 F). 35 microhm-cm
10 Electrochemical equivalent. (valence 3) 0.15254 mg per coulomb, (valence 5) 0.25876 mg per coulomb
G *2 Magnetic susceptibility.* minus 0.31×10^{-6} cgs at 18 C
J *1 Crystal structure.* Rhombohedral; $a = 4.151$ kX; alpha 53° 49′

* American Smelting and Refining Company, Barber, N. J.

Beryllium

COMPILED BY N. W. BASS AND BENGT KJELLGREN*

A *1 Common name.* Beryllium
6 Foreign equivalent. Glucinum

B *1 Typical uses.* As an alloying element in copper. In aluminum-base and magnesium-base alloys, beryllium decreases oxidation and combustibility of the melt and increases the fluidity (particularly of aluminum alloys). Vacuum-tight "windows" of pure beryllium are used in X-ray tubes. Also used as source of neutrons with radium, polonium or other elements.
2 Precautions in use. Beryllium oxidizes appreciably in air above 700 C. It reacts generally with dilute acids, alkalies and hot water. Liquid beryllium reacts with carbon.

C *1 Density* at 20 C (68 F). 1.816 g per cu cm (0.0658 lb per cu in.)

D *1 Melting point.* 1284 C (2343 F)
4 Boiling point. 2770 C (5030 F)
6 Thermal expansion 20 to 200 C (68 to 392 F). 0.0000124 per °C
11 Specific heat 30 to 100 C (86 to 212 F). 0.516 cal per g
13 Latent heat of fusion. 250 to 275 cal per g
15 Thermal conductivity at 20 C (68 F). 0.385 cgs

E *1 Volume conductivity* referred to standard copper. 38.9 to 43.1%
10 Electrochemical equivalent (valence 2). 0.04674 mg per coulomb

F *1 Reflectivity.* 50 to 55% in white light
4 Color. Gray

I *1 Resistance to corrosion.* Beryllium is resistant to acetic acid, concentrated nitric acid, ammonia and to air at room temperature. No actual corrosion resistance tests have been carried out on pure beryllium, so far as is known. The above observations are therefore highly qualitative. Organic substances such as sugar, formaldehyde, petroleum products and alcohols, will probably not attack beryllium appreciably.

J *1 Crystal structure.* Close-packed hexagonal; $a = 2.2680$ kX; $c = 3.5942$ kX
5 Minimum interatomic distance. 2.22 kX

K *Mechanical properties.*

Condition	Tensile Strength, psi	Yield Strength, (a) psi	Brinell Hardness (b)	Modulus of Elasticity, psi
Vacuum cast	17,000 to 21,000	.....	.....	42,000,000
Vacuum cast, forged and annealed(c)	27,000	26,400	97 to 114	36,800,000

(a) 0.2% offset
(b) 500 or 1000-kg load, 10-mm ball
(c) Elongation of this sample was zero.

N *1 Melting temperature.* 1284 to 1300 C (2343 to 2372 F)
5 Flux. Alkaline earth metal chlorides or fluorides
6 Precautions in melting. Avoid excessive contact with oxygen. Carbon easily produces Be_2C above 1300 C.
11 Suited to forming by casting (centrifugal, vacuum, air) and possibly by extrusion.

* The Brush Beryllium Company, Cleveland

Cadmium

COMPILED BY PAUL A. BECK AND JOHN F. COLLINS*

B *1 Typical uses.* Bearing alloys, electroplating, pigments, low-melting alloys.
2 Precautions in use. Good ventilation is necessary when melting, since poisonous fumes develop in large quantity. Maximum allowable cadmium vapor in air 1 mg per 10 cu meters.

C *1 Density.*
at 20 C (68 F). 8.65 g per cu cm
at 25 C (77 F). 8.62 g per cu cm
at 700 C (1292 F). 7.56 g per cu cm
at 720 C (1328 F). 7.54 g per cu cm
at 750 C (1382 F). 7.51 g per cu cm

D *1 Melting point.* 320.9 ± 0.1 C (609.6 ± 0.2 F)
4 Boiling point. 765 C (1409 F)
6 Thermal expansion (polycrystalline) at room temperature. 0.0000298 per °C
$L_{t+20} = L_{20}\,[1 + (95.1t + 38 \times 10^{-3}t^2 + 5 \times 10^{-6}t^3) \times 10^{-6}]$
7 Thermal expansion along *a*-axis 18 to 190 C (64 to 374 F). 0.0000185 per °C
$L_{t+20} = L_{20}\,[1 + (21.7t - 3.8 \times 10^{-3}t^2 + 13.4 \times 10^{-6}t^3) \times 10^{-6}]$
9 Thermal expansion along *c*-axis 18 to 190 C (64 to 374 F). 0.0000482 per °C
$L_{t+20} = L_{20}\,[1 + (55.8t - 15 \times 10^{-3}t^2 - 4.7 \times 10^{-6}t^3) \times 10^{-6}]$
11 Specific heat at room temperature. 0.055 cal per g
12 Specific heat versus temperature. See Fig. 1.
13 Latent heat of fusion. 13.2 cal per ■
15 Latent heat of vaporization. 286.4 cal per g
16 Thermal conductivity at room temperature. 0.22 cgs

E *1 Volume conductivity* referred to standard copper. 25.2%
2 Electrical resistivity at 0 C (32 F). 6.83 microhm-cm
5 Temperature coefficient of electrical resistivity at 0 C (32 F). 0.0042 per °C
7 Pressure coefficient of electrical resistivity at 100 C (212 F). minus 0.000011 per kg/sq cm
10 Electrochemical equivalent. 0.5824 mg per coulomb
11 Electrolytic solution potential. 0.4 volt
14 Hydrogen overvoltage. 0.4 volt
15 Hall effect. $+ 5.5 \times 10^{-13}$ volt-cm per ampere-gauss
16 Supraconductive at 0.6 K

F *1 Reflectivity.*
78% at $\lambda = 4100$ A — 72.5% at $\lambda = 5180$ A
74% at $\lambda = 4740$ A — 73% at $\lambda = 5540$ A
Reflectivity versus wave length. See Fig. 2.

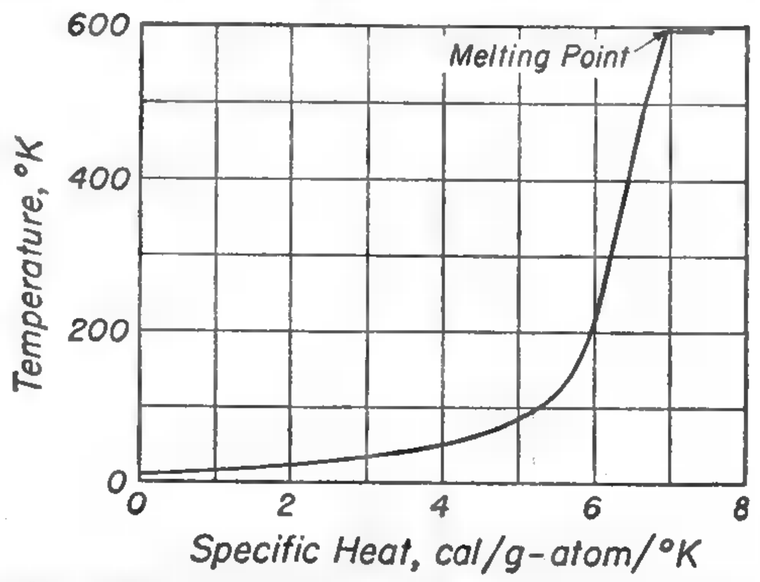

Fig. 1 Specific heat of cadmium versus temperature (Lange and Simon[1])

* University of Notre Dame, Notre Dame, Ind.

2 *Refractive index.* 1.8 at 5780 A
3 *Absorptive index.* 1.17 at 5780 A
G 2 *Magnetic susceptibility.* minus 0.18 × 10^{-6} cgs (electromagnetic)
J 1 *Crystal structure.* Close-packed hexagonal; $a = 2.9727$ kX; $c = 5.606$ kX
2 *Slip plane.* (0001). *Slip direction.* [11$\bar{2}$0]
3 *Twinning plane.* (10$\bar{1}$2)
5 *Minimum interatomic distance.* 2.972 kX
K *Mechanical Properties. Chill cast* (1-in. diam section): tensile strength 10,300 psi; elongation 50%; Brinell hardness number 21 to 23.
Sand cast: modulus of elasticity 8,000,000 psi
8 *Surface tension (liquid)* at 321 C. 630 dynes per cm
N 5 *Type of flux.* Zinc chloride

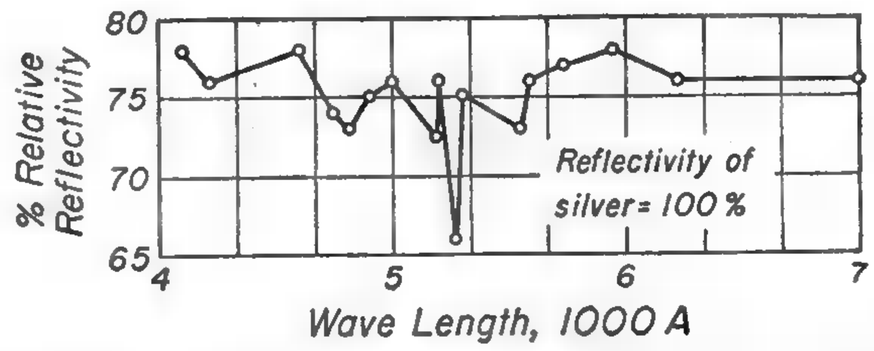

Fig. 2 Relative reflectivity of cadmium versus wave length (Cinamon[2])

Calcium

COMPILED BY C. L. MANTELL*

B 1 *Typical uses.* Modifying agent for aluminum, beryllium and magnesium alloys. Alloying agent for aluminum, beryllium, copper, lead and magnesium. Decarburizer and desulfurizer for ferrous metals and alloys. Deoxidizer for various ferrous and nonferrous metals. Evacuating agent for the production of high vacuum. Reducing agent in the preparation of chromium, thorium, uranium, zirconium, and calcium hydride. In its commercial forms, calcium is available as the direct or remelted product of the electric furnace, or as sublimed material, in chips, slugs, rods and sticks.
2 *Precautions in use.* Calcium is a reactive metal; it decomposes water and must be handled more carefully than magnesium.
C 1 *Density* at 20 C (68 F). 1.55 g per cu cm (0.056 lb per cu in.) at 450 C (842 F) the α phase in extruded wire has a density of 1.48 g per cu cm; at 480 C (896 F) the β phase has a density of 1.52 g per cu cm
3 *Compressibility.*
at 30 C (86 F) and 0 atm pressure. 5.885 × 10^{-6}
at 30 C (86 F) and 11,600 atm pressure. 5.300 × 10^{-6}
at 20 C (68 F) and 99 to 493 atm pressure. 5.8 × 10^{-6}
at 20 C (68 F) and 100 to 500 megabars per sq cm. 5.7 × 10^{-6}

$$\text{Compressibility} = -\frac{1}{\text{Vol (cu cm)}} \times \frac{\Delta \text{ Vol (cu cm)}}{\Delta \text{ Pressure (atm)}}$$

D 1 *Melting point.* 850 C (1562 F)
4 *Boiling point.* 1440 C (2625 F)
5 *Transformation temperature* (cooling). 450 C (840 F)
6 *Thermal expansion.*
(linear) 0 to 300 C (32 to 570 F). 0.0000220 per °C
(cubic) 0 to 21 C (32 to 70 F). 0.000717 per °C
11 *Specific heat* between minus 185 and 20 C (minus 301 and 68 F). 0.157 cal per g
0 to 100 C (32 to 212 F). 0.149 cal per g
15 *Latent heat of vaporization.* 45,300 cal per g-atom
16 *Thermal conductivity.* Of the same order as that of sodium and the alkali metals.
18 *Heat of combustion.* 151.9 cal per
E 1 *Volume conductivity* referred to standard copper. 48.7%
2 *Electrical resistivity* at 0 C (32 F). 3.43 microhm-cm
5 *Temperature coefficient* of electrical resistivity at 20 C (68 F). 0.00457 per °C
10 *Electrochemical equivalent* (valence 2). 0.20762 mg per coulomb
11 *Electrolytic solution potential* vs hydrogen. —2.76 volts
F 4 *Color.* In its commercial forms, calcium on freshly cut surfaces is white, approximating the color of silver. Fractured surfaces are more brilliant than steel.
G 2 *Mass magnetic susceptibility.*[2] plus 1.10 × 10^{-6} cgs
I 1 *General resistance to corrosion.* Readily corroded by water, acids, alkalies and halogens.
J 1 *Crystal structure.* Face-centered cubic, $a = 5.56$ kX
5 *Minimum interatomic distance.* 3.93 kX
K *Mechanical properties.* Cast slab: tensile strength 8000 psi, yield strength 5500 psi, elongation 53 to 60%, Brinell hardness number (500-kg load) 17, Rockwell B 36 to 40, modulus of elasticity 3 to 4 × 10^6 psi
N *Casting.* Because of its rapid oxidation at or above the melting point, calcium cannot be cast by usual foundry methods. When melted in the absence of air, other oxidizing influences, or reactive gases, it can be cast into various shapes. Recently, melting and casting procedures employing protective fluxes have been worked out for the production of cast forms of the metal from the irregularly shaped cabbages separated from furnace electrodes.
11 *Suited to forming* by machining, turning, drilling, threading, sawing, wire drawing, pressing and hammering. The wire is extruded between 420 and 460 C.

* Consulting Chemical Engineer, New York

Chromium

COMPILED BY C. O. BURGESS AND F. E. BACON*

A 1 *Common name.* Chromium, Chrome Metal, Electrolytic Chromium
B 1 *Typical uses.* Alloying agent in steel and cast irons (0.25 to 35%); alloying agent in nonferrous alloys of nickel, copper, aluminum and cobalt; electroplating; powder metallurgy; X-ray targets; mirrors.
2 *Precautions in use.* No special precautions necessary.
C 1 *Density* at 20 C (68 F).[1] 7.19 g per cu cm (0.260 lb per cu in.)
3 *Density versus pressure (compressibility).*[2]

At 30 C (86 F) $\frac{\Delta V}{V_0} = -5.187 \times 10^{-7}p + 2.19 \times 10^{-12}p^2$

At 75 C (167 F) $\frac{\Delta V}{V_0} = -5.310 \times 10^{-7}p + 2.19 \times 10^{-12}p^2$

6 *Transformation volume change.*[3,4,5] Hexagonal form

* Union Carbide and Carbon Research Laboratories, Niagara Falls, N. Y.

(sp gr 6.08) changes to body-centered cubic (sp gr 7.21) at 26 C or above. An α-manganese type (sp gr 7.48) has also been identified.

D *1 Melting point.* 1800 ± 50 C (3270 ± 90 F)
4 Boiling point at 760 mm Hg.[10] 2500 (4500)
5 Transformation temperature. Below 20 C (68 F) the close-packed hexagonal form is produced in electroplating, while the cubic form is produced above 20 C. The α-manganese form (58 atoms per unit cube) identified as electroplated, slowly ages to the cubic form.[3,4,5] The α-manganese form appears above 26 C.
6 Thermal expansion[6,7] at 20 C (68 F). 0.0000062 per °C

$$L_t = L_0 [1 + (5.88t + 0.00774t^2 - 0.00000388t^3) \times 10^{-6}]$$

11 Specific heat[8] at 20 C (68 F). 0.11 cal per g
12 Specific heat versus temperature[8] 273 to 1873 K (0 to 1600 C). $C_p = 4.84 + 2.95 \times 10^{-3}t$
13 Latent heat of fusion.[9] 75.6 cal per g
15 Latent heat of vaporization[10] at boiling point. 1470 cal per g
16 Thermal conductivity at 20 C (68 F). 0.16 cgs

E *1 Volume conductivity* referred to standard copper 8.8%
2 Electrical resistivity[1] at 0 C (32 F). 18.9 microhm-cm
5 Temperature coefficient of electrical resistivity[11] at 0 C (32 F). 0.00588 per °C. Some anomalies occur in the specific resistance of chromium with temperature.[12,13]
9 Contact potential versus constantan. +511 × 10^{-7} volts per degree
10 Electrochemical equivalent[14]
(valence 3). 0.08983 mg per coulomb
(valence 6). 0.17965 mg per coulomb
11 Electrolytic solution potential[15] (valence 3) versus hydrogen electrode. 0.5 volt
14 Hydrogen overvoltage.[15] 0.38
16 Chromium is not supraconductive down to 2.5 K.[11]

F *1 Reflectivity.*[16]

67% at λ = 3,000 A	63% at λ = 10,000 A
70% at λ = 5,000 A	88% at λ = 40,000 A

2 Refractive index.[17] 1.64 to 3.28 for λ from 2570 to 6080 A
3 Absorptive index.[17] 2.25 to 1.31 for λ from 2570 to 6080 A
4 Color. Steel gray
5 Emissivity.[18] Total at 100 C (212 F) in nonoxidizing atmosphere, 0.08; spectral (at 6500 A) for solid chromium, 0.34; for liquid, 0.39

G *2 Magnetic susceptibility.*[12] 3.49 × 10^{-6} cgs

I *2 Resistance to specific agents.*[19,20] (Ten per cent solutions at 55 F were used unless otherwise noted.)

Chromium is resistant to the following acids: acetic, benzoic (saturated), butyric, carbonic, citric, fatty, hydrobromic, hydroiodic, lactic, nitric, oleic, oxalic, palmitic, phosphoric, picric, salicylic, stearic and tartaric.

Chromium is not resistant to hydrochloric acid.

Chromium is resistant to the following agents: acetone, air, ethyl and methyl alcohol, higher alcohols, aluminum chloride, aluminum sulfate, ammonia, ammonium chloride, barium chloride, beer, benzyl chloride (saturated and 100%), calcium chloride, carbon dioxide, carbon disulfide, carbon tetrachloride (saturated and 100%), dry chlorine, chlorobenzene (saturated and 100%), chloroform, copper sulfate, ferric chloride, ferrous chloride, foodstuffs, formaldehyde, fruit products, glue, hydrogen sulfide (100%), magnesium chloride, milk, mineral oils, motor fuels, crude petroleum products, phenols, photographic solutions, printing ink, sodium carbonate, sodium chloride, sodium hydroxide, sodium sulfate, sugar, sulfur (100%), sulfur dioxide (100%), chlorinated, distilled, or rainwater, zinc chloride and sulfate.

J *1 Crystal structure.*[21] Body-centered cubic α, $a = 2.878$ kX; close-packed hexagonal β, $a = 2.71$ kX, $c = 4.41$ kX. Chromium with the α-manganese structure and $a = 8.717$ kX
5 Minimum interatomic distance. 2.493 kX
6 Microstructure. See Fig. 23 in reference 22.

K *Mechanical properties.*[1, 23, 24] Brinell hardness number: as cast 110 to 170, electrodeposited 500 to 1250 (depending on the amount of hydrogen in the deposit), electrodeposited and annealed 70 to 90.
5 Coefficient of friction.[23] 0.12 for sliding condition, 0.14 for static condition.

L *1 Metallography.* Polishing: same as for steel.
Etching: Vilella's reagent, used electrolytically, according to Adcock's directions.[22]

M *Composition limits.*

Material	C min	C max	Cr min	Fe max
Electrolytic chromium	...	...	99	...
Pyrometallurgical or thermit chromium	...	0.2	97	1
Pyrometallurgical or thermit chromium	...	0.5	97	1
Pyrometallurgical or thermit chromium	9.0	...	87	1.25

N *7 Hot working temperature.*[25] 1250 C (2280 F)
13 Compacting pressure.[25] 40,000 psi
14 Sintering temperature.[25] 1300 C (2370 F) in vacuo until free from gas, then further heating at 1600 to 1700 C in argon.
17 Joining.
Silver solder with low-melting-point silver brazing alloys, potassium fluoborate flux, and reducing flame.

Columbium

COMPILED BY L. F. YNTEMA*

A *6 Foreign equivalent.* Niobium

B *2 Precautions in use.* Columbium oxidizes in air above 250 C (482 F). Soluble in HF and in alkalies.

C *1 Density* at 20 C (68 F). 8.57 g per cu cm (0.310 lb per cu in.)

D *1 Melting point.* 2415 C (4379 F)
6 Thermal expansion. 0.0000071 per °C
11 Specific heat at 0 C (32 F). 0.0647 cal per g
15 Latent heat of vaporization. 1840 cal per g

E *1 Volume conductivity* referred to standard copper. 13.2%
2 Electrical resistivity at 18 C (64 F). 13.1 microhm-cm
5 Temperature coefficient of electrical resistivity at 20 C (68 F). 0.00395 per °C
10 Electrochemical equivalent (valence 5). 0.1926 mg per coulomb

* Director of Research, Fansteel Metallurgical Corporation, North Chicago, Ill.

G *2 Magnetic susceptibility.* plus 1.5×10^{-6} cgs

I *2 Resistance to corrosion.*

Columbium is resistant to the following: acetic, lactic, nitric, perchloric and tartaric acids, and aqua regia; ammonium hydroxide; phenol; oxygen when cold; air; distilled, rain and sea water. It is attacked moderately by: hydrochloric, phosphoric, oxalic and sulfuric acids; sodium carbonate; and hydrogen peroxide. It is attacked severely by: sodium hydroxide, potassium hydroxide, and hydrofluoric acid.

J *1 Crystal structure.* Body-centered cubic; $a = 3.294$ kX

K *Mechanical properties.*

Form and Condition	Section, in.	Tensile Strength, psi	Percentage Elongation
Sheet, annealed	0.010	50,000	30
Sheet, worked	0.010	100,000	1
Wire, worked	0.005	100,000	1

L *1 Metallography.* Polishing: emery to 000, levigated alumina to finish. Etching: $HF\text{-}NH_4F$ solution.
M *Composition limits.* For sheet, wire and compacts the allowable percentages for various impurities are: 0.20 Ta; 0.002 Ti; 0.03 Si; 0.01 Fe; and 0.02 C.
2 Consequences of exceeding impurity limits. Reduction in elongation; high yield and tensile strength; no change in resistance to corrosion.
N *7 Hot working temperature.* None; it is worked cold.
9 Annealing temperature. Above 1050 C in vacuo
10 Maximum reduction between anneals. Not limited
11 Suited to forming by all conventional methods such as rolling, drawing, pressing, bending, and swaging.
12 Precautions in forming. For drawing, a nonloading die material is used; other practices conventional.
16 Standard finishes. Dull or bright rolled finish for sheet; smooth dull finish for wire.
17 Joining.
Rivet composition. Columbium
Carbon-arc welding. Special techniques under protective liquids. *Resistance welding.* Spot and seam

19 Recrystallization temperature. 900 C (1650 F)

■ *1 Volume conductivity* referred to standard copper. 33.3%

2 Electrical resistivity at 0 C (32 F). 5.17 microhm-cm

5 Temperature coefficient of electrical resistivity at 25 C (77 F). 0.0033 per °C. *See* Fig. 5.

9 Thermal emf against platinum 0 to 100 C. 1.45 mv

10 Electrochemical equivalent (valence 6). 0.1658 mg per coulomb

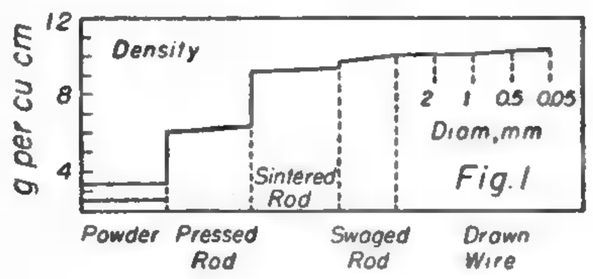
14 Hydrogen overvoltage. 0.168 ± 0.003 v

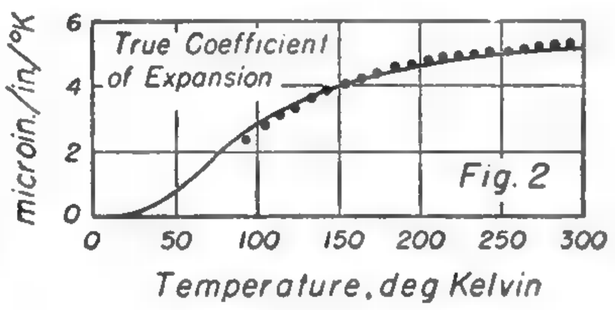
F *1 Reflectivity* at $\lambda = 5000$ A. 46% *See* Fig. 6.

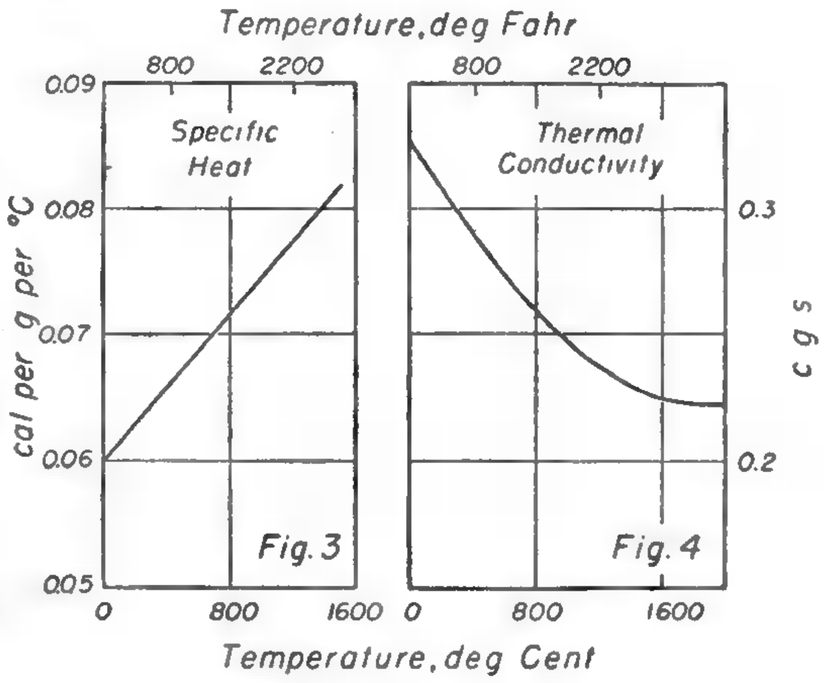
4 Color. Silvery white

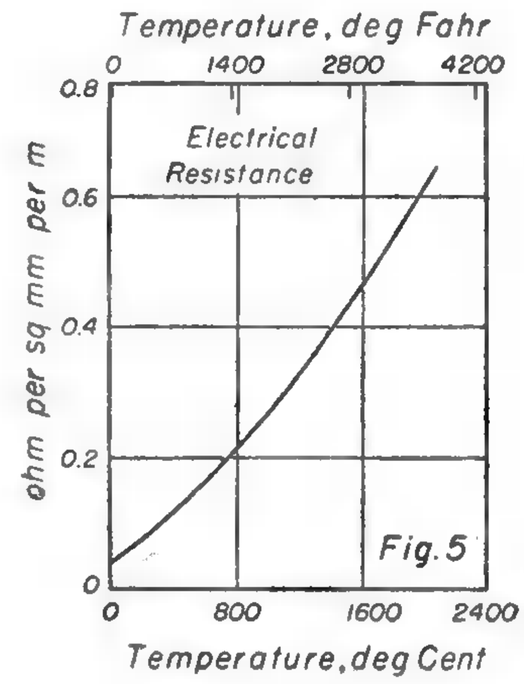
5 Emissivity
at 1000 C (1832 F). 0.13
at 1500 C (2732 F). 0.19
at 2000 C (3632 F). 0.24

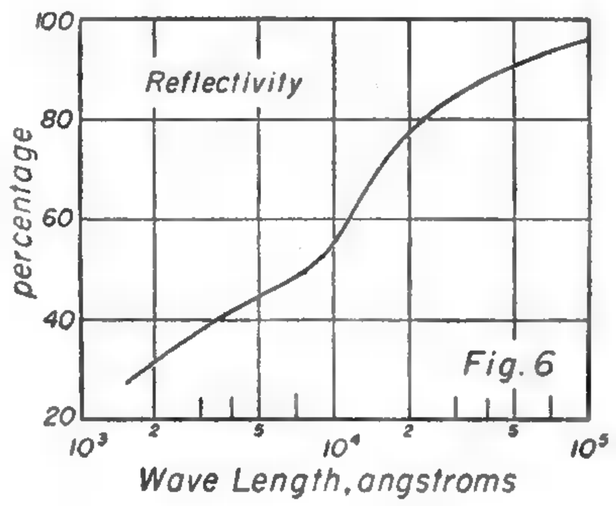
* Research Laboratory, Climax Molybdenum Company, Detroit

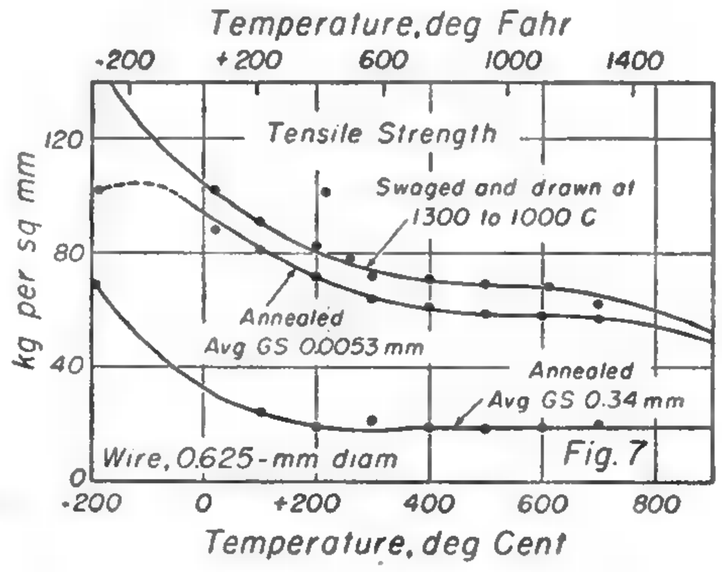


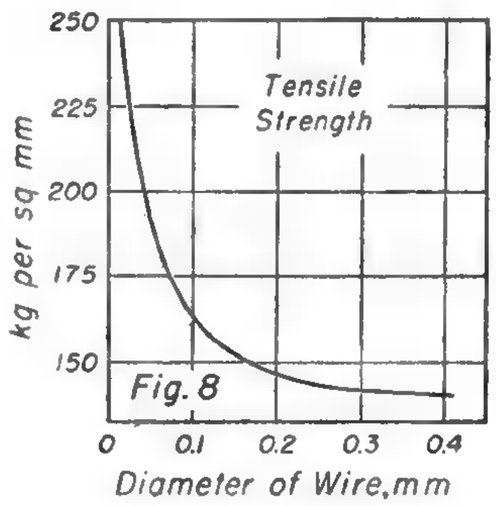


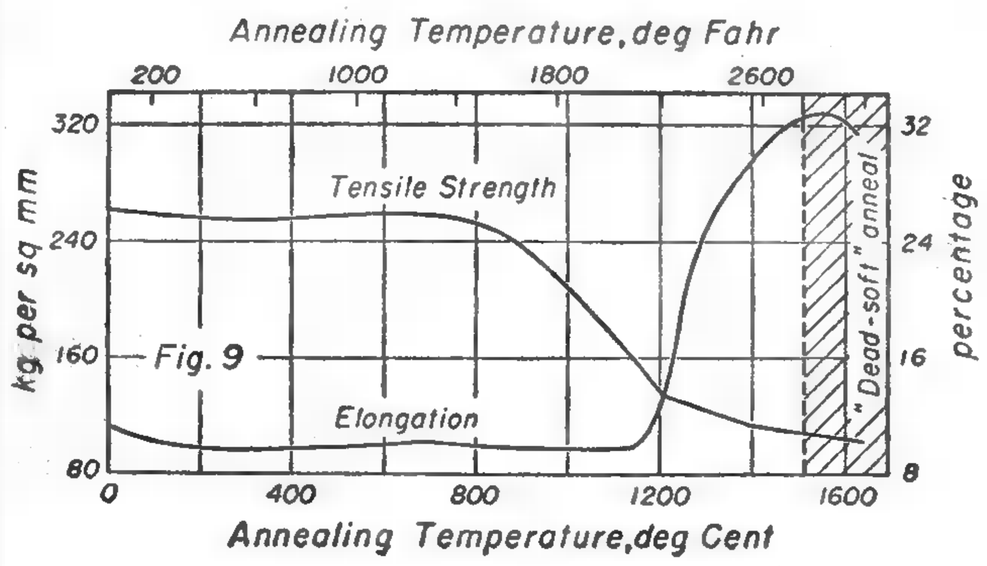


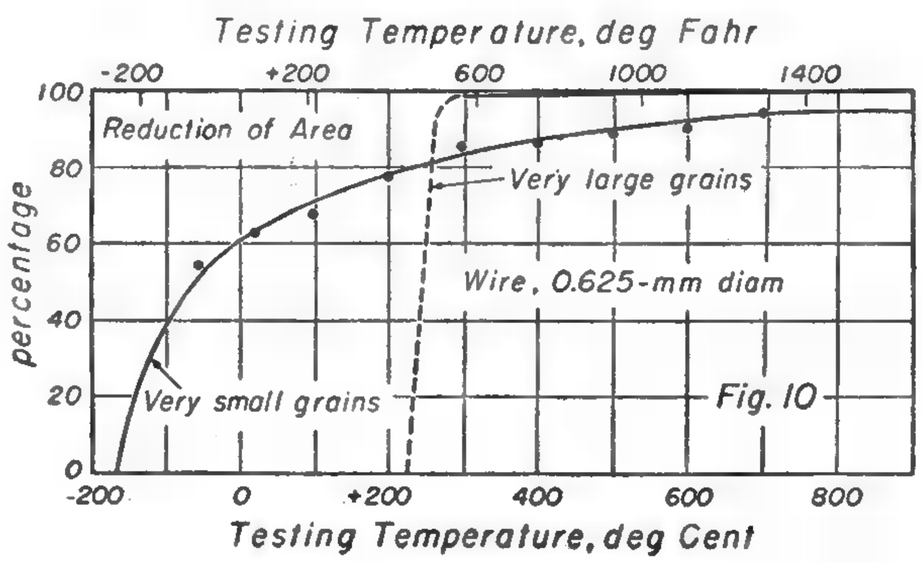












G 2 *Magnetic susceptibility.* 0.04×10^{-6} cgs
H 1 *Velocity of sound.* About 16,000 ft per sec
I 2 *Resistance to specific agents.*

Molybdenum is resistant to the following: hydrofluoric acid, air, ammonia, bismuth salts, bromine, chlorine, iodine, cadmium salts, carbon dioxide, hydrogen sulfide, lead nitrate, nitrous and nitric oxides, phosphorus, potassium hydroxide, sulfur and sulfur dioxide, and distilled, rain and sea water. It is resistant to hydrochloric acid, but subject to severe attack in hot dilute acid. It is resistant to cold sulfuric acid, but is severely attacked in the hot concentrated acid. Molybdenum is moderately resistant to ammonium hydroxide and ferric chloride. It is severely attacked by fluorine, nitric acid, and mixed acids (aqua regia).

J 1 *Crystal structure.* Body-centered cubic; $a = 3.1400$ kX at 20 C
2 *Slip planes.* (112) (110). *Slip direction.* [111]
5 *Minimum interatomic distance.* 1.2115 kX
K *Mechanical properties* of pressed and sintered molybdenum.
Tensile strength of wire.
0.125-mm diam. 200,000 to 260,000 psi
0.070-mm diam. 230,000 to 270,000 psi
0.038-mm diam. 270,000 to 310,000 psi
Tensile strength of sheet. 100,000 psi
See also Fig. 7, 8 and 9.
Elongation and reduction of area. See Fig. ■ and 10.
Yield strength,
Unannealed. 57,000 to 85,000 psi
Annealed. Up to 57,000 psi
Modulus of elasticity. 50,000,000 psi
Brinell hardness number,
Rolled, unannealed. 160 to 185
Highly sintered bar. 156

Sheet thickness, mm	8	4	2	1
Bhn	229	240	245	255

Shear modulus. 6.6×10^{11} dynes per sq cm
2 *Directional properties.* The tensile strength of rolled molybdenum sheet is about 20% greater in the direction of rolling than when the inclination of the direction of tension to that of rolling is 45 or 90°.
3 *Properties of single crystals.* Tensile strength 50,000 psi
L 1 *Metallography.* Polish with diamond paste.
Etching: (1) 1:1 10% NaOH + 30% $K_3Fe(CN)_6$
(2) 50% HNO_3, wash with conc HCl
(3) $NH_4OH + H_2O_2$
(4) $HNO_3 + HF$
N 11 *Suited to forming* by swaging, wire drawing and rolling.
13 *Compacting pressure.* 13,500 to 56,000 psi
15 *Heat treatment.* Annealing at 300 to 400 C above the recrystallization temperature produces a large-grained equiaxed structure with the grains covered by films of impurities. The mechanical properties are poor for metal in this condition.
17 *Welding.* Molybdenum can be butt-welded by resistance heating in vacuum, or it can be welded in the atomic hydrogen arc.

Sodium

COMPILED BY H. N. GILBERT*

B 1 *Typical uses.* Removal of antimony from lead and solder, production of metals by reduction of their chlorides, production of alloys such as sodium-lead and sodium-zinc, descaling of metals by the sodium-hydride process, in heat-transfer systems, coolant for exhaust valves of internal-combustion engines, refining of the grain size of metals and alloys, lowering of the surface tension of molten metals, production of bearing metals, deoxidizing of metals.

2 *Precautions in use.* For many purposes it is convenient to handle sodium in liquid form. The metal may be melted and pumped through heated pipe lines. In adding solid or liquid sodium to a molten metal that has a melting point higher than the boiling point of sodium, care must be taken to add the sodium in small increments because of the violent boiling of the sodium. Sodium may be boiled in iron equipment. Sodium does not inflame in air at temperatures below 120 C but it is always desirable to conduct operations involving molten sodium under nitrogen to avoid losses of the metal by oxidation.

C 1 *Density*[1] at 20 C (68 F). 0.97 g per cu cm (0.035 lb per cu in.); at 97.6 C, 0.93 g per cu cm; at 877 C, 0.74 g per cu cm
7 *Surface tension*[1] at the melting point. 293.6 dynes per cm (in CO_2), at 250 C 211 dynes per cm (in high vacuum)
8 *Viscosity*[2] at 98 C. 0.00726 cgs

* Electrochemicals Department, E. I. du Pont de Nemours & Company, Niagara Falls, N. Y.

D 1 *Melting point.*[3] 97.7 C (207.9 F)
2 *Boiling point.*[4] 892 C (1638 F)
Vapor pressure.[4]

15 *Latent heat of vaporization*[6] at the melting point. 24,600 cal per g-atom
16 *Thermal conductivity*[7] at room temperature. 0.32 cal/cm²/cm/°C/sec

E 2 *Electrical resistivity*[5] at 0 C (32 F). 4.2 microhm-cm
10 *Electrochemical equivalent.*[8] 0.2384 mg per coulomb

G 2 *Mass magnetic susceptibility.*[9] plus 0.51×10^{-6} cgs

I *Chemical properties.*

Water reacts with sodium to form hydrogen and caustic soda. The reaction is violent and usually explosive. Water vapor or steam also reacts. For this reason, operations that involve the handling or storage of sodium should be conducted in a dry room away from steam or water pipes and automatic sprinkler systems.

Oxygen combines with sodium and forms sodium monoxide, and at higher temperatures sodium peroxide. Solid sodium rapidly becomes coated with a layer of white oxide when exposed to air. The coating also absorbs CO_2 and water from the air to form sodium carbonate and caustic soda. Liquid sodium can be handled in air at 110 C with only moderate oxidation on the surface. If a pure nitrogen atmosphere is employed, sodium can be handled indefinitely in closed systems.

Ammonia gas combines with molten sodium to form sodamide.

Chlorinated hydrocarbons react violently with sodium, and extinguishers that contain carbon tetrachloride should not be used on sodium fires.

Carbon monoxide and carbon dioxide react with sodium. Solid CO_2 will detonate with molten sodium and should not be used on burning sodium.

Sodium fires are best extinguished by excluding air from the reaction vessel or by adding nitrogen to the equipment. Unconfined fires are best extinguished by adding an excess of dry soda ash or dry salt. Extinguishers of the acid – soda ash type should never be used on sodium.

Dry liquid hydrocarbons such as benzene, toluene, xylene and refined mineral oils do not react with solid sodium and may be used to protect it from the air.

Sodium reacts with alcohols to form hydrogen and alcoholates. This reaction is sometimes used to dispose of residues that contain sodium. When used for this purpose the operation should always be conducted in an open vessel.

J *1 Crystal structure.* Body-centered cubic, $a = 4.2820$ kX at 20 C.

K *Brinell hardness number.*[10] 0.07, using 10-mm ball, 3.2-kg load

M *Composition limits.* Sodium is available with a purity of 99.9 + %.

Tantalum

COMPILED BY L. F. YNTEMA*

B *1 Typical uses.* Corrosion-resistant metal in heat-transfer area in acidproof chemical equipment. Rectifier element in the rectification of alternating current. Surgical usage as suture wire, cranioplasty and fixation plates. Electronic usage as anode and grid element in vacuum tubes.

2 Precautions in use. Tantalum oxidizes in air above 300 C (570 F). It is soluble in hydrofluoric acid, in strong alkalies and in solutions that contain free sulfur trioxide.

C *1 Density* at 20 C (68 F). 16.6 g per cu cm (0.600 lb per cu in.)

D *1 Melting point.* 2996 C (5425 F)

6 Thermal expansion. 0.0000065 per °C (0.0000036 per °F)

11 Specific heat at 0 C (32 F). 0.036 cal per g

16 Thermal conductivity at 20 C (68 F). 0.130 cal/sq cm/cm/°C/sec

18 Heat of combustion. 1380 cal per ■

E *1 Volume conductivity* referred to standard copper. 13.9%

2 Electrical resistivity at 18 C (64 F). 12.4 microhm-cm

5 Temperature coefficient of electrical resistivity 0 to 100 C (32 to 212 F). 0.00382 per °C

10 Electrochemical equivalent (valence 5). 0.3749 mg per coulomb

F *2 Refractive index.* 2.05

G *2 Magnetic susceptibility.* plus 0.93×10^{-6} cgs

I *1 General resistance to corrosion.* Tantalum is resistant to corrosion except when subject to galvanic couple action.

2 Resistance to specific agents.

Tantalum is resistant to the following chemicals: acetone; acetic, butyric, carbonic, citric, fatty, formic, hydrochloric, hydrobromic, lactic, nitric, and tartaric acids; ethyl, methyl and higher alcohols; aluminum sulfate; ammonium chloride, hydroxide, nitrate and sulfate; calcium chloride; carbon dioxide and tetrachloride; copper sulfate; ferric chloride; foodstuffs; formaldehyde; fruit products; hydrogen peroxide; magnesium chloride and sulfate; milk; mineral oils; motor fuels; petroleum products; phenols; potassium tri-iodide, chloride and nitrate; refrigerants; sodium chloride, nitrate and sulfate; sugar; sulfur; chlorinated, distilled, rain and sea water.

Tantalum is resistant to the following chemicals when cold: oxalic, phosphoric and sulfuric acids; air; ammonia; bromine, chlorine and iodine; hydrogen sulfide; oxygen; and sulfur dioxide. It is resistant to mixed acids and acid salts if fluorides are absent. It is resistant to bleaching solutions, dyestuffs, and photographic solutions, except when alkaline. It is subject to moderate general attack by sodium carbonate. It is attacked severely by hydrofluoric acid, fuming sulfuric acid, potassium hydroxide, and sodium hydroxide.

J *1 Crystal structure.* Body-centered cubic; $a = 3.296$ kX

K *Mechanical properties.* See Table I.

2 Directional properties. The tensile strength and elongation, measured parallel and transverse to the direction of rolling, are substantially equal in both worked and annealed sheet.

4 Machinability. Tantalum is like cold rolled steel. Carbon tetrachloride and light oil should be used as a cutting fluid.

5 Coefficient of friction. Galls against itself and 18-8 steel.

Table I. Mechanical Properties of Wrought Tantalum

Form and Condition	Section, in.	Tensile Strength, psi	Elongation in 2 in., percentage	Rockwell Hardness
Sheet, annealed	0.010	50,000	40	E 60
Sheet worked	0.010	110,000	1	E 95
Wire, annealed	0.002	100,000	11	....
Wire, worked	0.002	180,000	1.5	....
Plate, hardened	0.010	145,000	18	B 103

L *1 Metallography.* Polishing: emery to 000, levigated alumina to finish; etching: HF-NH_4F solution

M *Composition limits.* Allowable percentages of impurities for sheet, wire and compacts are: 0.03% C, and 0.01% Fe.

2 Consequences of exceeding impurity limits. Reduction in elongation; high yield and tensile strengths; no change in resistance to corrosion.

N *3 Alloying.* Add tungsten as powder when high tensile strength, higher yield strength and higher annealing temperature are required. Add thorium as powder for special electronic properties.

7 Hot working temperature range. None; it is worked cold.

9 Annealing temperature. Above 1050 C (1920 F) in vacuo

10 Maximum reduction between anneals. Not limited

11 Suited to forming by all conventional methods such as rolling, drawing, pressing, bending and swaging.

12 Precautions in forming. For drawing, a nonloading die material is used; other practices conventional.

16 Standard finishes. Dull or bright rolled finish for sheet; smooth dull finish for wire.

17 Joining.

Rivet composition. Tantalum

Silver solder. Not readily soldered except by special techniques.

Braze with copper in vacuum.

Carbon-arc welding. Special techniques under protective liquids.

Resistance welding. Spot and seam

Titanium

COMPILED BY J. T. MILEK*

B *1 Typical uses.* As an addition agent in alloying with aluminum, copper, magnesium, steel, nickel, and other metals; to produce grain refinement in aluminum alloys; to enhance mechanical and physical properties (strength, ductility, hardness); and, as powder, in pyrotechnics.
2 Precautions in use. Powdered titanium is stable at room temperature, but begins to oxidize at about 120 C (250 F). It unites readily with nitrogen and hydrogen at low temperatures. The consolidated metal may be heated to at least 800 C (1470 F) in air without taking fire. Static electric charges will ignite dry powdered titanium at room temperature; consequently the powder is transported wet.
C *1 Density* at 20 C (68 F). 4.54 g per cu cm (0.164 lb per cu in.) α form
at 875 C (1607 F). 4.31 g per cu cm (0.156 lb per cu in.) β form
6 Transformation volume change (α to β on heating). 5.5%
D *1 Melting point.* 1820 ± 100 C (3300 ± 180 F)
5 Transformation temperature (cooling). 875 C (1607 F)
6 Thermal expansion at 20 C (68 F). 0.0000085 per °C
11 Specific heat at 25 C (77 F). 0.126 cal per ■
12 Specific heat versus temperature.[1] See Fig. 1.

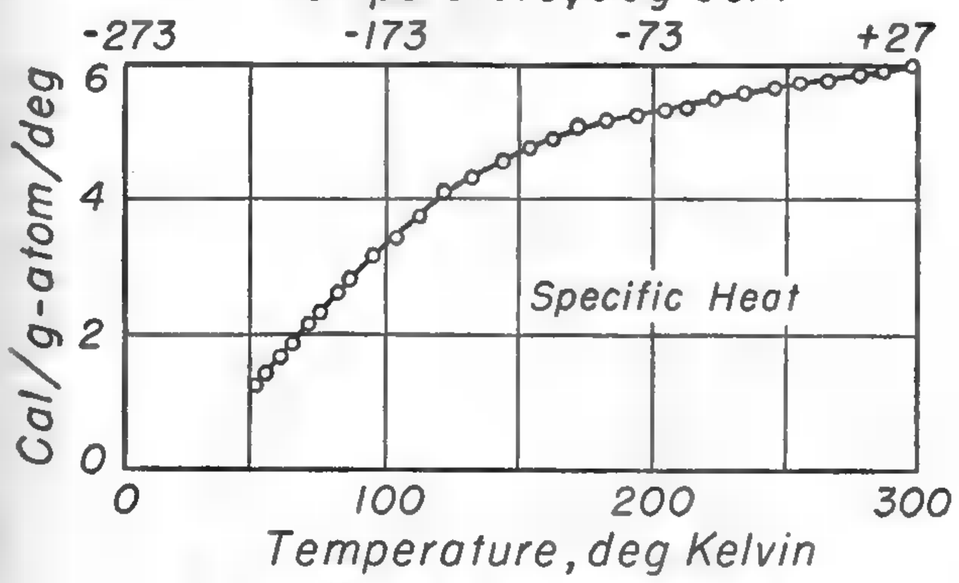

Fig. 1 Specific heat of titanium at low temperature

18 Heat of combustion. 510 cal per ■
E *1 Volume conductivity* referred to standard copper. 2.2%
2 Electrical resistivity at 0 C (32 F). 80 microhm-cm
Volume resistivity 0.000056 ohm per cu cm
F *4 Color.* The powdered form is dark gray; the fused metal, similar to polished steel.

* Research Laboratory, The Titanium Alloy Manufacturing Company, Niagara Falls, N. Y.

G *2 Magnetic susceptibility versus temperature.*

Temperature, °C	−170	−140	−110	−80	+20
Susceptibility, 10^6 cgs	1.6	1.4	1.3	1.25	1.25

I *1 General resistance to corrosion.* Titanium has resistance to corrosion similar to that of 18-8 steel. It is attacked by sulfuric and hydrochloric acids. Dilute sulfuric acid attacks the metal slowly. Concentrated and dilute nitric acid have no appreciable effect. The metal does not tarnish during exposure to laboratory atmospheres, nor during 30 days in salt spray.
J *1 Crystal structure.*

Type	a, kX	c, kX	deg Cent	deg Fahr
α ..... Close-packed hexagonal	2.95	4.73	up to 880	up to 1616
β ..... Body-centered cubic	3.32	...	above 880	above 1616

6 Microstructure. See micrographs in reference 2.
K *Mechanical properties* (all sections $\frac{1}{16}$ in. thick).

Condition	Tensile Strength, psi	Yield Strength, psi	Elongation, percentage	Rockwell Hardness, G scale
Annealed	78,700	62,800	25.2	76
¼ hard, 20% reduction	110,500	101,100	8.2	86
½ hard, 40% reduction	122,200	113,300	7.5	91
Hard, 60% reduction	111,500	.....	1.5	92

Modulus of elasticity 16,800,000 psi, annealed
L *1 Metallography.*[2] Etchant: 5% solution of HF.
M *2 Effects of impurities.* Oxygen and nitrogen cause brittleness, higher strength and hardness, and lower elongation. Small amounts of silicon cause embrittlement.
N *3 Alloying.* Titanium alloys with most metals, especially copper, tin, iron, aluminum, chromium, cobalt, molybdenum, and tungsten. Columbium, molybdenum and tungsten harden titanium considerably. Alloys with thorium are very soft. All alloys of titanium and tantalum are malleable when hot.
4 Preferred deoxidizers. None
6 Precautions in melting. Oxygen, hydrogen, nitrogen and carbon must be excluded during melting, which must be done in a vacuum or an argon atmosphere.
7 Hot working temperature range. Rolling at 500 C (930 F) permits greater reductions per pass and larger total reductions between anneals. The temperature is below the recrystallization temperature of titanium and material so rolled work hardens, but to a much slighter extent than in cold rolling.
9 Annealing temperature. 400 to 1100 C (750 to 2010 F)
10 Maximum reduction between anneals. 60%
11 Suited to forming by the usual processes of swaging, hot and cold rolling, and wire drawing
12 Precautions in forming. For wire drawing, air an-

nealing is preferred to vacuum annealing because of the formation of an oxide film that prevents the metal from sticking to the dies.

13 Compacting pressure. 100,000 psi

14 Sintering temperature. 950 to 1000 C (1740 to 1830 F); time 16 hr; atmosphere 10^{-4} mm Hg.

Vanadium

COMPILED BY JEROME STRAUSS*

B *1 Uses.* Alloying element in steel and nonferrous metals.

2 Precautions in use. Oxidizes in molten unkilled steel.

C *1 Density* at 22 C (71.6 F). 6.0 g per cu cm (0.217 lb per cu in.)

D *1 Melting point.* 1735 ± 50 C (3150 ± 90 F)

4 Boiling point. 3400 C (6150 F) calculated

11 Specific heat 20 to 100 C (68 to 212 F). 0.120 cal per

E *2 Electrical resistivity* at 20 C (68 F). 26 microhm-cm

5 Temperature coefficient of resistivity. 0.0028 per °C

10 Electrochemical equivalent (valence 5). 0.1056 mg per coulomb

G *2 Magnetic susceptibility.* 1.5×10^{-6} cgs

I *2 Resistance to specific agents.* Vanadium metal dissolves easily in nitric acid, both concentrated and dilute. It reacts very slowly with strong hydrochloric acid, but is not attacked by dilute hydrochloric or by concentrated or dilute sulfuric acids.

J *1 Crystal structure.* Body-centered cubic; $a = 3.033$ kX

K *Mechanical properties.* Ductile enough to be cold worked.

* Vanadium Corporation of America, New York

Zirconium†

B *1 Typical use.* As a "getter" in vacuum tubes, because of ability to absorb gases at high temperature.

C *1 Density* at 20 C (68 F). 6.5 g per cu cm

D *1 Melting point.* 1750 ± 700 C (3200 ± 1300 F)

6 Thermal expansion near 20 C (68 F). 0.000005 per °C

11 Specific heat at 20 C (68 F). 0.066 cal per g per °C

E *2 Electrical resistivity* at 0 C (32 F). 41.0 microhm-cm

I *1 General resistance to corrosion.* Excellent. Resists all dilute acids and will withstand hydrochloric and nitric acids in hot concentrated solutions. Also resists hot concentrated caustic solutions.

J *1 Crystal structure.* Close-packed hexagonal, $a = 3.223$ kX, $c = 5.123$ kX. Other forms known or probable.

K *Mechanical properties.* See Table I.

N *Working data.* Fully annealed zirconium is soft and ductile, and can be drawn and shaped easily. The metal work hardens rapidly, but has a high capacity for work hardening. By a special method, zirconium wire has been drawn as fine as 0.0012-in. diam.

Table I. Mechanical Properties of Zirconium (Raynor)

Property	Hard Drawn	Tempered at 850 F	Annealed at 1450 F
Cold Reduced From ¼-in. Turned Bars Rolled and Swaged to ⅛-in. Diam (76.9% reduction in area)

Form and Arrangement of the Section

IN ALL PREVIOUS EDITIONS OF THE METALS HANDBOOK, the articles about the constitution of binary and ternary alloys were distributed throughout the several ferrous and nonferrous sections of the book. For the present edition, the Metals Handbook Committee decided that all such articles, with the included phase diagrams, should be placed in a single section and prepared according to a uniform style. The Phase Diagram Committee was organized to plan the new section and to direct the preparation of it.

After the general outlines for the section were complete, the Phase Diagram Committee appointed sectional chairmen — listed above — to supervise the construction of the diagrams involving the principal metals. In collaboration with these chairmen and with the Committee, 82 authors have prepared the 284 diagrams and have written the discussions that go with them.

An enlargement in the size of the phase diagrams and a twofold increase in the number of them have made it necessary to reduce the amount of space given to the text accompanying each diagram. Discussions of controversial data and of physical properties of alloys have therefore been omitted, except where space was available in the column next to a particular diagram. For most of the articles, journal references have been limited to publications actually used in constructing the selected phase diagram.

The alloy systems are arranged in the alphabetic order of the chemical symbols of the components; for example, silver-cadmium is listed under "Ag", iron-carbon under "C". The component having alloys of the greater commercial importance in a binary system appears at the left side of the diagram. Intermediate phases have been designated by consecutive Greek letters from left to right, except where phases have other designations that are generally accepted.

The co-ordinates of the diagrams are in weight percentage and degrees Centigrade; atomic percentages are marked on the top, and degrees Fahrenheit on the right of each diagram. Temperatures of reaction horizontals are indicated in Centigrade with a plain degree sign; compositions at line intersections are shown by numbers without the per cent sign.

All complete binary phase diagrams are reproduced to a scale of 10 weight per cent equals one centimeter. On the partial diagrams also, one weight per cent corresponds to a simple multiple of one millimeter. The temperature scale has been drawn so that either 25, 50, 100, 200 or 400 degrees Centigrade equals one centimeter. Thus, both weight percentage and degrees Centigrade can be read directly from each binary diagram by using a centimeter scale.

Dashed lines signify doubt as to the position of the line in question. Dotted lines show the temperatures of magnetic changes. A dot-dash line indicates the existence of an ordered structure. Because of present uncertainty in the data concerning superstructures, it has been necessary in some diagrams to show constructions that are not in harmony with general laws of phase equilibrium.

Melting points of the pure components are shown according to the temperatures given in the table of Physical Properties of the Elements, on pages 20 and 21. The temperatures of polymorphic transformations in the metallic elements have also been standardized. In order to obtain consistency in these transformation and melting temperatures, adjustments in other data have sometimes been necessary.

Ag-Cd Silver-Cadmium

By F. C. Kracek*

At the liquidus the diagram[1,3,4,5,7] bears a close resemblance to that of silver-zinc. Below the liquidus the relationship is more complex in the β field; microscopic and thermal studies[2,3,4] show the existence of β (disordered?), β' (ordered?) and ζ (complex hexagonal) phases. X-ray studies on quenched powdered samples[8,9,11] do not reveal the ζ phase, which appears not to be retained because of extremely rapid transformation to β' (plus α or γ); measurements obtained with a high-temperature camera indicate the existence of all the three phases (β, β', ζ) in the β field.[10] The phase boundaries that are given in the diagram were deduced from the microscopic examination of quenched specimens.[3,4] These boundaries are not in good agreement with those based on X-ray studies.[11]

Ag-Co Silver-Cobalt

According to Petrenko,[1] silver and cobalt are insoluble in the liquid state at 1600 C. Tammann and Oelsen,[2] using a sensitive magnetic method, determined a solubility between 0.0001 and 0.001% Co in silver after the solidification of silver liquid solutions to which small amounts of cobalt had been added at a temperature of 1000 or 1200 C.

Ag-Cr Silver-Chromium

Hindrichs[1] investigated alloys of silver and impure chromium, both of which melted at temperatures considerably lower than the melting points of the pure metals. His results indicate a monotectic reaction about 100 C below the melting point of chromium, and a miscibility gap extending from about 10 to 90% Cr. All solid alloys contained two metallic phases, silver and chromium.

Reference

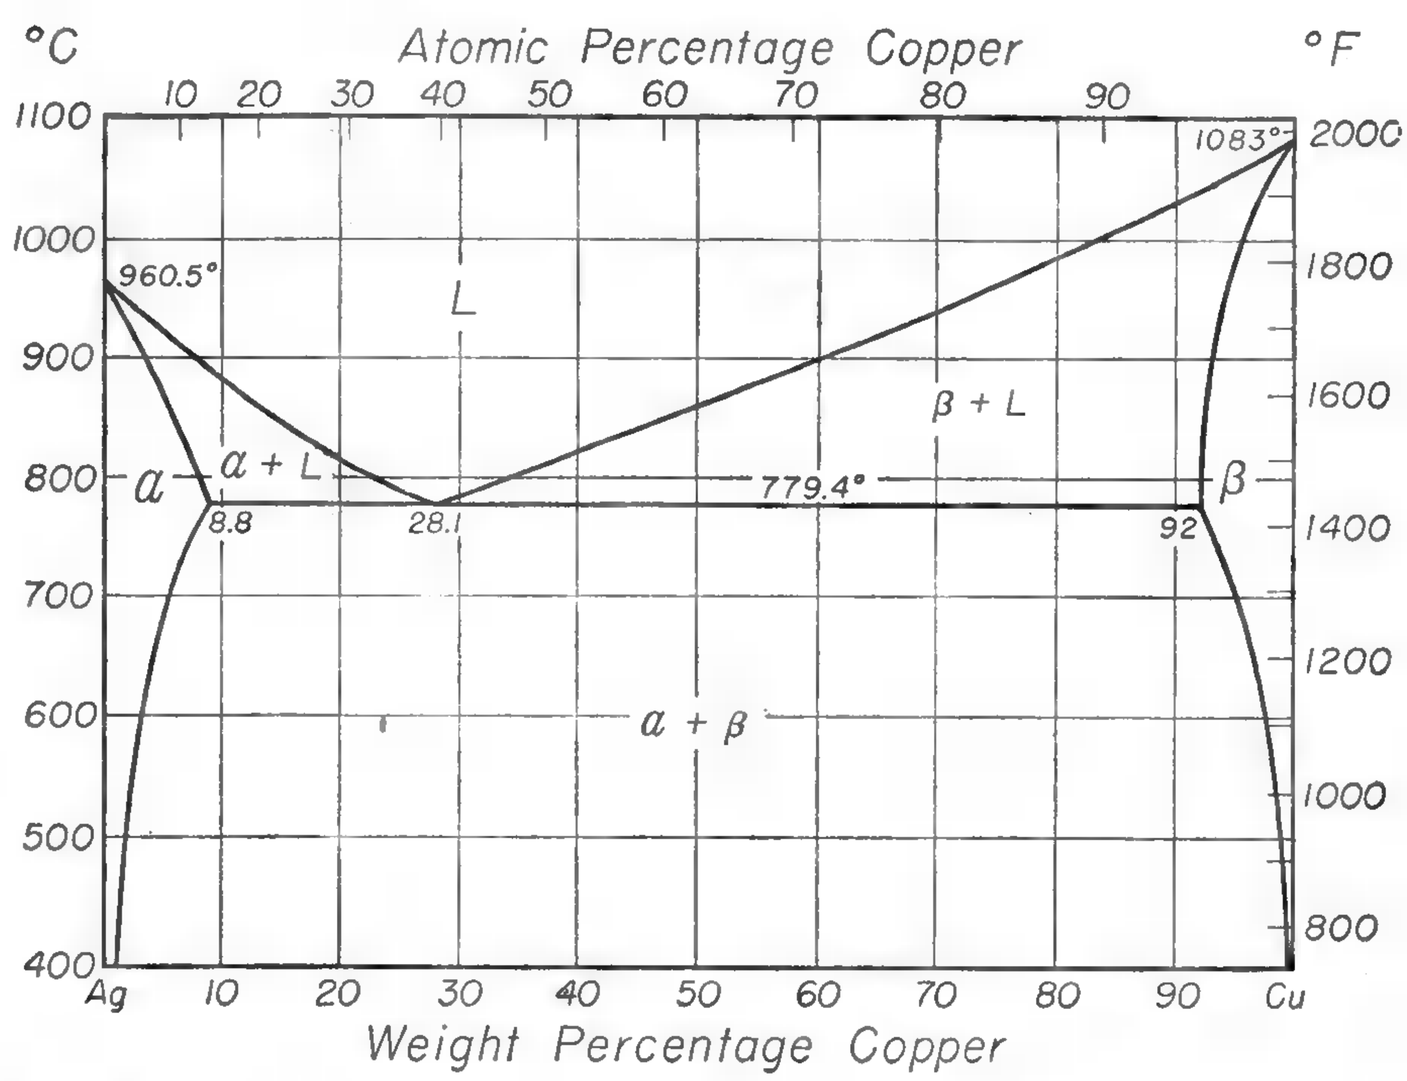
Ag-Cu Silver-Copper

By Cyril Stanley Smith*



The liquidus is based on the results of Heycock and Neville[1], Friedrich and Leroux[2] and Hirosé.[3] The eutectic temperature[4] and composition[5] have been the subject of special investigations and are known with unusual accuracy. The extent of solid solution at each end of the diagram has been determined by microscopic examination,[6,7] X-ray[8,9,10] and electrical conductivity[7] methods, all of which are in substantial agreement.

Both solid solutions are face-centered cubic. The lattice parameter of the copper-rich solid solution increases lineally with atomic percentage of silver from 3.608 to 3.633 kX at 8.0% Ag, and that of the silver-rich solution decreases lineally from 4.077 to 4.029 kX at 8.0% Cu.

Ag-Fe Silver-Iron

By R. M. Parke*

Silver and iron are insoluble in the liquid state at 1600 C[1] and are virtually insoluble in the solid state. Tammann and Oelsen[2] report that ▮ × 10^{-4}% Fe dissolves in silver at 1600 C and 4 × 10^{-4}% Fe dissolves in silver at 1000 C. Dornblatt[3] reports that 0.01% Ag dissolves in Armco iron, but Wever[4] states diagrammatically, without the inclusion of data on temperature, that silver is insoluble in iron.

Ag-Ga Silver-Gallium

On a scale of atomic percentage, the liquidus and solidus of the α phase are approximately the same as those in the silver-tin system. Close-packed hexagonal ζ forms peritectically at 611 C, and transforms eutectoidally at 378 C into α and ζ'. The ζ' phase has a complex hexagonal structure the same as the ζ phase in the silver-zinc system. The solubility of gallium in silver is 18.7 atomic % at 611 C, 17.6 atomic % at 378 C, and 12.2 atomic % at 211 C.

Reference. Hume-Rothery and Andrews, J Inst Metals, 68, 133 (1942)

Ag-Ge Silver-Germanium

The phase diagram for the silver-germanium system is similar to that for the gold-germanium system (*see* page 1172). Both diagrams are of the eutectic type with no intermediate phases. The silver-germanium eutectic point is at 19% Ge[1] and 651 C.[2] The α solubility decreases from 7.9 atomic % Ge at 575 C to 1.5 atomic % Ge at 270 C.[3] The solubility of silver in germanium is apparently very slight.

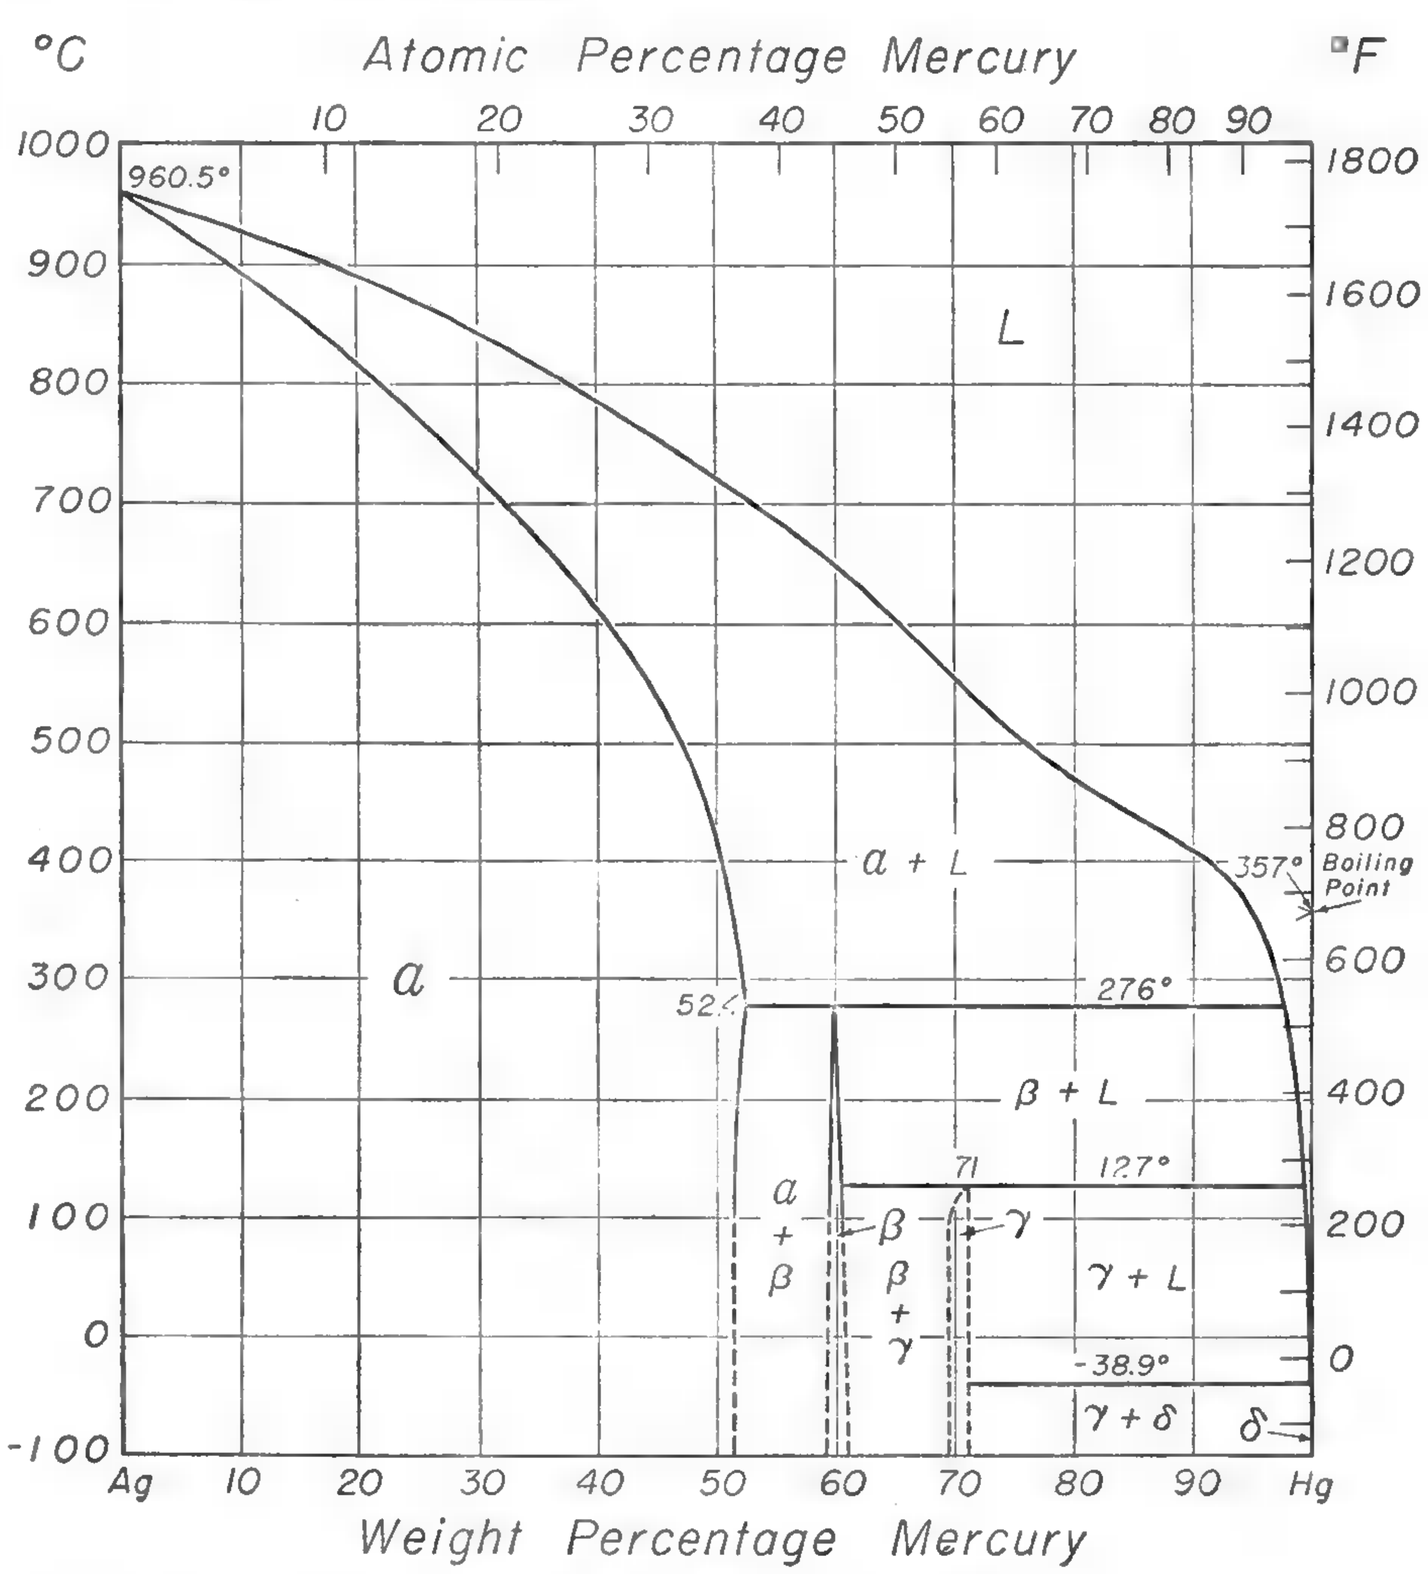
Ag-Hg Silver-Mercury

By W. Earl Lindlief*



According to Murphy,[1] γ is formed quite rapidly by reaction of mercury with finely divided silver at room temperature. However, in the alloys containing more than 52% Hg there is a strong tendency for metastable conditions to be developed during cooling after fusion. The reaction between α and liquid and that between β and liquid proceed slowly and are entirely suppressed by cooling rates such as those employed in thermal analysis. For example, an alloy containing 95% Hg must be annealed for 3 days at 100 C before the thermal arrest observed on a heating curve is equivalent to that obtained when an unfused amalgam of the same composition is being heated at the same rate.

The solubility of silver in liquid mercury at 19 C is approximately 0.034%.[2,3]

Crystal structures and lattice parameters of the α, β and γ phases are given in the table below the diagram.

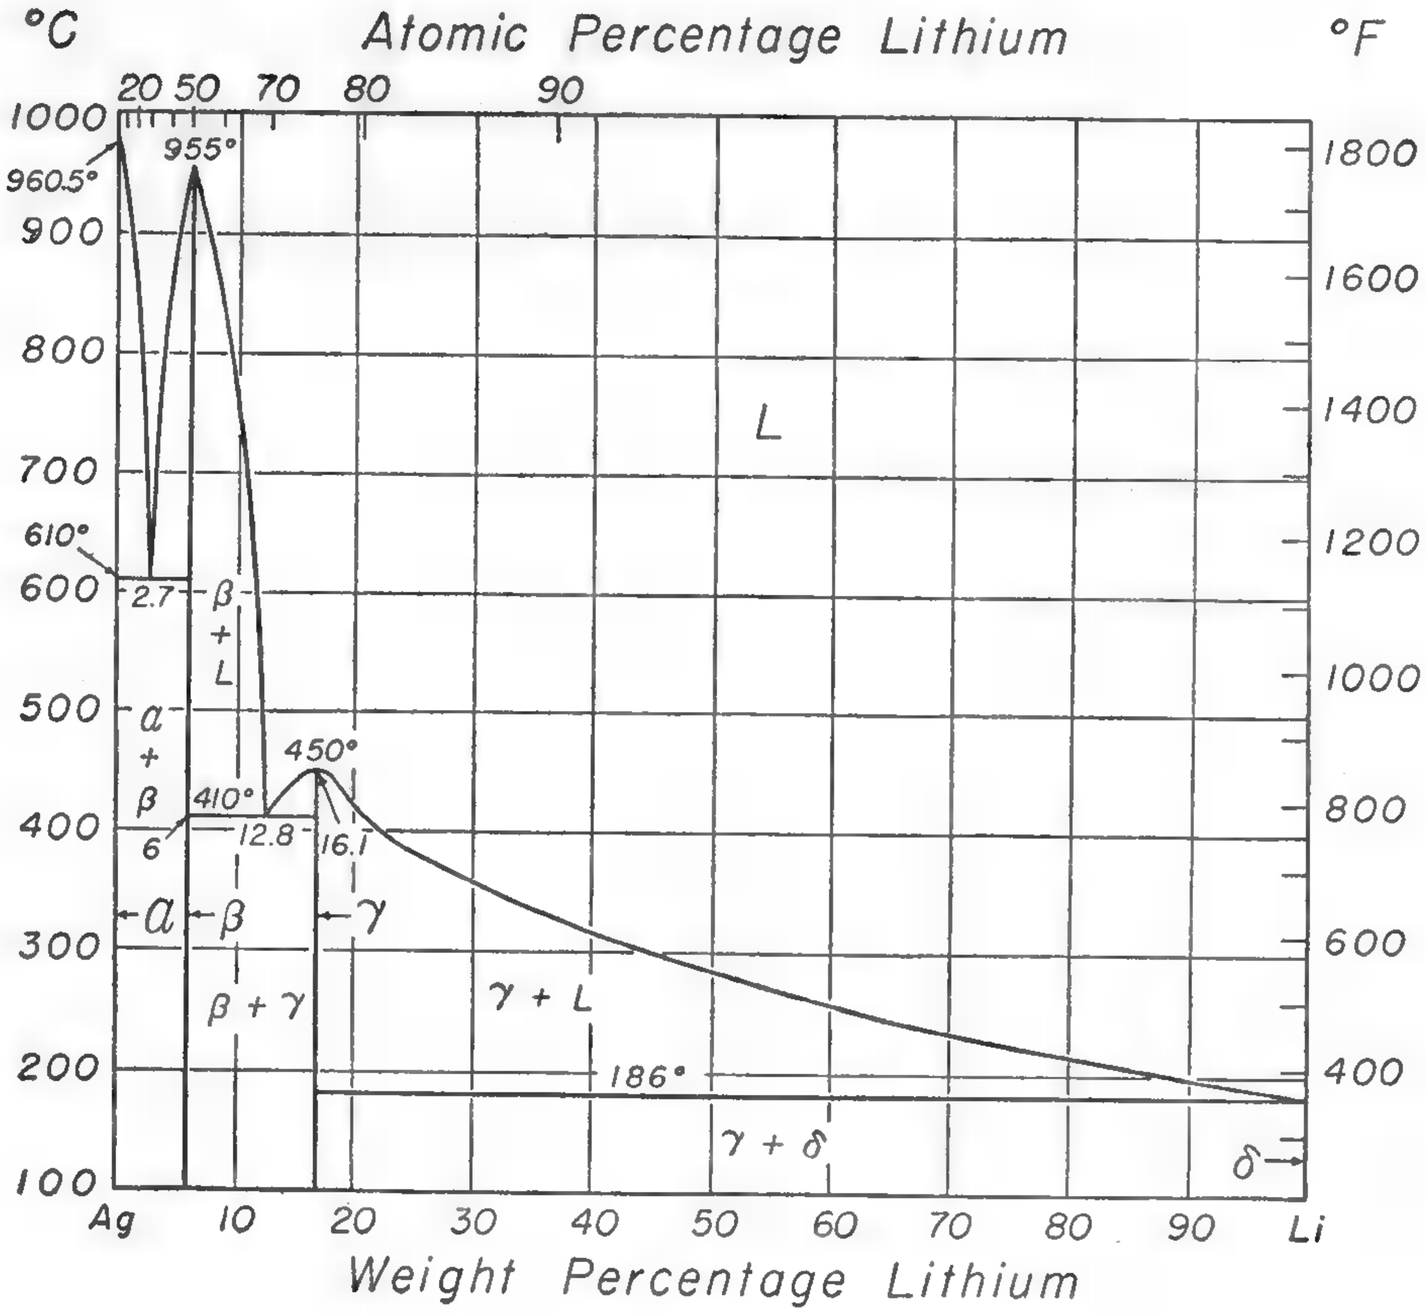
γ	Ag saturated	Body-centered cubic	10.013	....
γ	Hg saturated	Body-centered cubic	10.031	....

The α-phase alloys were annealed 500 hr at 270 C and quenched; β- and γ-phase alloys were annealed at 100 C.

Ag-Li Silver-Lithium

By H. E. Cleaves*



Data for the liquidus and eutectics of silver-lithium alloys were obtained by Pastorello[1] using lithium melting at 180 C, six degrees below the melting point of pure lithium.[2] Hence the temperatures of the liquidus and eutectics may be slightly in error.

No evidence of solid solubility of lithium in silver or of silver in lithium was observed.[1]

The existence of the compounds β and γ was confirmed and their structures were determined.[3,4] These compounds correspond to the compositions LiAg and Li_3Ag respectively.

The β phase has a body-centered cubic structure of the same type as β brass; the lattice parameter is 3.168 ± 0.003 kX.[3]

The γ phase is simple cubic with a lattice parameter of 9.94 kX.[4]

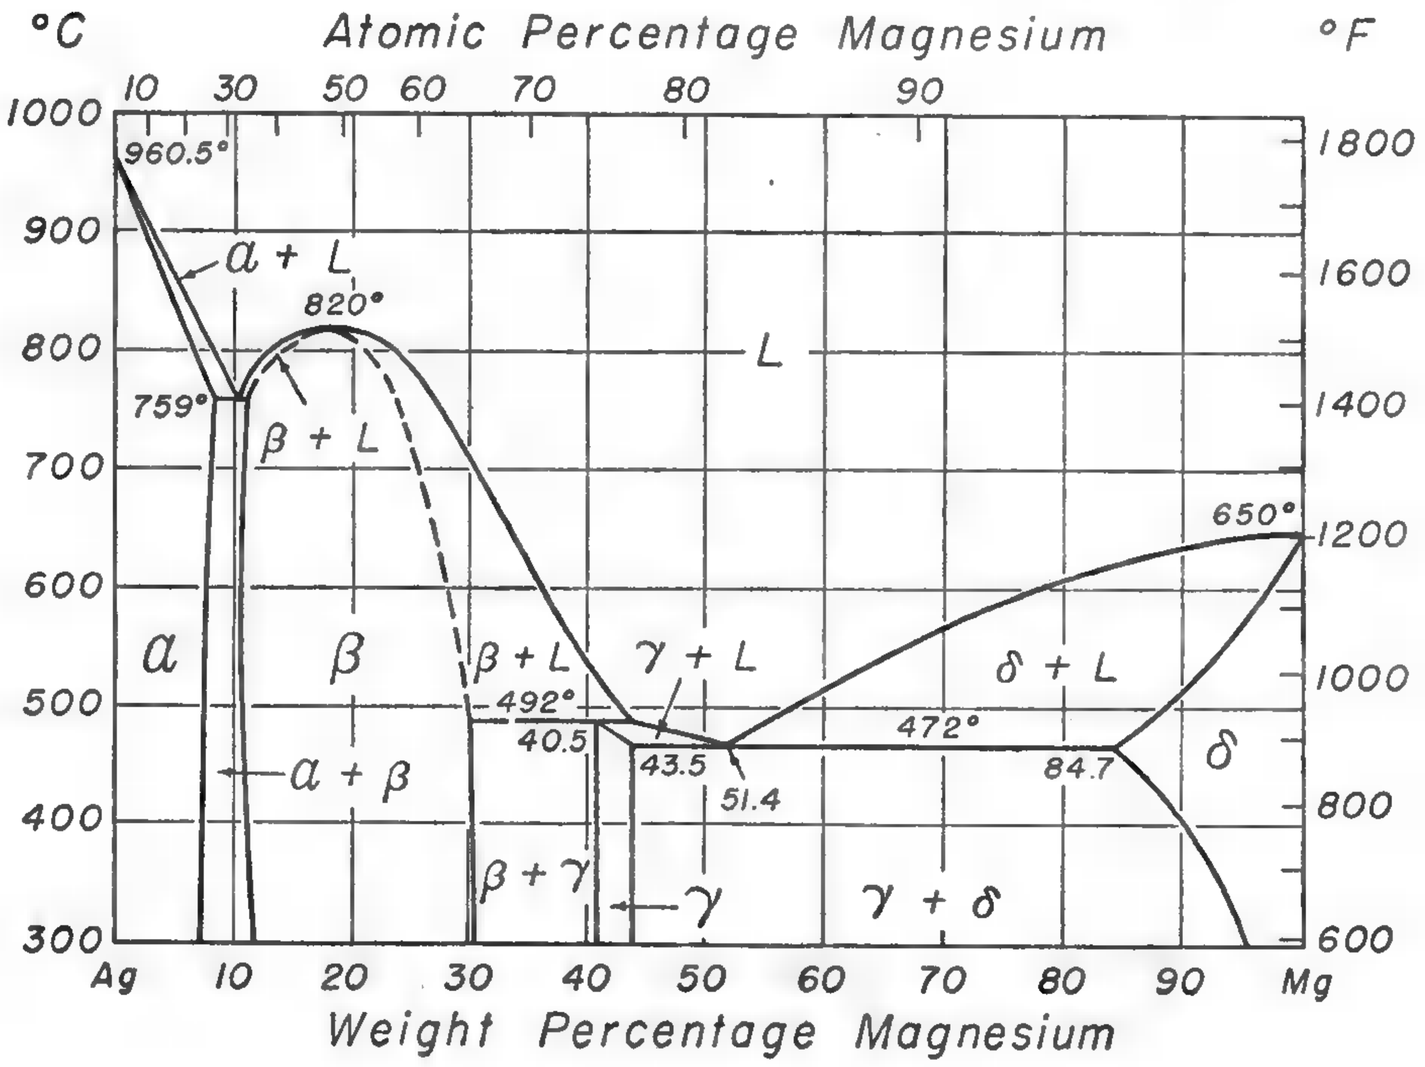
Ag-Mg Silver-Magnesium

By G. F. Sager* and B. J Nelson*



The width of the β field is not firmly established. The solubility of magnesium in silver is 8.54% at 759 C, 7.51% at 300 C. The solubility of silver in magnesium is 15.3% at 472 C, 9.0% at 400 C, 3.9% at 300 C, and 1.6% at 200 C.

The β phase is body-centered cubic (CsCl type)[1] with a lattice parameter of 3.28 kX; γ was first reported to be hexagonal,[2] but later work[5] indicates a more complicated structure.

A superstructure has been found in the β phase near 50 atomic % Mg.[5]

Ag-Ni Silver-Nickel

By John L. Christie*

The limited terminal solubilities have not been determined precisely.[1] The solubility of nickel in solid silver is very low, 0.102% at 922 C and 0.012% at 400 C.[2]

Silver-rich silver-nickel mixtures have characteristics desirable for electrical contacts. Because of the low solubility of each metal in the other, most compositions must be prepared by the methods of powder metallurgy. The properties of these materials, in the composition range from 0 to 40% Ni, are discussed in the article "Silver Materials for Electrical Contacts", on page 1114 in this Handbook.

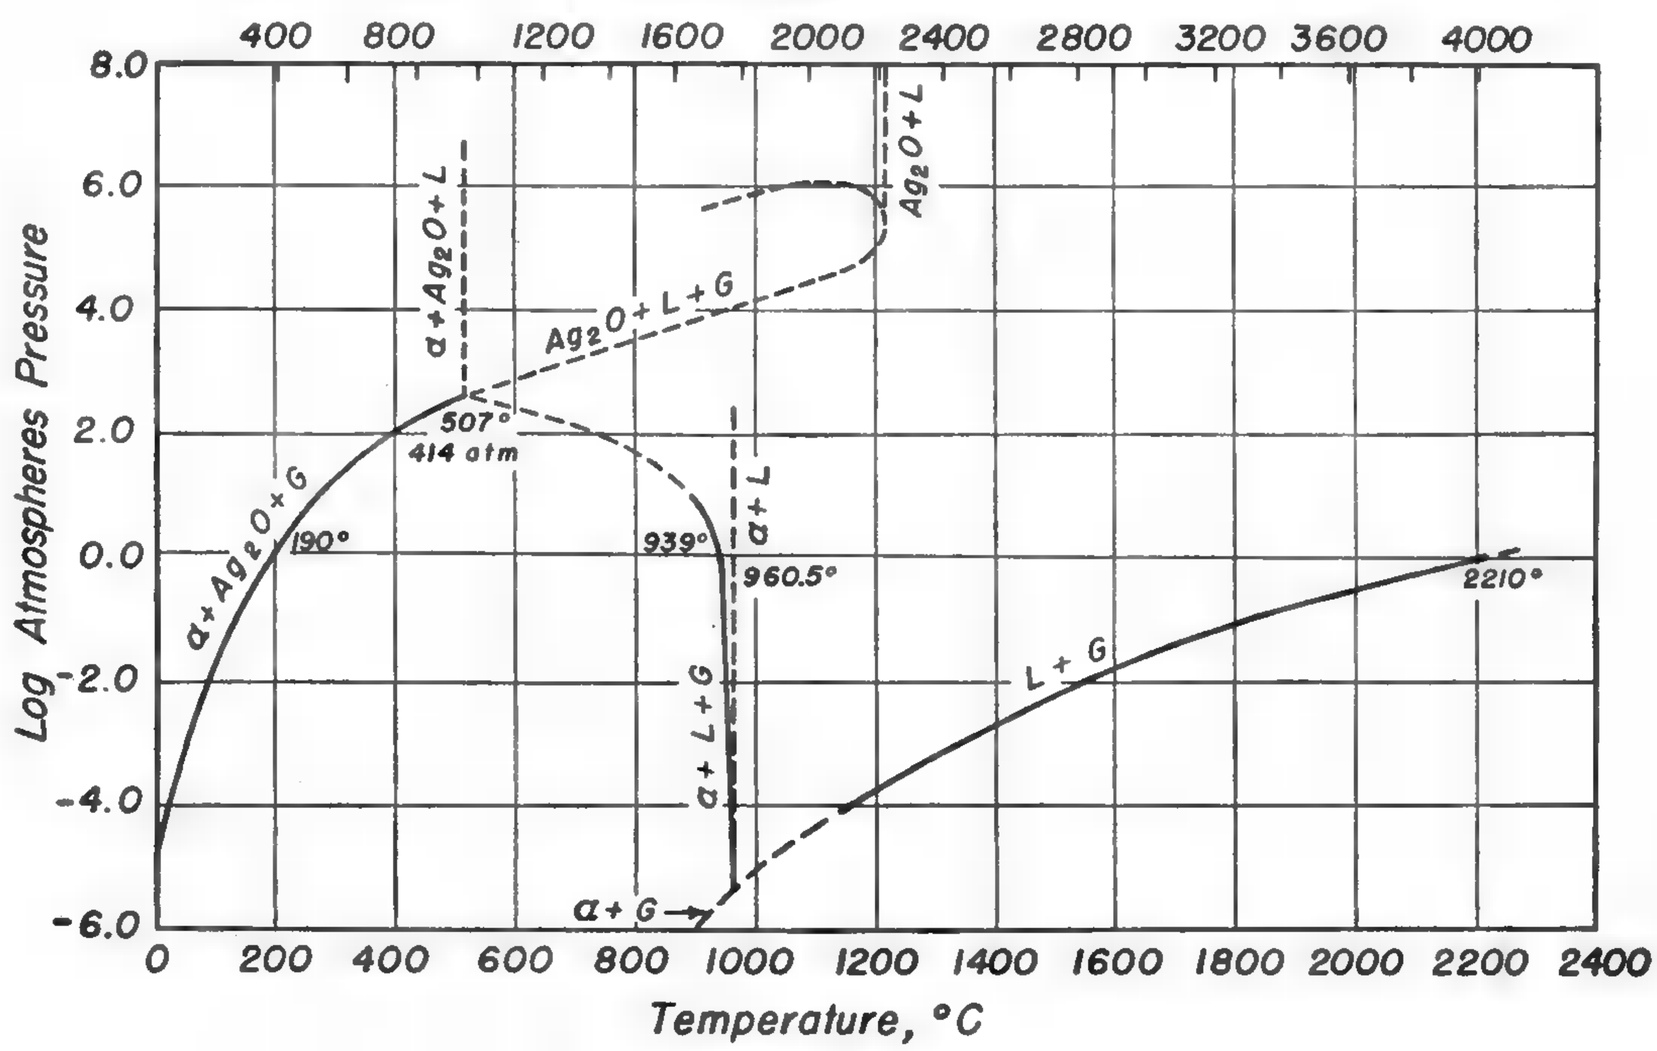
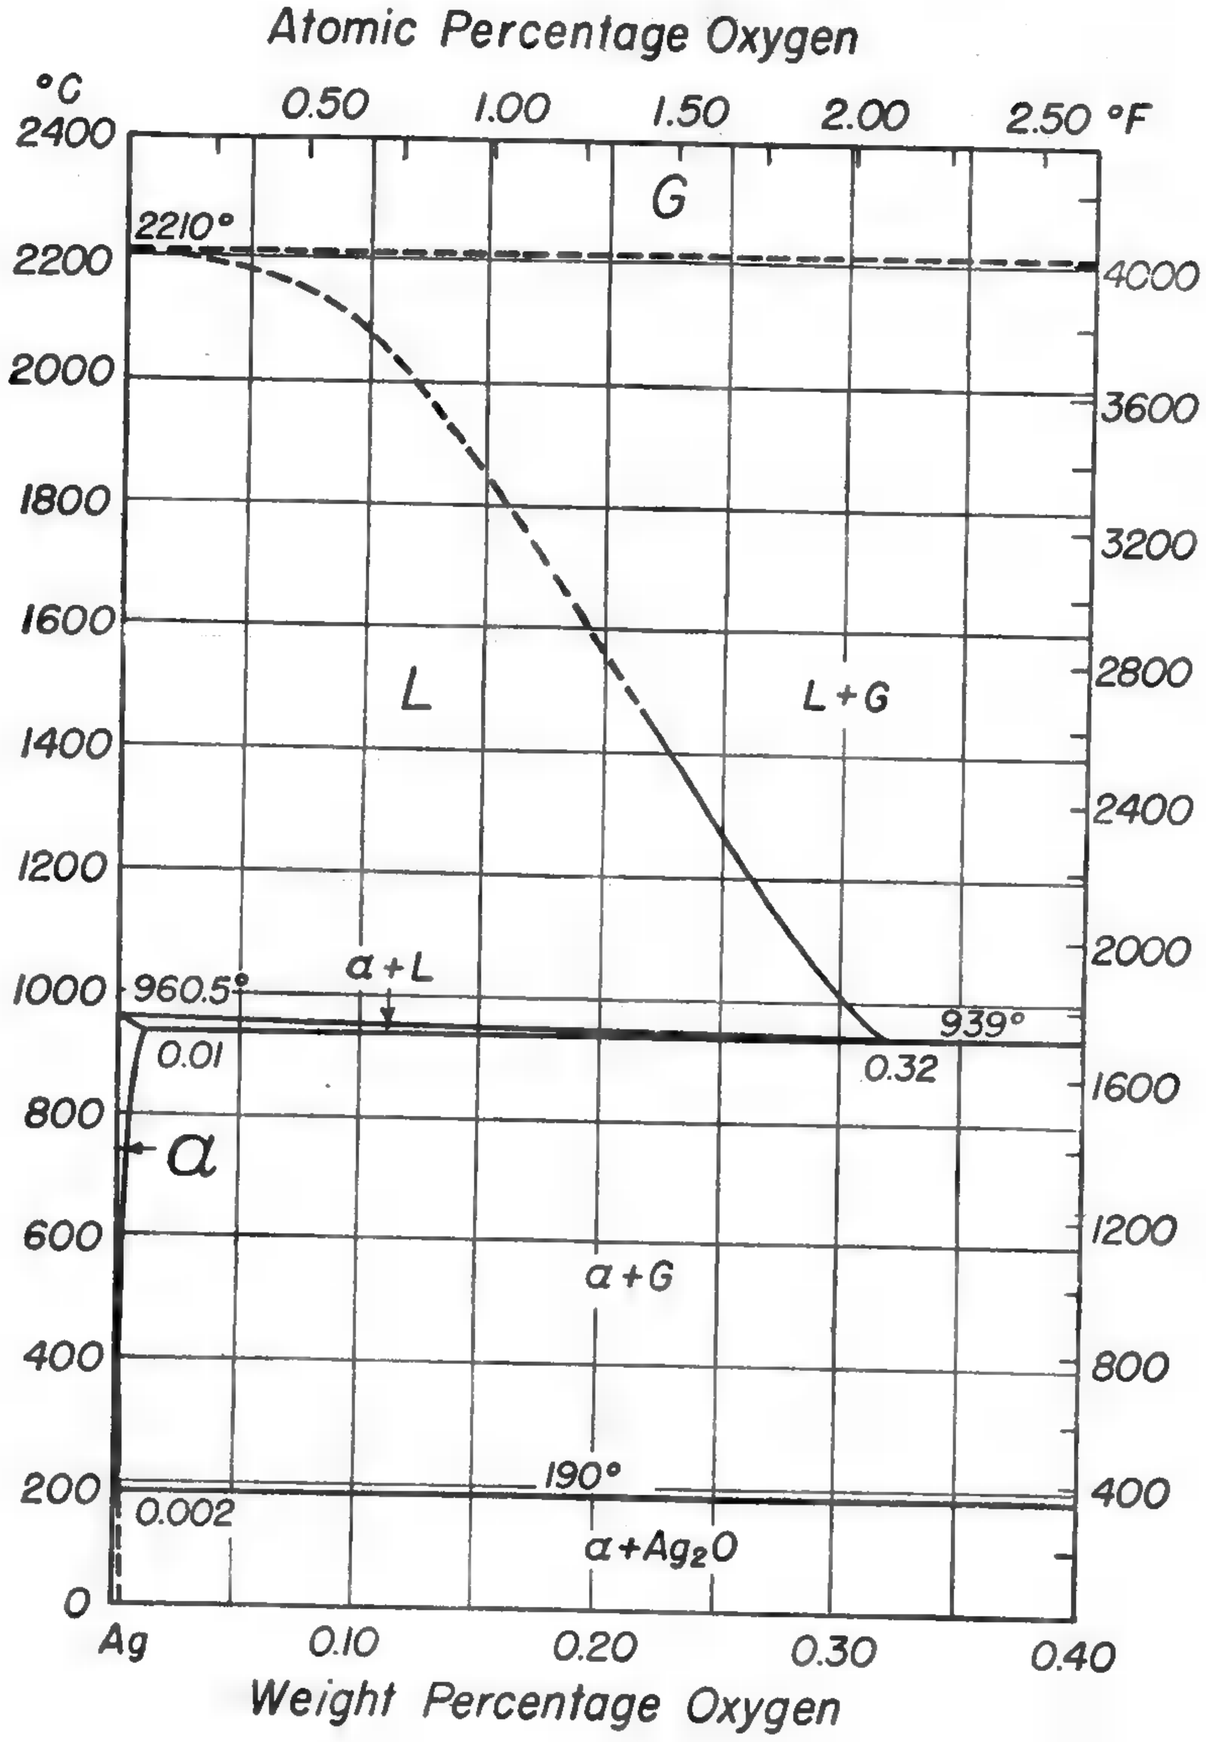
Ag-O Silver-Oxygen

By H. C. Vacher*



* National Bureau of Standards, Washington, D.C.



Available information on the silver-oxygen system is summarized by two diagrams: temperature versus composition at one atmosphere pressure, and pressure versus temperature.

The solubility of oxygen in silver is based on the work of Steacie and Johnson.[3] Their results, obtained between 200 and 800 C and at pressures between 20 and 80 cm Hg, indicated that the solubility was lowest at 400 C, and from the curves, these authors concluded that it was greater at room temperature than at 200 C. These authors admit that the reversal in the solubility curve is difficult to explain, and suggest, after thermodynamic considerations, that it is associated with the possible existence of oxygen dissolved as Ag_2O at low temperatures and as atomic oxygen at temperatures above 400 C.

Silver oxide crystallizes in the cubic system; $a = 4.72$ kX units. The unit cell contains four silver and two oxygen atoms arranged in the $2a$ and $2d$ special positions of the O_h^4 space group.[4]

Ag-Pb Silver-Lead

By A. A. Smith, Jr.*

The diagram is based largely on the work of Heycock and Neville,[1] Friedrich,[2] and Petrenko.[3] The solubility of lead in solid silver is about 1.6% at the eutectic temperature.[4,5] Silver has very restricted solubility in solid lead; according to Seith and Keil[6] it is about 0.1% at the eutectic temperature and 0.05% at 200 C.

The solubility curve of lead in silver above the eutectic temperature passes through a maximum at about 650 C and 5% Pb.[4] This retrograde solubility is unusual, but appears to have been firmly established by the microscopic and X-ray results of Raub and Polaczek-Wittek.[4]

A lead-silver alloy (containing 1% Sn to improve the resistance to humid air) is used commercially for coating and joining. Some properties of this alloy (97.5 Pb – 1.5 Ag – 1 Sn) are listed in the Lead Section, page 964.

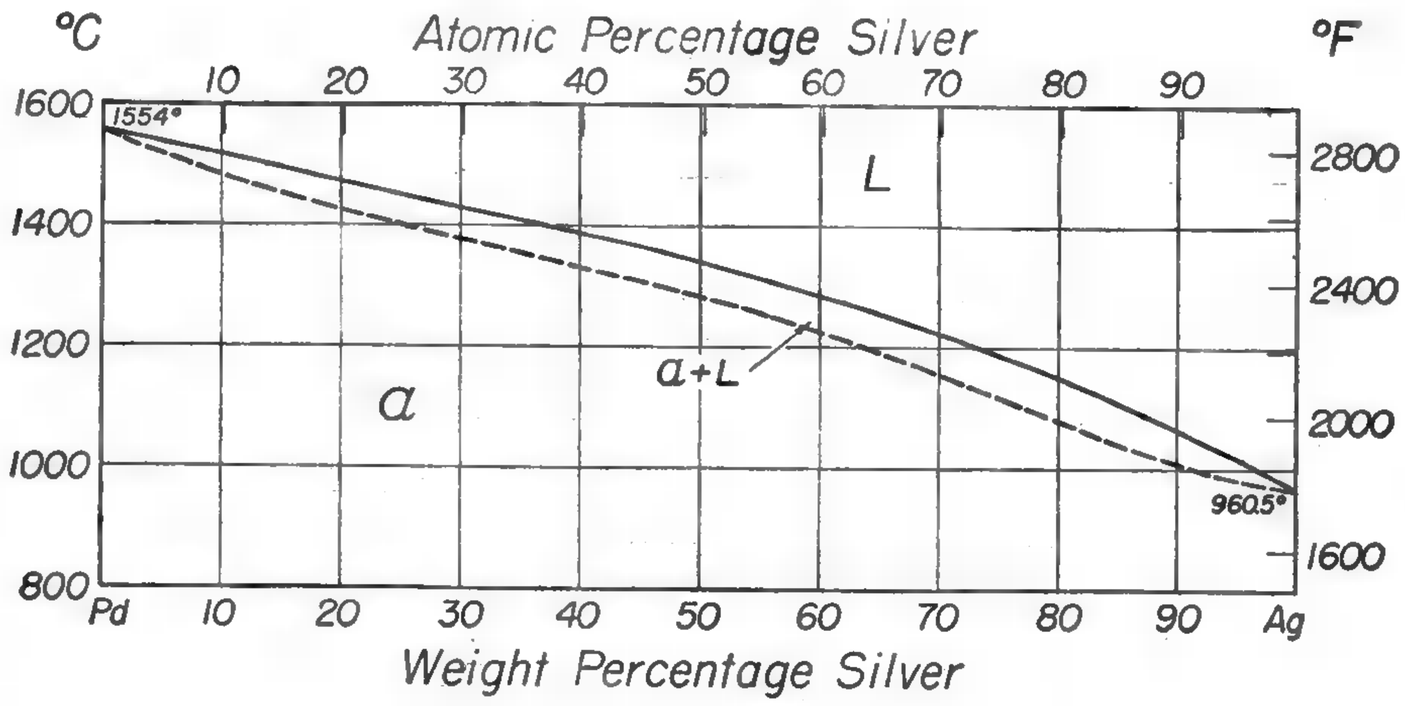
Ag-Pd Silver-Palladium

By E. M. Wise*



The liquidus has been established by Ruer[1] and modern investigators. The location of the solidus is less exactly known, but it is close to the liquidus throughout.

Lattice parameter measurements plotted against composition in atomic per cent are almost linear; the parameter of the 50% alloy is only slightly less than the mean of the end members.[3]

The hardness and tensile strength of silver-palladium alloys are maximum at about 30% Ag — 100 Bhn and 55,000 psi in the annealed condition, 180 Bhn after 66% reduction and 99,000 psi after 50% reduction by cold working.[4]

The electrical resistivity has a maximum value of 42 microhm-cm at about 40% Ag.[5–9] The temperature coefficient of resistivity reaches a very low value of 0.00002 per °C (0 to 100 C) at 44% Ag.*

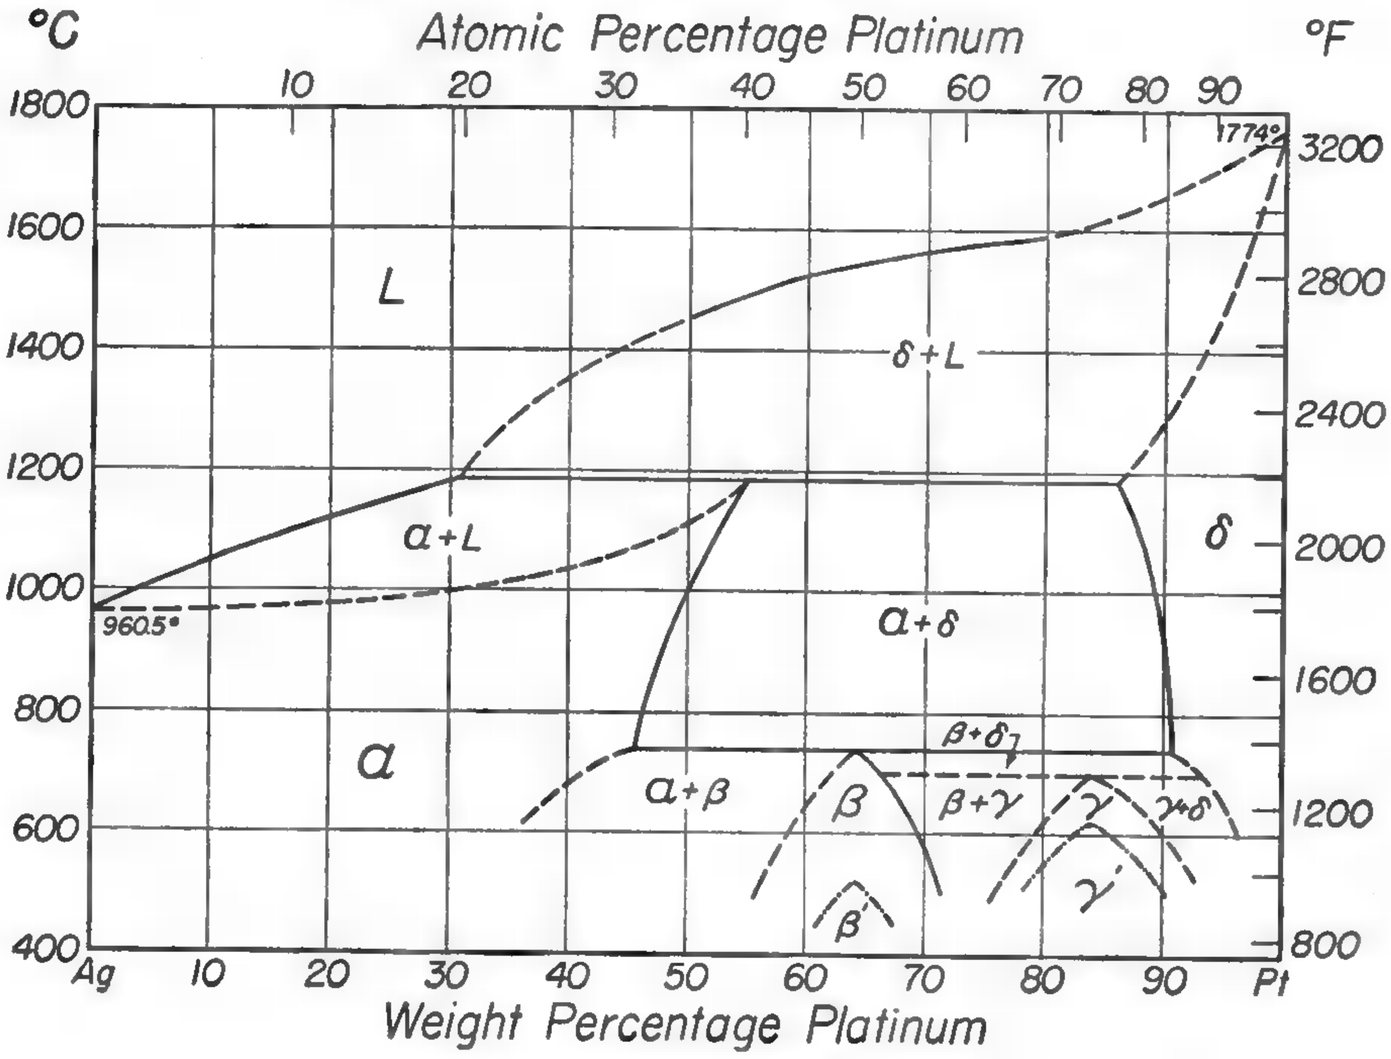
Ag-Pt Silver-Platinum

By E. M. Wise*



The general form of the liquidus and solidus was established by Doerinckel.[1] Schneider and Esch[2] have confirmed many of the results of Johansson and Linde[3] concerning the low-temperature intermediate phases and have reported the ordered phases β' and γ'. Other phases reported below the peritectic temperature have been omitted from the diagram, since X-ray, microscopic, and electrical measurements are not in agreement.

The 20% Ag alloy has a Brinell hardness number of 360 after quenching and aging at about 550 C.

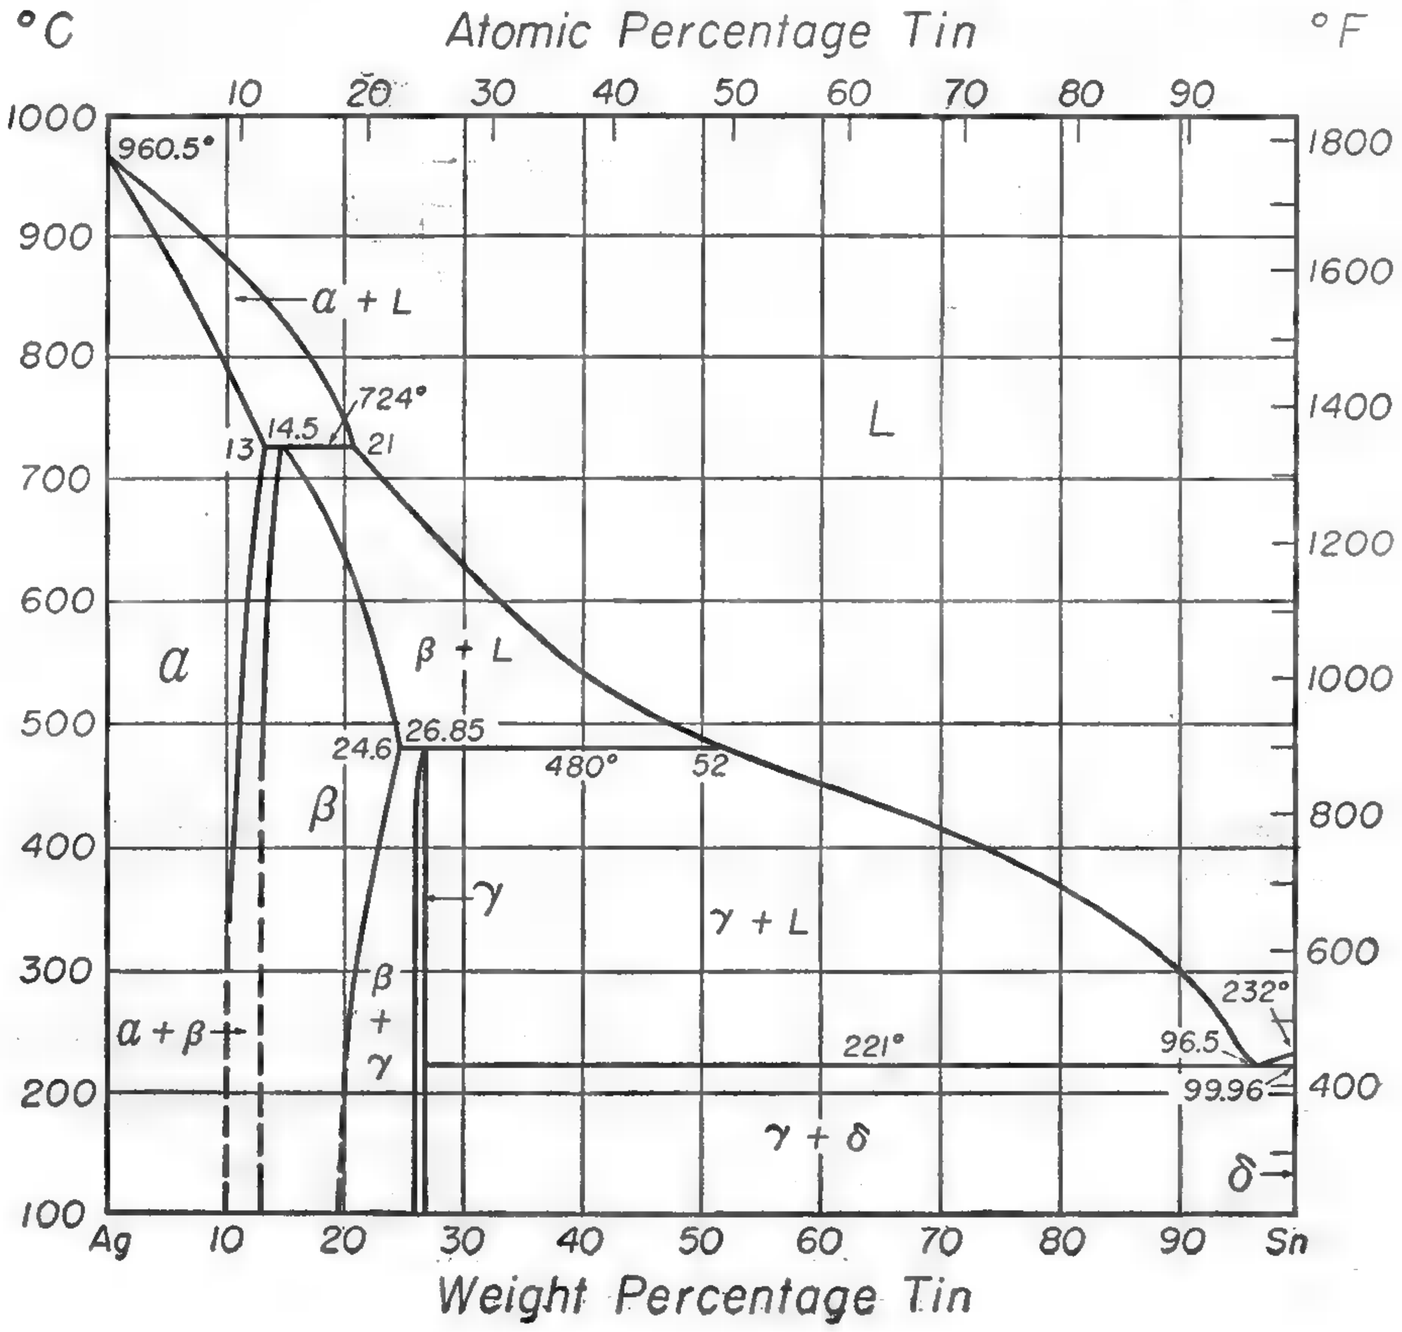
Ag-Sn Silver-Tin

By R. I. Jaffee* and H. P. Nielsen†



Petrenko reported a polymorphic change in γ at 232 C, but Murphy, through extensive tests, could not find evidence for such a change, except a discontinuity at 60 C in the curve of electrical conductivity versus temperature.

Murphy found that as little as 0.2% Ag inhibited the allotropic change of tin to its brittle form.

The β phase containing 21.3% Sn is close-packed hexagonal with $a = 2.925$ kX and $c/a = 1.616$.[5] The γ phase (Ag_3Sn) is rhombohedral with $a_1 = 2.985$ kX, $a_2 = 5.144$ kX, and $a_3 = 4.771$ kX.[5]

A tin-silver alloy containing 5% Ag is in commercial use as a solder (*see* page 1073 in this Handbook).

Ag-Zn Silver-Zinc

By F. C. Kracek*

The phase diagram[1-8,13,20] is closely analogous to that of copper-zinc; the delta phase of the latter system is absent, however. Phase boundaries evaluated from X-ray data on quenched alloys[14-19] have been shown to be inexact.[20]

In the β field a transformation on slow cooling normally occurs from a disordered β phase (cubic) to a hexagonal ζ phase; between 28 and 34% Zn, β appears to transform below 200 to 227 C unstably to an ordered β' phase of CsCl type on quenching[17,18,21,22] from above 380 C. The β–ζ transformation is much less rapid than β–β', and has a wide hysteresis range. Equilibrium values of the transformation temperatures[20] are given in the diagram.

Al-B Aluminum-Boron

By W. L. Fink* and L. A. Willey*

At least two intermetallic phases appear in the aluminum-boron system. These have compositions that correspond to the formulas AlB_2[1] and AlB_{12}.[2] The AlB_2 phase apparently forms at about 1350 C by peritectic reaction between the AlB_{12} phase and liquid containing less than 4% B in solution.[1] Boron is only slightly soluble in liquid aluminum. Saturation limits of about 2% at 1300 C, 0.7% at 1100 C, 0.35% at 950 C, 0.17% at 785 C and 0.09% ■ in aluminum at 730 C have been observed in unpublished research at the Aluminum Research Laboratories.

AlB_2 is hexagonal,[1] with $a = 3.00$ kX, $c = 3.24$ kX. AlB_{12} is monoclinic[2] with $a = 17.01$, $b = 10.98$, $c = 18.80$ kX, $\beta = 110°\ 54' \pm 6'$.

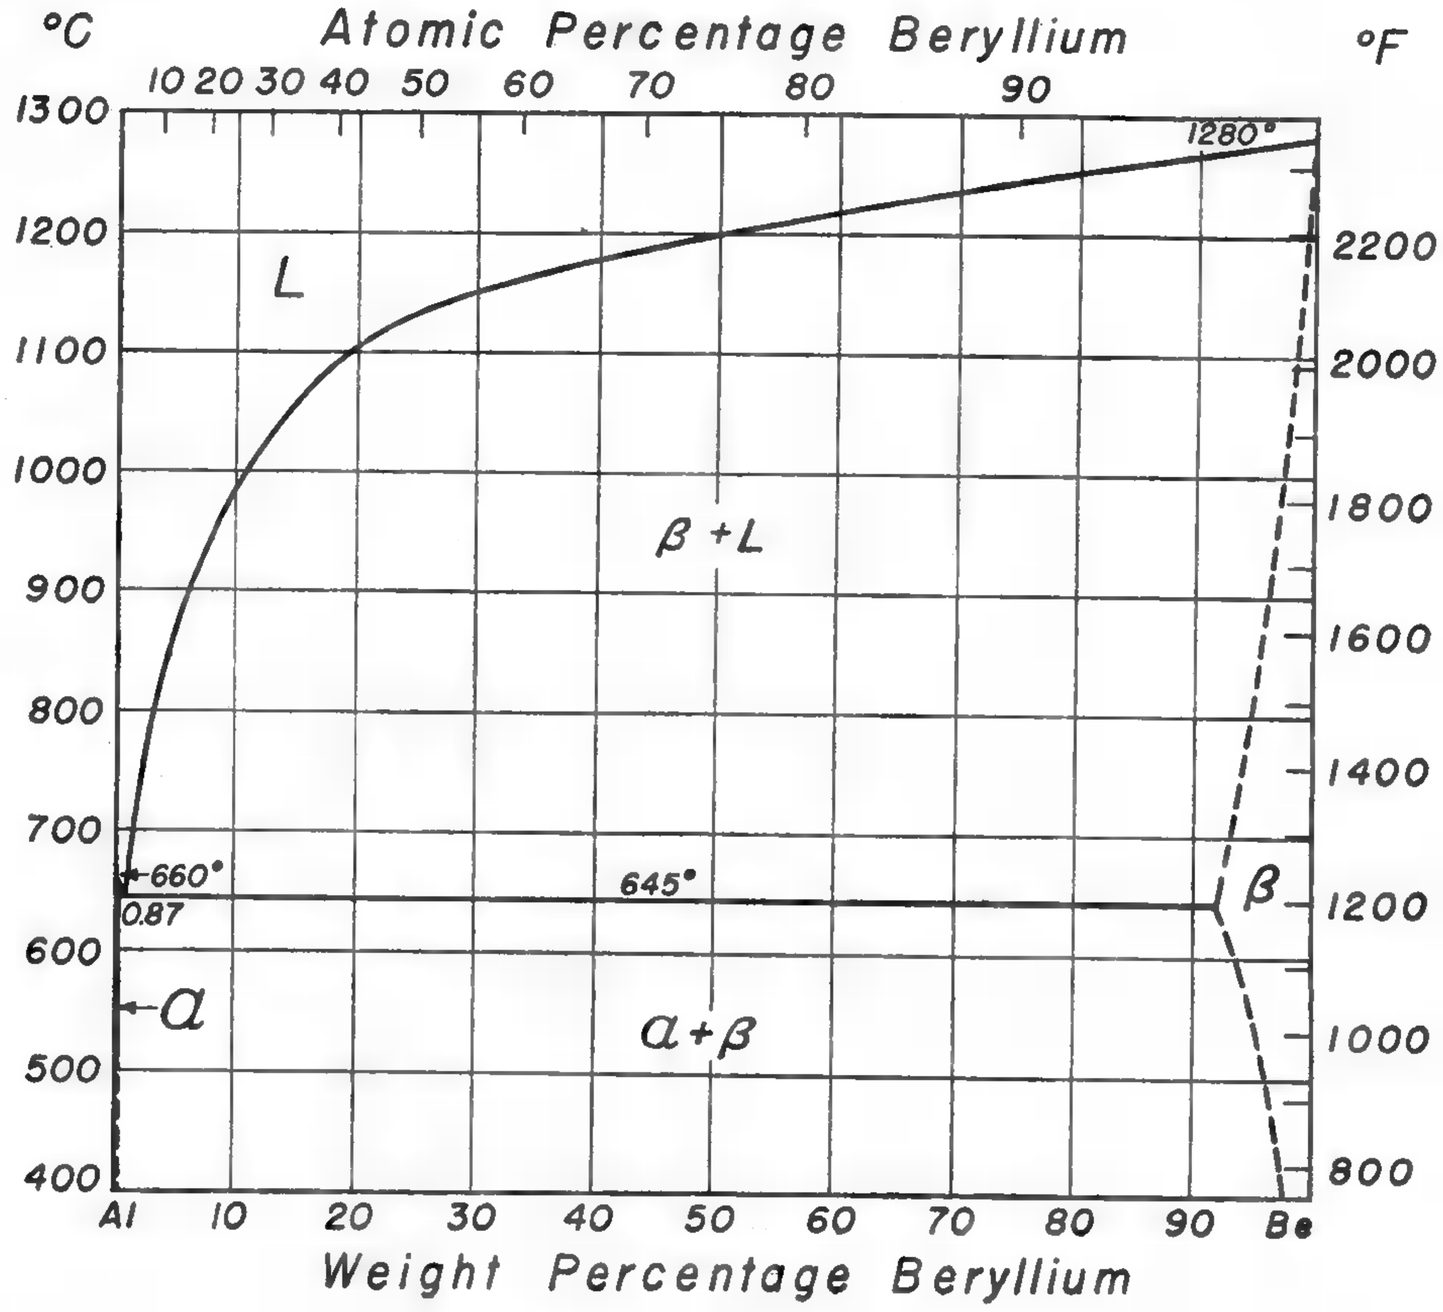
Al-Be Aluminum-Beryllium

By W. L. Fink* and L. A. Willey*



The solid solubility of beryllium in aluminum is from 0.04 to 0.05% at 630 C.[2,5] It decreases to about 0.005% Be at 500 C. A thorough investigation of the solubility of aluminum in solid beryllium has not been made but it is reported as up to 8%[1,3] and also as less than 1.27% Al at 650 C.[4]

The Brinell hardness of a quenched alloy containing 0.75% Be increases from 27 to 43 after aging at room temperature.[2]

The use of beryllium in aluminum has often been suggested as a means for increasing the modulus of elasticity, decreasing the coefficient of thermal expansion and decreasing the density, but the high cost of beryllium and the high liquidus temperatures of alloys containing large amounts of beryllium have prevented the use of such alloys.

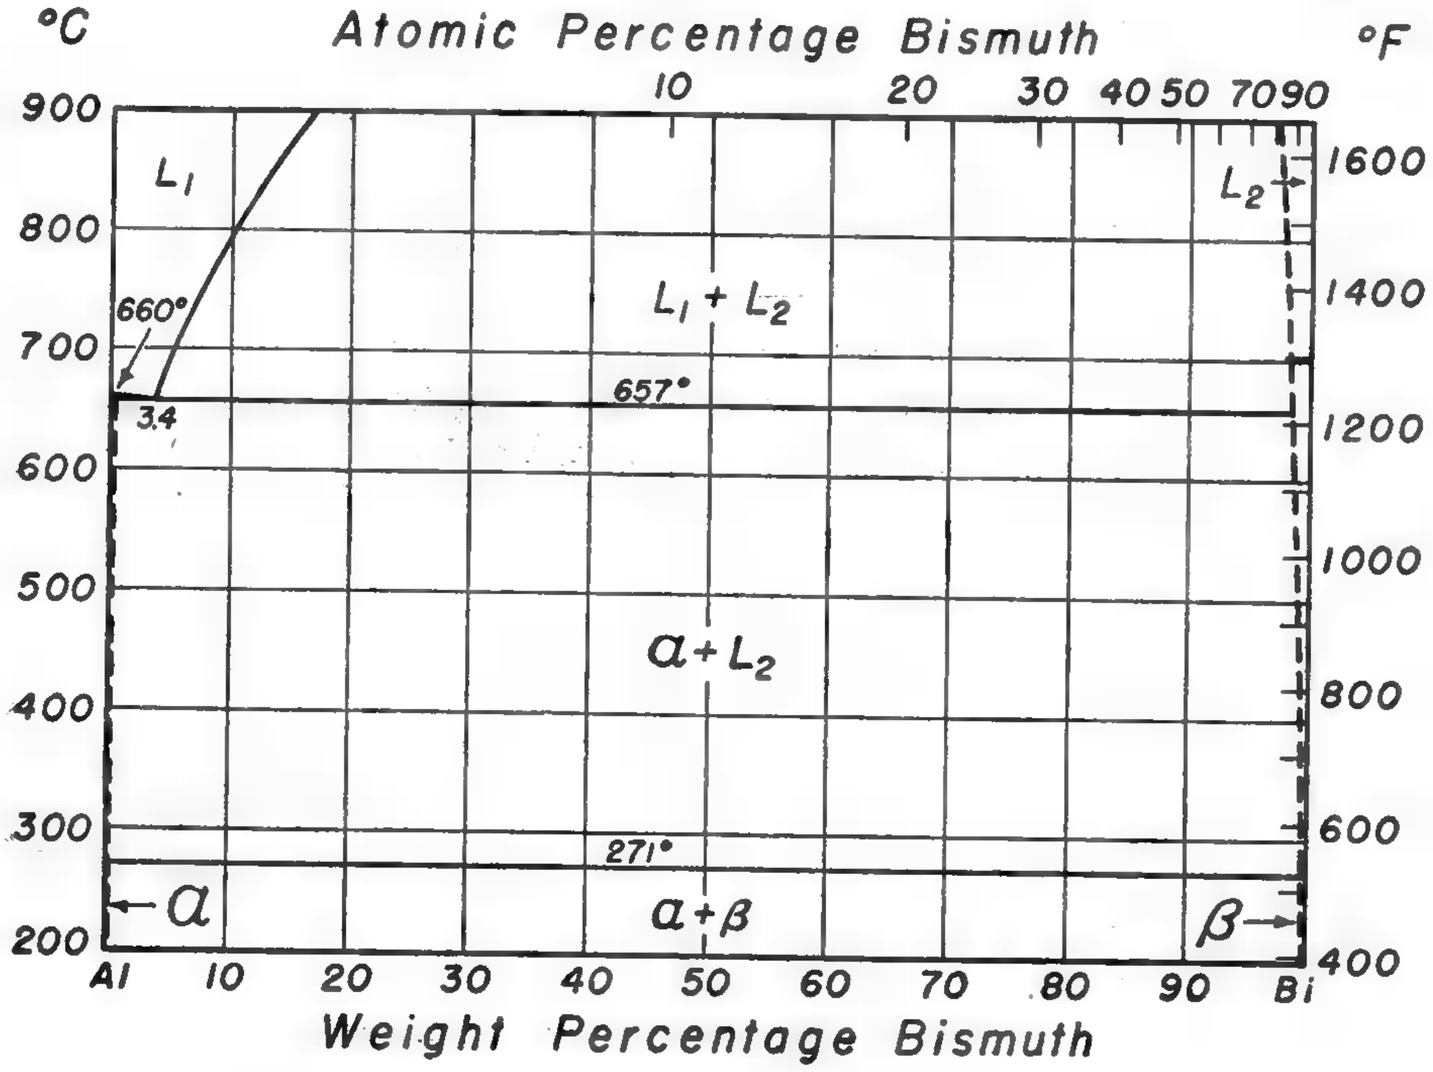
Al-Bi Aluminum-Bismuth

By W. L. Fink* and L. A. Willey*



The solid solubility of bismuth in aluminum has not been thoroughly investigated. It is, however, reported to be less than 0.2% at the monotectic temperature (657 C).[2] Neither the liquid nor the solid solubility of aluminum in bismuth has been determined. These are probably low.

The solubility of bismuth in liquid aluminum is decreased slightly by the presence of about 5% Cu.[2]

Bismuth is used in aluminum alloys only for the purpose of improving the machining characteristics. It is usually employed with lead, which has a similar phase diagram with aluminum, and which has the same beneficial effect on machinability.

Al-Ca Aluminum-Calcium

By W. L. Fink* and L. A. Willey*

The solubility of calcium in solid aluminum has been reported to be as low as 0.6% at 600 C[3] and as high as 2.8% at 616 C.[4] The latter value appears to be excessive. No determination of the calcium-rich solid solution has been made.

According to most investigators[1,2,3] the β phase corresponds to the formula Al_3Ca but it has been more recently reported as Al_4Ca.[4] This phase is tetragonal with $a = 4.35$, $c = 11.07$ kX.[4] γ is face-centered cubic with $a = 8.022$ kX.[4]

Alloys of aluminum and calcium have no commercial importance. However, calcium has been used commercially as a minor alloying addition to duralumin-type aluminum-base alloys, to improve the hot workability.

Al-Cd Aluminum-Cadmium

By W. L. Fink* and L. A. Willey*

The system has received relatively little attention. The type of diagram has been established but many of the details have not been determined with sufficient accuracy.

The solubility of cadmium in solid aluminum has been found to be less than 1% at the monotectic temperature (649 C).[1] Information pertaining to the solubility of aluminum in either liquid or solid cadmium is lacking. These solubilities are probably very small.

Cadmium has been recommended for use in aluminum solders, aluminum-base bearing alloys, and in free-cutting aluminum alloys.

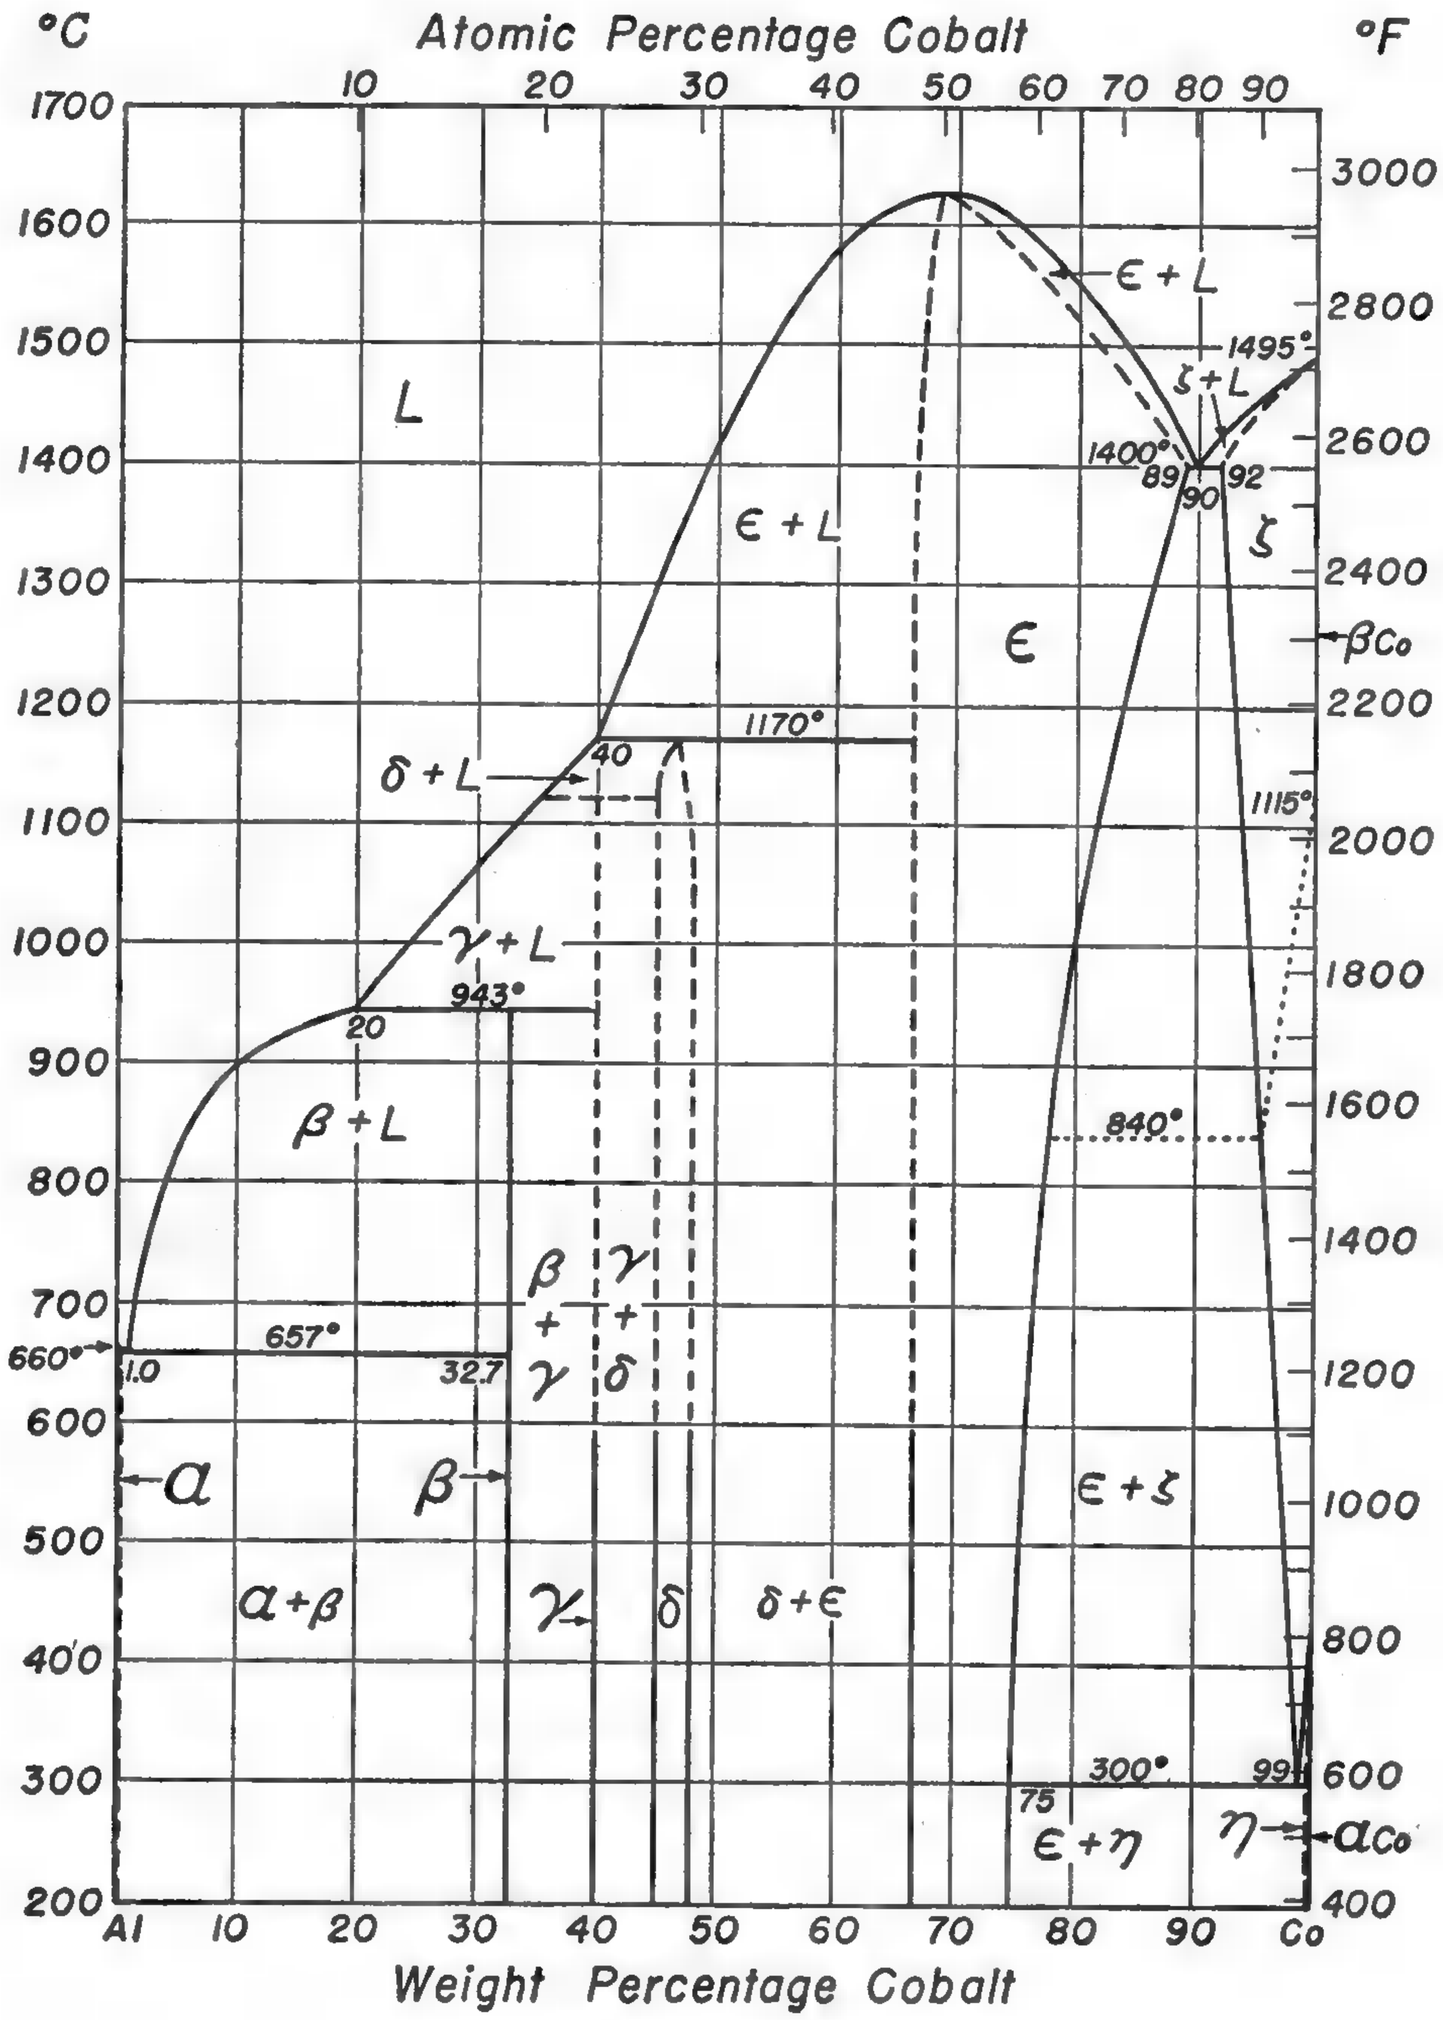
Al-Co Aluminum-Cobalt

By W. L. Fink* and L. A. Willey*



In addition to the four intermetallic phases shown in the diagram the presence of another in alloys containing from 42 to 44% Co has been reported.[2] This phase has not been isolated or definitely identified and cannot be reconciled with the present knowledge of the system above 600 C.

The solid solubility of cobalt in aluminum is less than 0.02% at the eutectic temperature (657 C).[1] The solubility of aluminum in the hexagonal form of cobalt is slight.[2] The solubility of aluminum in cubic cobalt is 7, 4, and 2% at 1300, 800 and 500 C, respectively.[3]

The ζ phase is hexagonal; ϵ is body-centered cubic with $a = 5.8565$ kX.[3]

Al-Cr Aluminum-Chromium

By W. L. Fink* and L. A. Willey*

Only the aluminum end of this diagram has been investigated sufficiently for complete and accurate reproduction. The β phase, existing in equilibrium with aluminum-rich solutions, has been found to correspond to the formula $CrAl_7$.[2] Some investigators[1,3] have found evidence that this phase forms by peritectic reaction between liquid and a solid phase of higher chromium content at a temperature between 710 and 800 C. The reaction was not observed in alloys containing up to 2% Cr.[3]

X-ray analysis[3] of aluminum-chromium alloys indicates the existence of at least nine different intermetallic phases in addition to the two terminal solid solutions. The maximum solid solubility of aluminum in chromium is given[3] as about 29% in the range 975 to 1350 C.

The solubility of chromium in solid aluminum is, as follows:[2,4]

Temperature, °C	630	580	530	480	400
Percentage Chromium	0.61	0.38	0.21	0.14	0.07

The β phase is orthorhombic with $a = 19.99$, $b = 34.51$, and $c = 12.47$ kX.[3]

A few commercial aluminum alloys contain small amounts of chromium (0.1 to 0.3%). In some alloys, the addition of chromium causes a decided improvement in resistance to corrosion. Substantial quantities of chromium, however, increase the liquidus temperature beyond commercial limits.

Al-Cu Aluminum-Copper

By W. L. Fink,* L. A. Willey* and C. S. Smith*

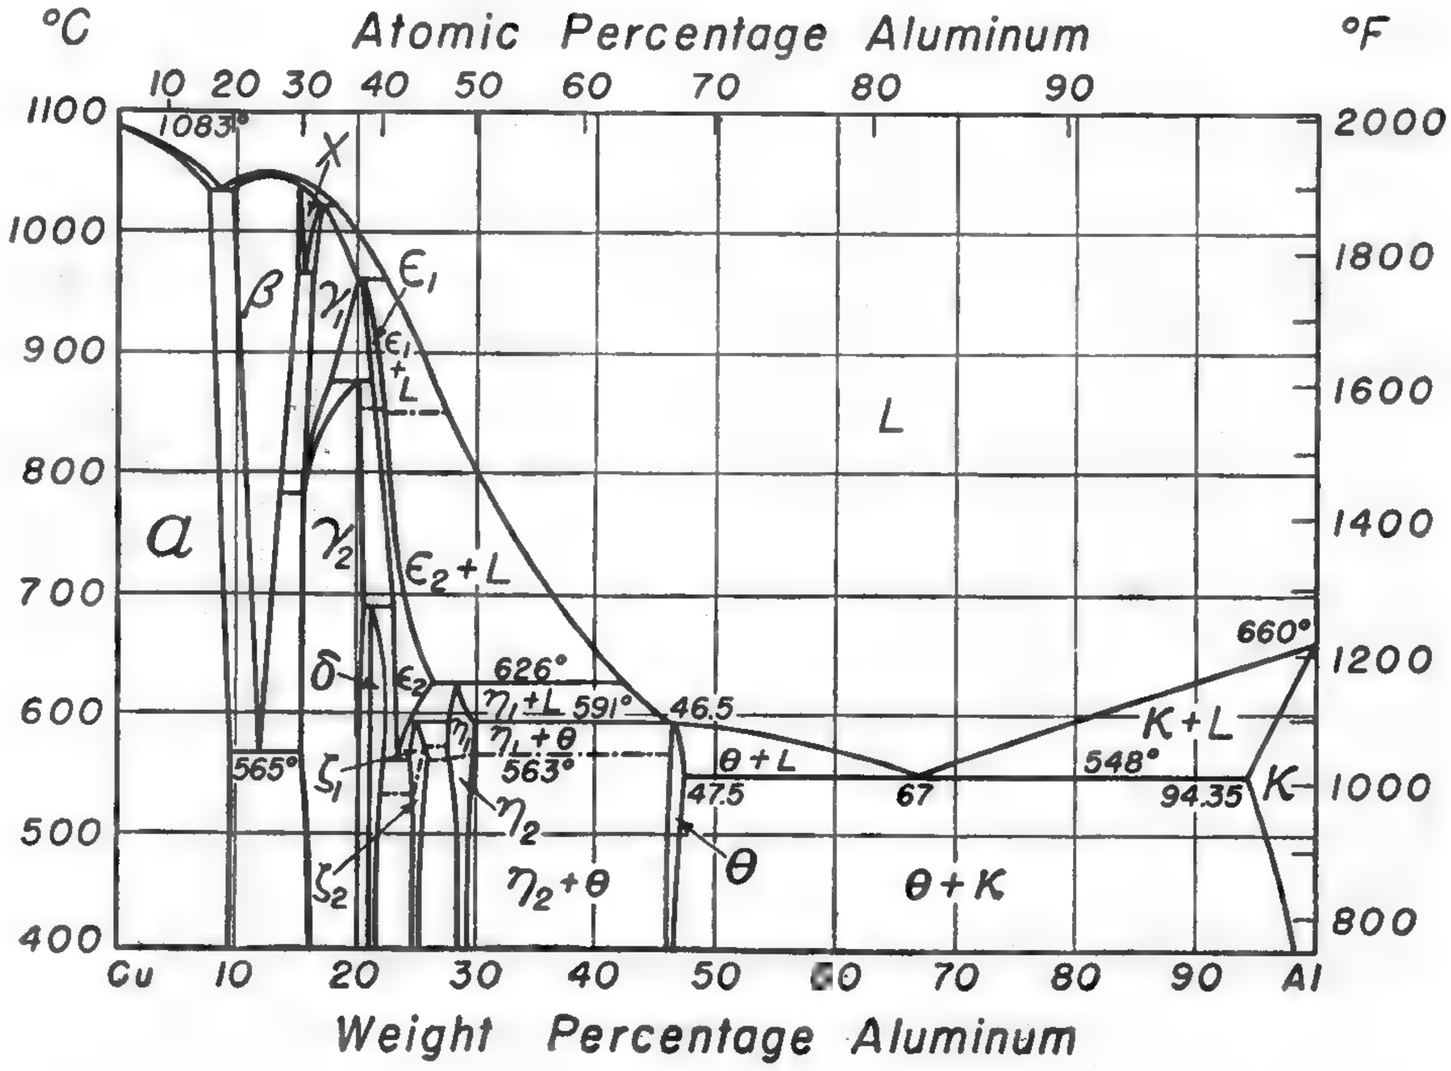
The diagram shown is similar to that proposed by Raynor.[1] The equilibrium relations in the range between 20 and 30% Al are complex and have not been firmly established.

During rapid cooling the β phase transforms to one of three metastable phases, each bearing some relation in structure to one of the stable phases. For a summary of these transitional structures, see the paper by Greninger,[2] and also the article "The Martensite Transformation", page 263 in this Handbook.

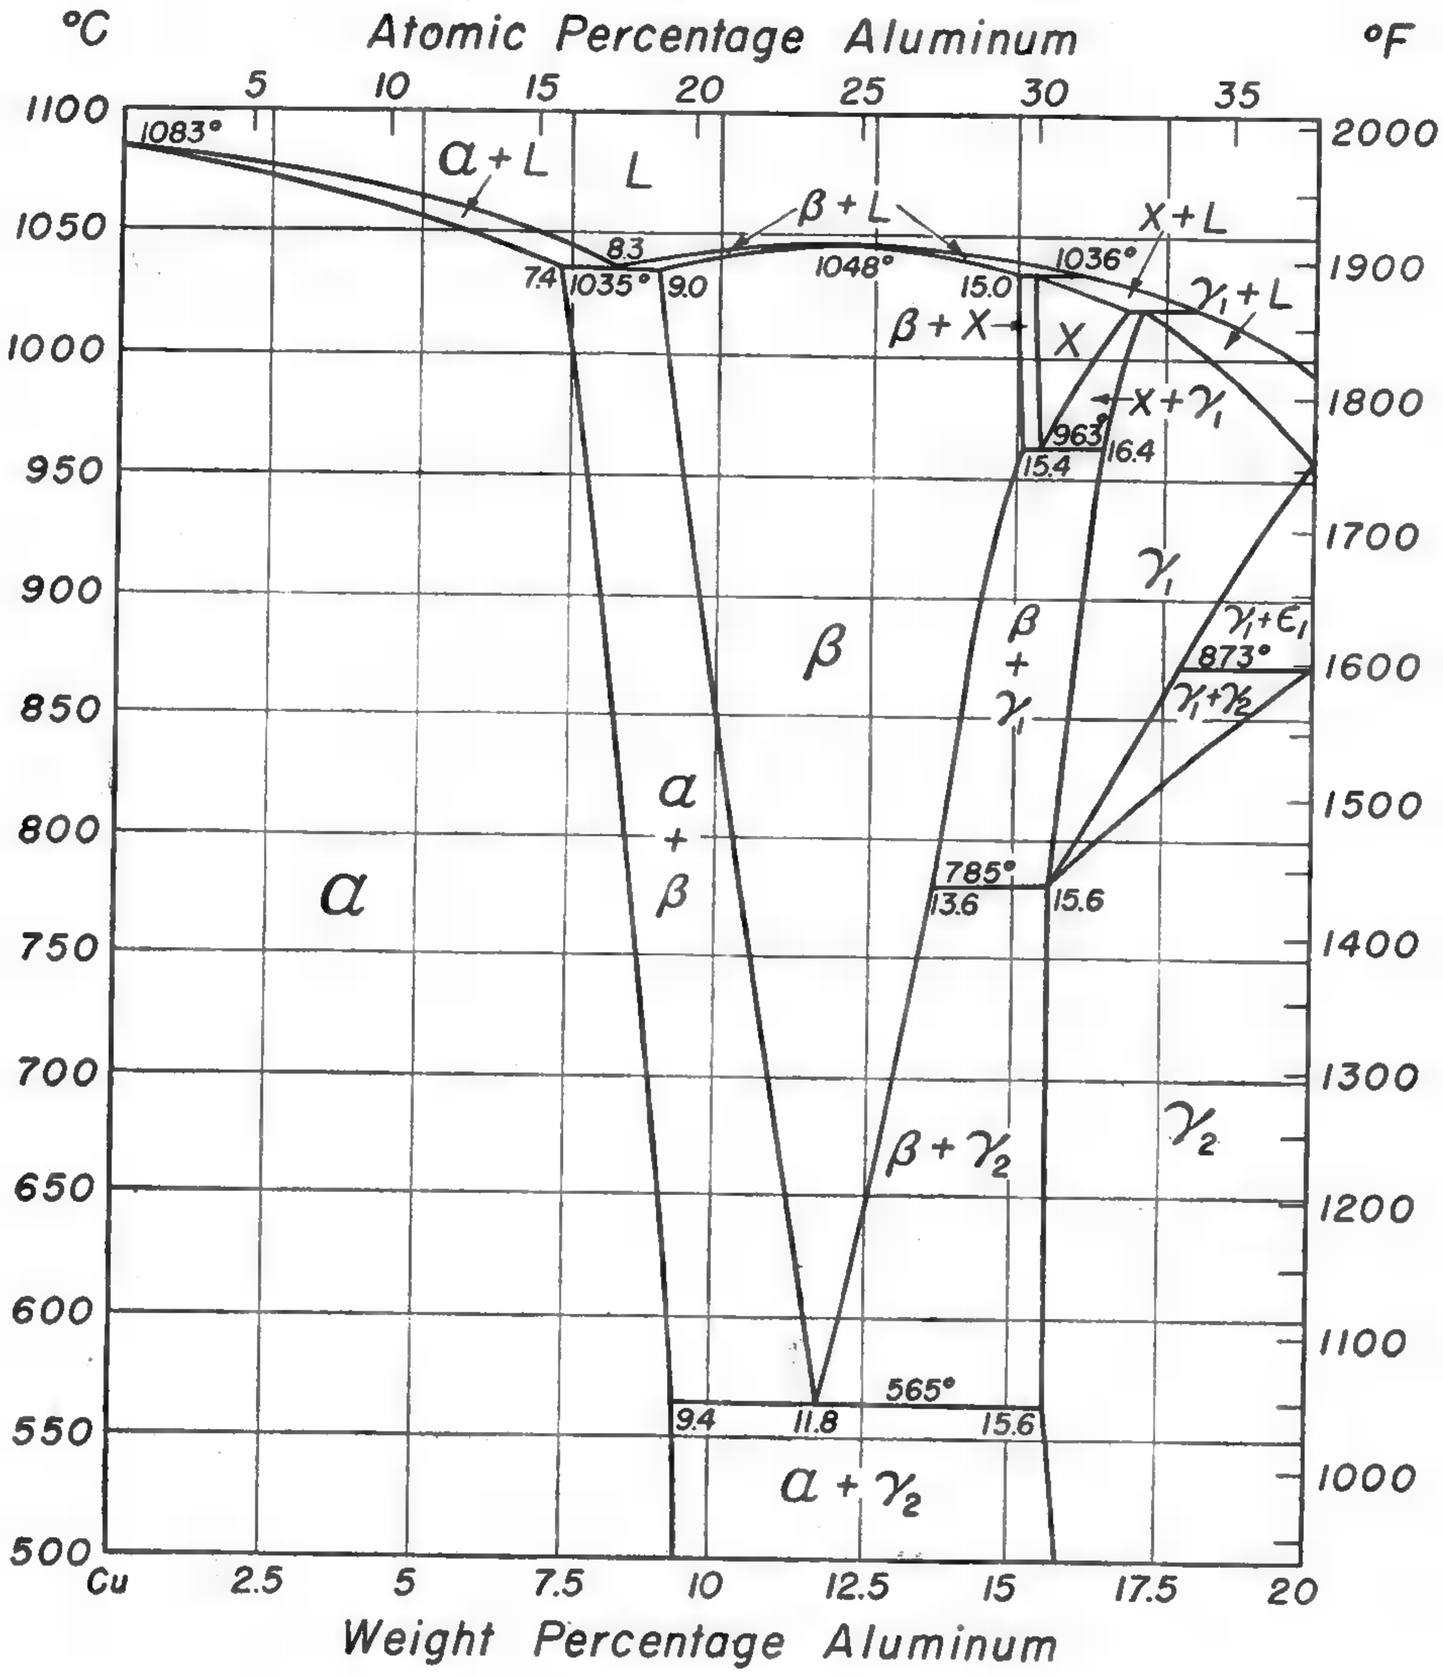
The solubility of copper in solid aluminum is, as follows: 4.10% at 500 C, 2.60 at 450, 1.50 at 400, 0.85 at 350, and 0.45 at 300.[3,4]

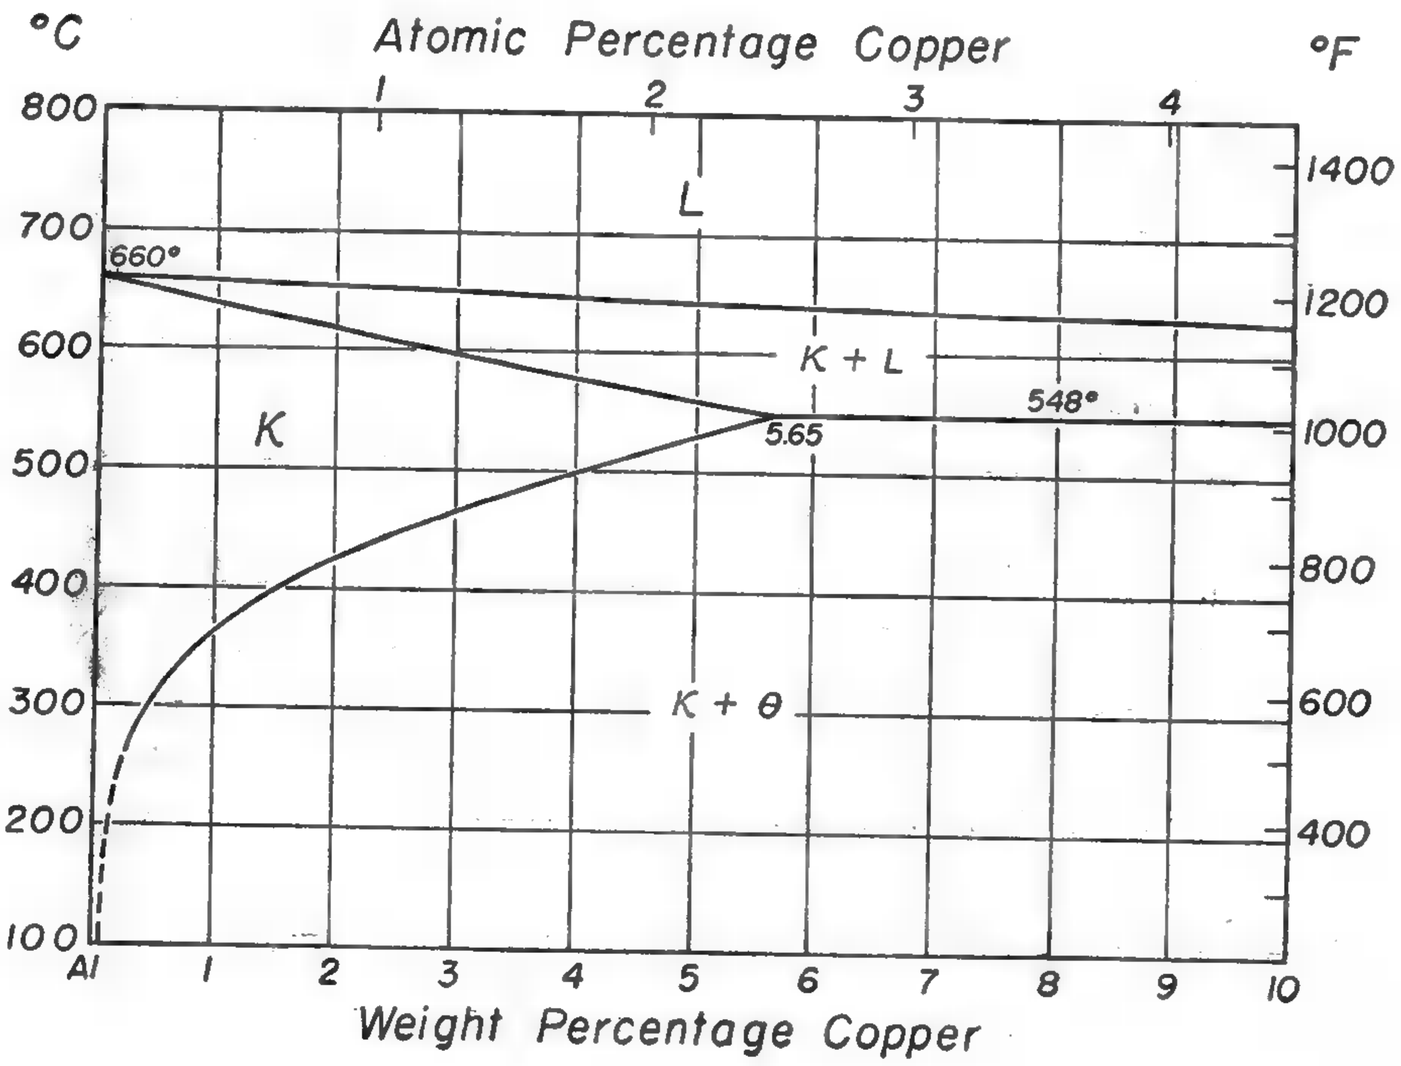
The solubility of aluminum in solid copper is, as follows: 8.0% at 890 C, 8.5 at 795, 9.0 at 690, and 9.4 at 565.[1,5,6,7]

(*continued on the next page*)



* Aluminum Research Laboratories, New Kensington, Pa.
* University of Chicago, Chicago





The structures of the intermediate phases are: β, body-centered cubic,[8] $a = 2.94$ kX; γ_2, cubic,[9,10] $a = 8.7$ kX; ϵ_1 cubic;[9] ζ_2, hexagonal;[10] η_2, orthorhombic;[10] θ, tetragonal,[5] $a = 6.04$ kX, $c = 4.86$ kX.

Highly important commercial alloys are found at both ends of the aluminum-copper system.

The copper-rich alloys are aluminum bronzes, containing from 4 to 11% Al with or without other alloying elements, principally iron or iron and nickel. For additional information concerning commercial aluminum bronzes, the reader may refer to pages 928 to 933 (wrought alloys) and 941, 942 (castings).

The aluminum-rich alloys of this system may contain as much as 12 to 15% Cu, although the wrought alloys generally do not contain more than 5% Cu. Both the wrought and the cast aluminum-rich alloys are subject to improvement in strength and hardness by heat treatment. (*See* "Properties of Aluminum-Copper Alloys", page 803.)

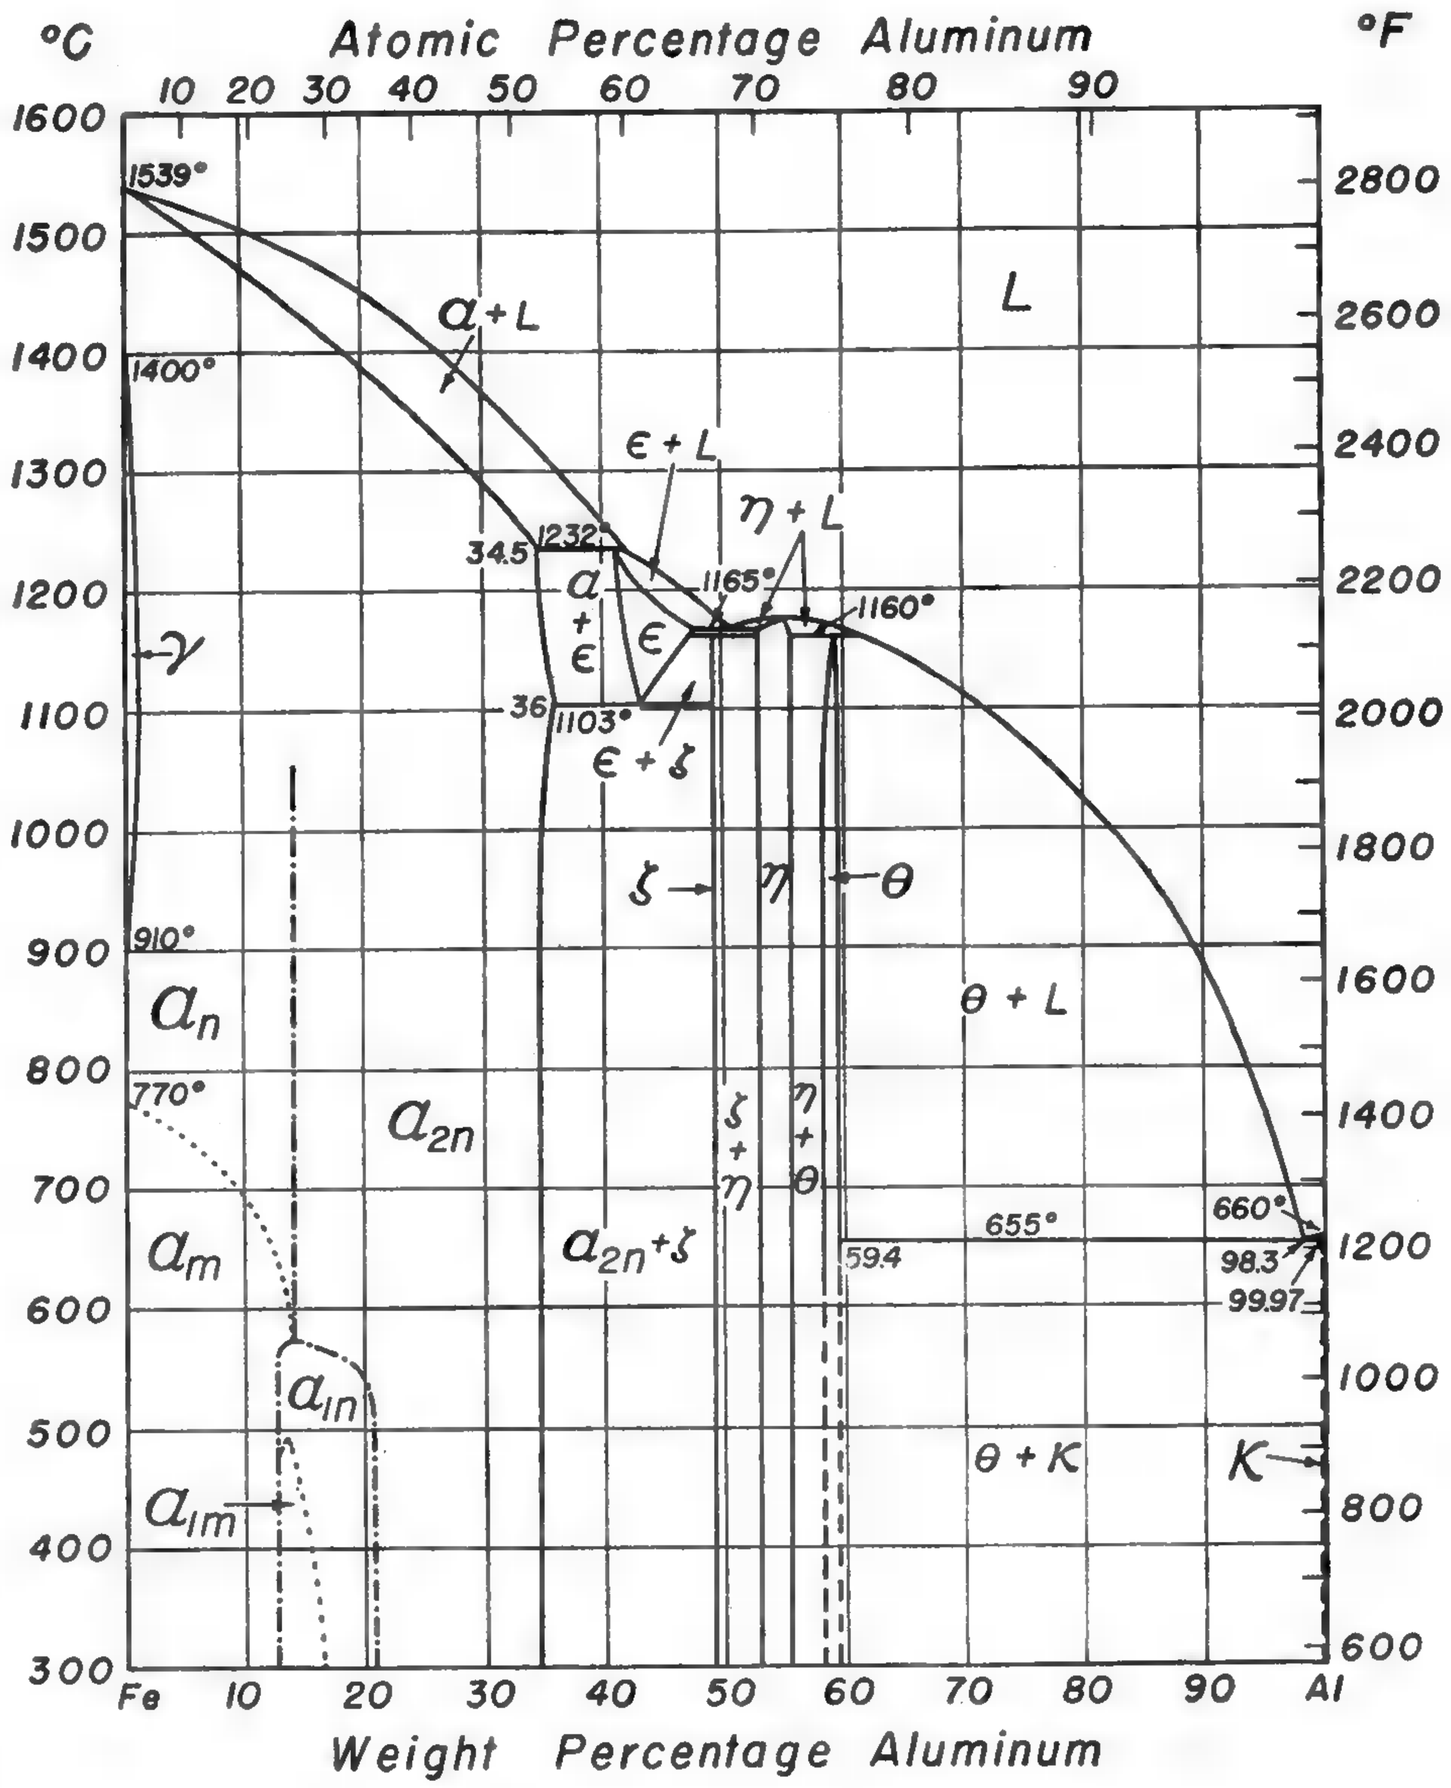
Al-Fe Aluminum-Iron

By W. L. Fink* and L. A. Willey*



Evidence has been presented [12] that the θ phase, which corresponds approximately to the formula $FeAl_3$, is converted to Fe_2Al_7 at a temperature somewhat below 600 C. The mechanism of this conversion has not been established.

The solubility limit of iron in high-purity aluminum has been found to be about 0.03% at the eutectic temperature (655 C).[13] It was also established that this limit decreased at lower temperatures.

In the solid solution field of aluminum in α iron, order-disorder as well as magnetic to nonmagnetic transformations have been shown to exist.[7, 8, 9, 11, 12] Since no phase changes are involved in these transformations, the boundaries have been shown in the diagram as dashed and dotted lines. After Bradley and Taylor,[12] the regions of the α phase field have been marked with subscripts: *m* and *n* indicating the magnetic and nonmagnetic phases respectively, and *1* and *2* indicating ordered structures of the type Fe_3Al and FeAl respectively.

* Aluminum Research Laboratories, New Kensington, Pa.

The θ phase is orthorhombic[10] with $a = 47.43$ kX, $b = 15.46$ kX and $c = 8.08$ kX.

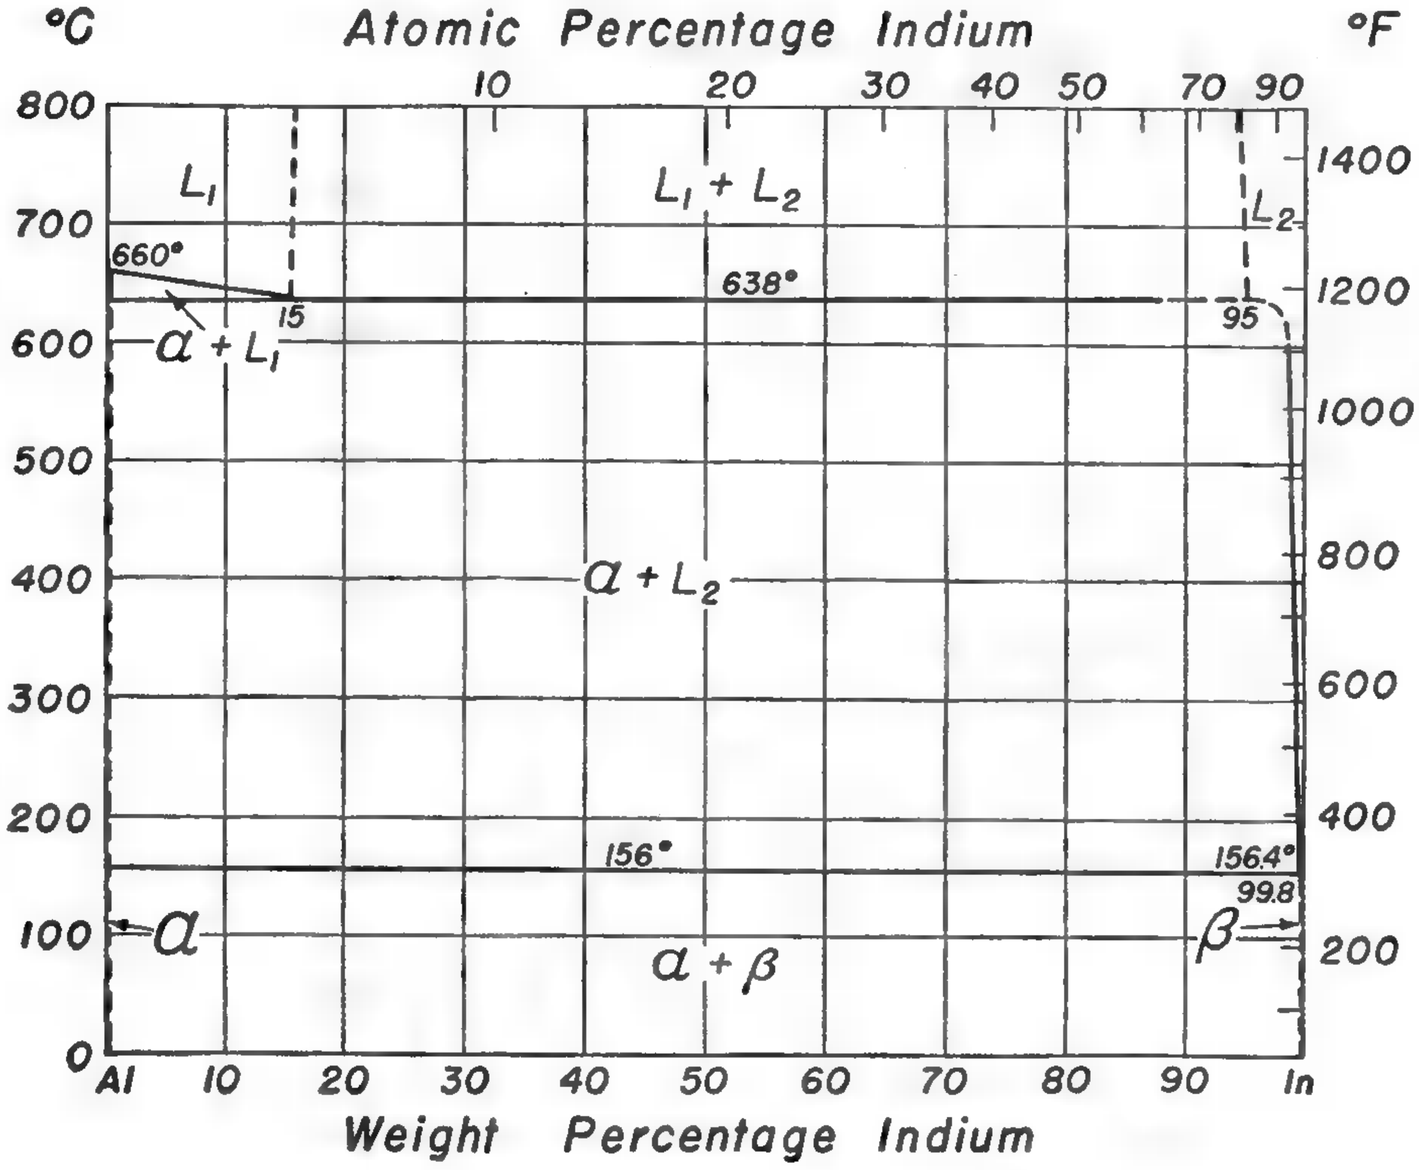
Al-In Aluminum-Indium

By H. M. Davis*



The diagram for the aluminum-indium system has been constructed entirely from unpublished work by H. M. Davis and G. H. Rowe.*

Indium apparently has a slight solubility in aluminum. The α phase at 250 C contains enough indium to produce a barely discernible shift in the X-ray diffraction pattern from that of high-purity aluminum.

Note Added in Proof. A report[1] published after the construction of this diagram, generally confirms it. The eutectic temperature and the monotectic temperature are reported as 156 C and 634 C, respectively. The miscibility gap is reported to extend from 13 to 98% In at 634 C.

Reference

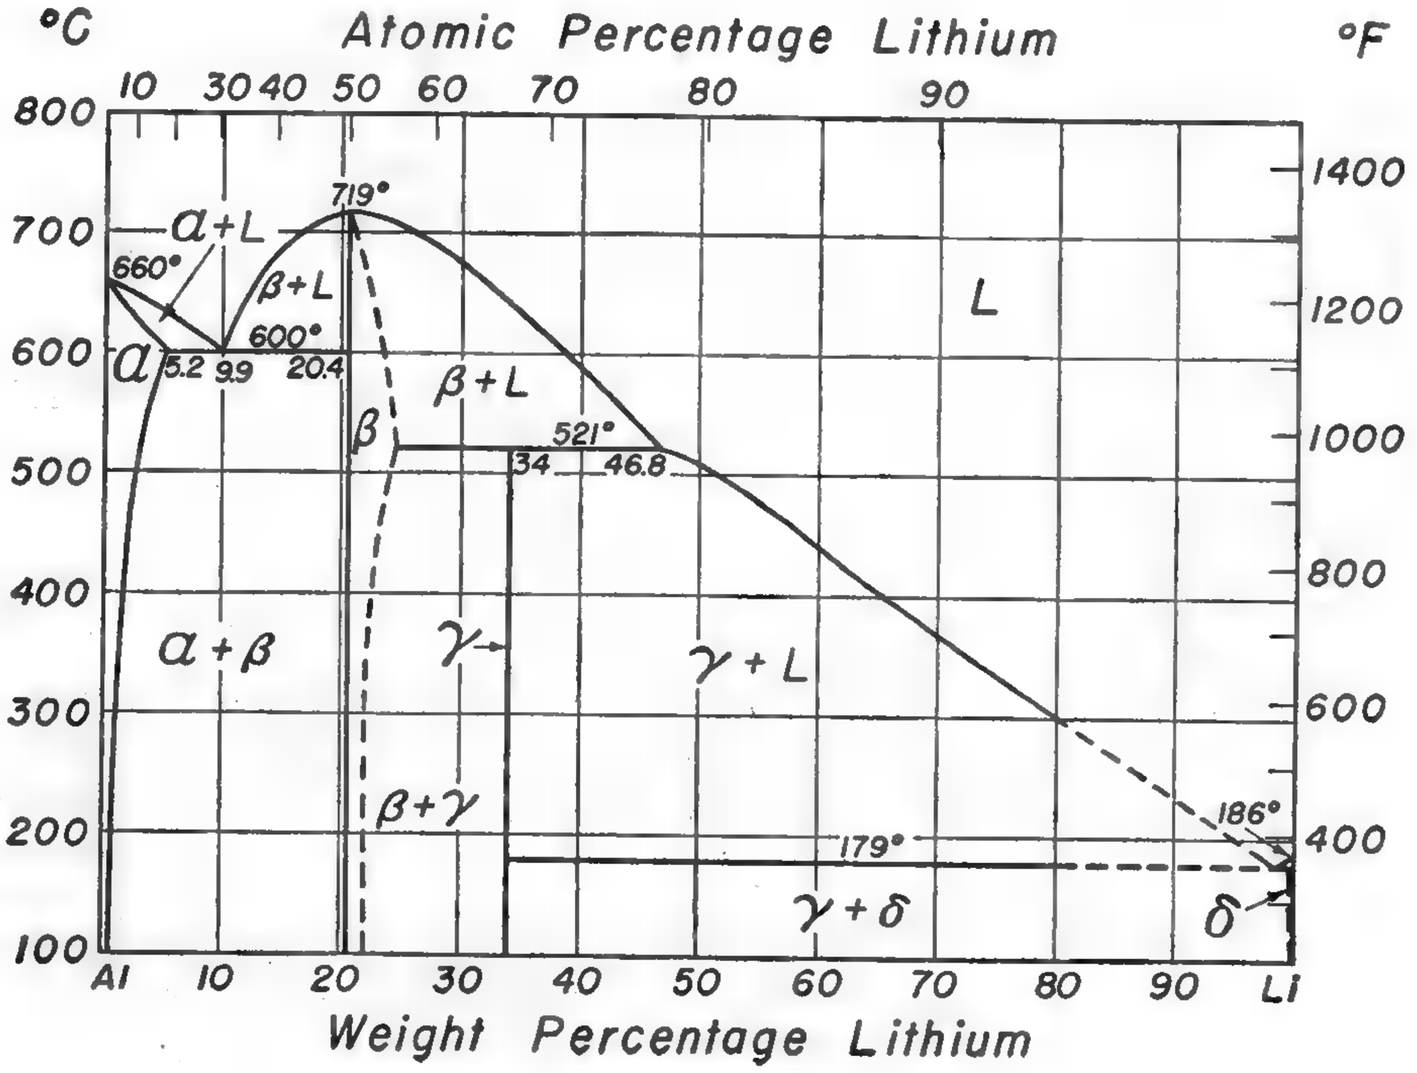
1 S. Valentiner and I. Pazicha, Metallforschung, 2, 127 (1947)

* Associate Professor of Metallurgy, The Pennsylvania State College, State College, Pa.

* Editor's Note. In the original work, the melting point of indium was determined as 157.3 C, and the eutectic temperature as 156.9 C. On the diagram shown here, these temperatures have been changed to be consistent with the melting point of indium as employed elsewhere in this Handbook, 156.4 C.

Al-Li Aluminum-Lithium

By W. L. Fink† and L. A. Willey†



The β phase, which has a composition corresponding to the formula LiAl, appears to form a rather extensive solid solution with lithium.[2,3] It has also been reported[4] to dissolve appreciable aluminum but this has not been confirmed.

A lack of agreement exists in regard to the location of the eutectic between the γ phase and the lithium-rich solid solution. The solubility of aluminum in solid lithium has not been determined.

The solubility of lithium in solid aluminum is, as follows:[1] 5.2% at 600 C, 3.6 at 550, 2.5 at 500, 1.7 at 400, 0.9 at 220. The β phase is body-centered cubic[4,5] with $a = 6.36$ kX.

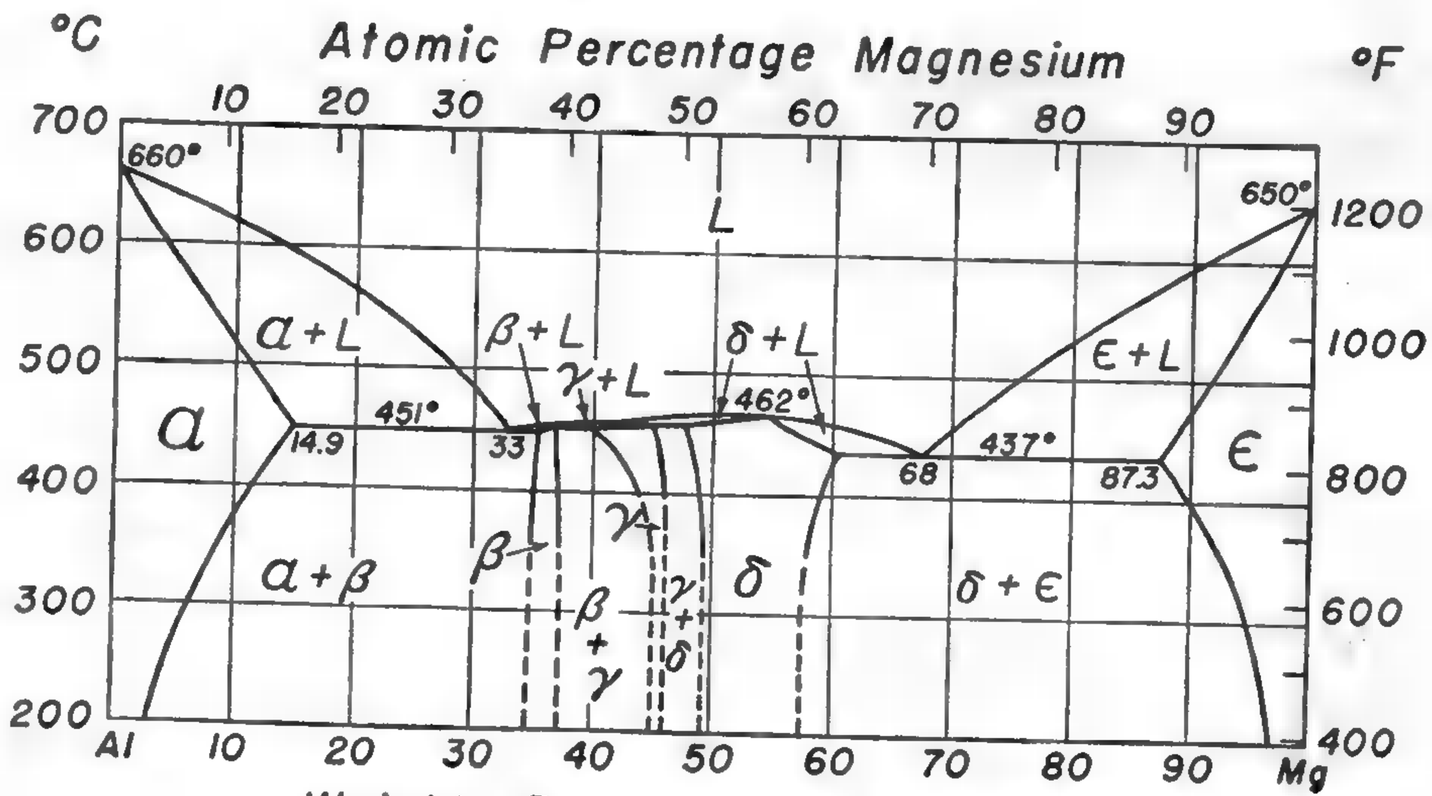
Al-Mg Aluminum-Magnesium

By W. L. Fink* and L. A. Willey*



The diagram from 38 to 49% Mg has not been well established. γ may be unstable below 300 C; it has been reported to decompose into β and a fourth intermetallic phase containing approximately 40% Mg.[5] The latter phase apparently decomposes into β and γ at 390 C.

The solubility of magnesium in solid aluminum is, as follows:[2] 11.5% at 400 C, 8.7 at 350, 6.4 at 300, 4.3 at 250, 2.9 at 200.

The solubility of aluminum in magnesium is, as follows:[3,6] 10.6% at 400 C, 7.3 at 350, 5.3 at 300, 4.1 at 250, 3.2 at 200.

The β phase is hexagonal with $a = 11.38$ kX, $c = 17.87$ kX;[8] δ is body-centered cubic with $a = 10.52$ kX.[8]

The aluminum-rich alloys are discussed in the article on page 807.

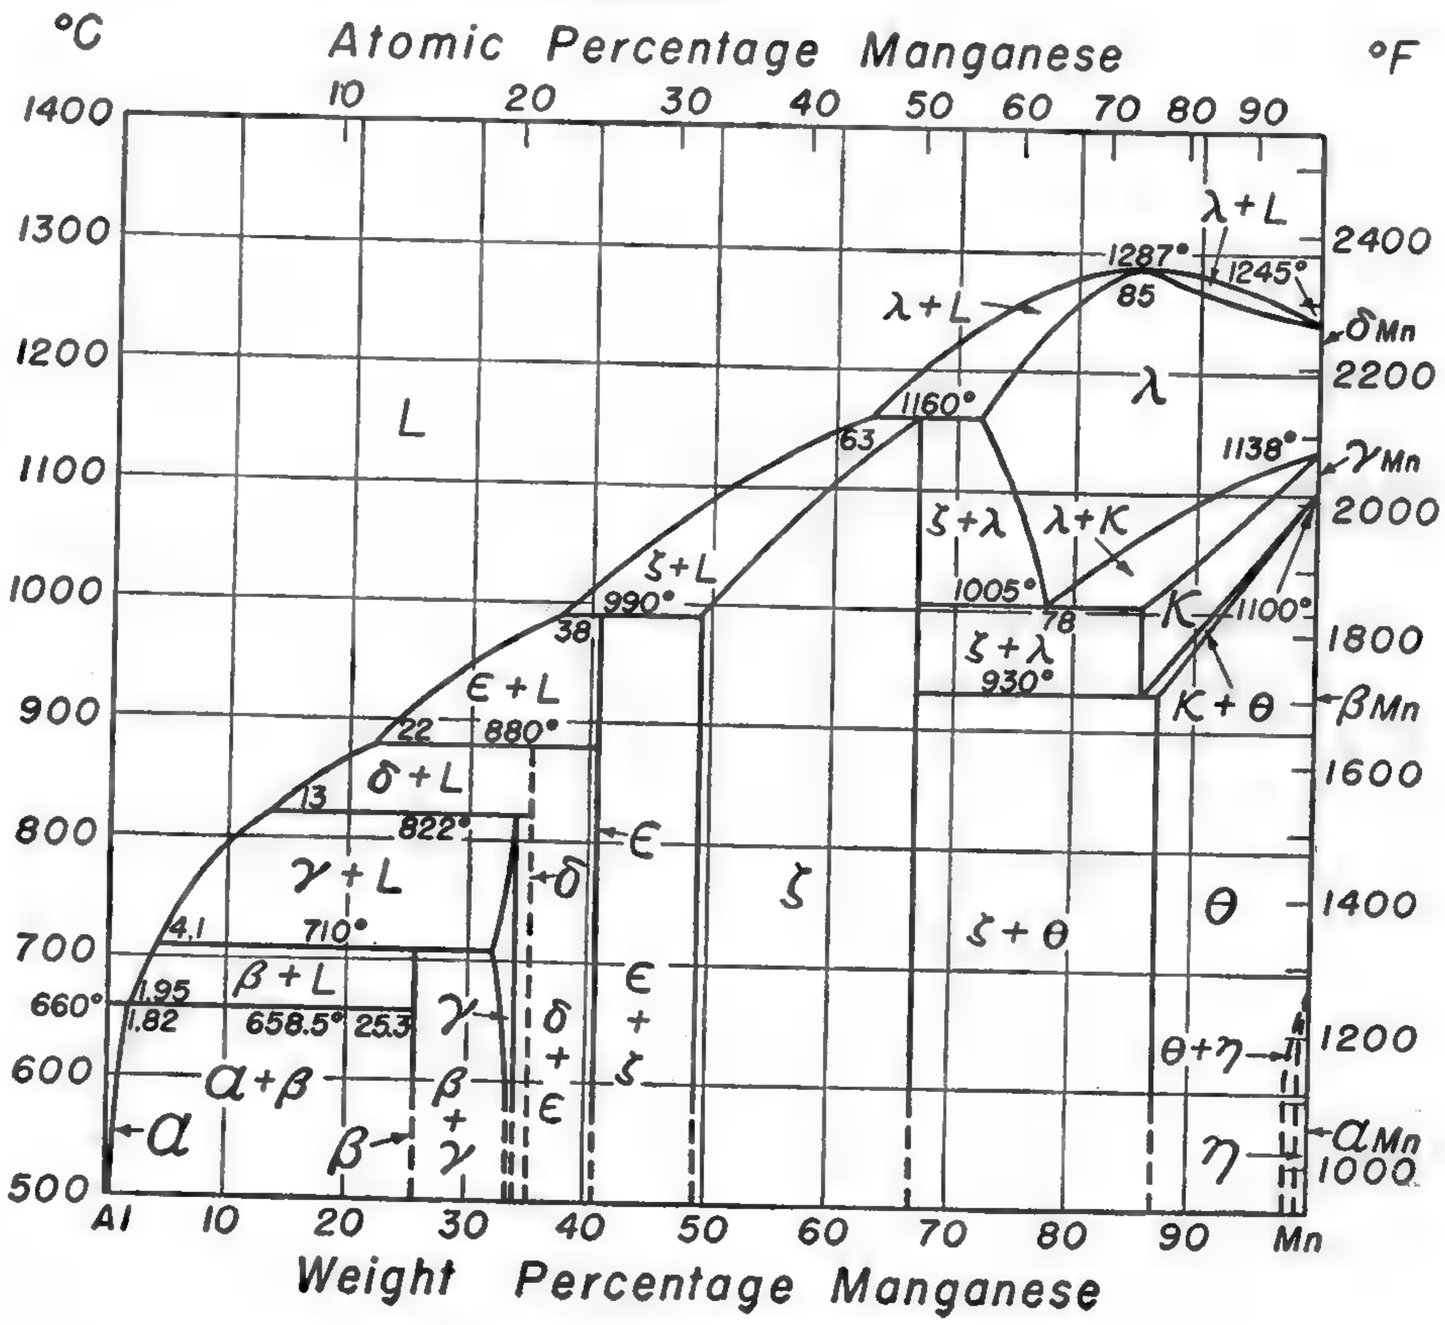
Al-Mn Aluminum-Manganese

By W. L. Fink* and L. A. Willey*



The composition of δ is not known; this phase has been observed only in specimens containing either γ or ϵ.

The solubility of aluminum in alpha manganese is reported to be low;[1] the actual boundaries of the $\theta + \eta$ field have not been determined. The solubility of manganese in aluminum is, as follows:[2] 1.35% at 626 C, 0.78 at 570, 0.36 at 500.

The β phase ($MnAl_6$) is orthorhombic with $a = 6.51$ kX, $b = 7.57$ kX, $c = 8.87$ kX;[3] γ ($MnAl_4$) is hexagonal with $a = 28.35$ kX, $c = 12.36$ kX;[3] ϵ ($MnAl_3$) is orthorhombic with $a = 14.79$ kX, $b = 12.6$ kX, $c = 12.43$ kX;[3] ζ is body-centered cubic.[7]

Al-Na Aluminum-Sodium

By W. L. Fink* and L. A. Willey*

Aluminum and sodium are practically immiscible in each other in both the liquid and solid states.[1] No binary intermetallic phases are formed between these two elements. The eutectic apparently lies very near 100% Na and at a temperature close to its melting point. The monotectic occurs at less than 0.1% Na and near the melting point of aluminum. The solubility of sodium in liquid aluminum has been found to decrease from about 0.13% at 800 C, to about 0.1% at 700 C.[2]

* Aluminum Research Laboratories, New Kensington, Pa.

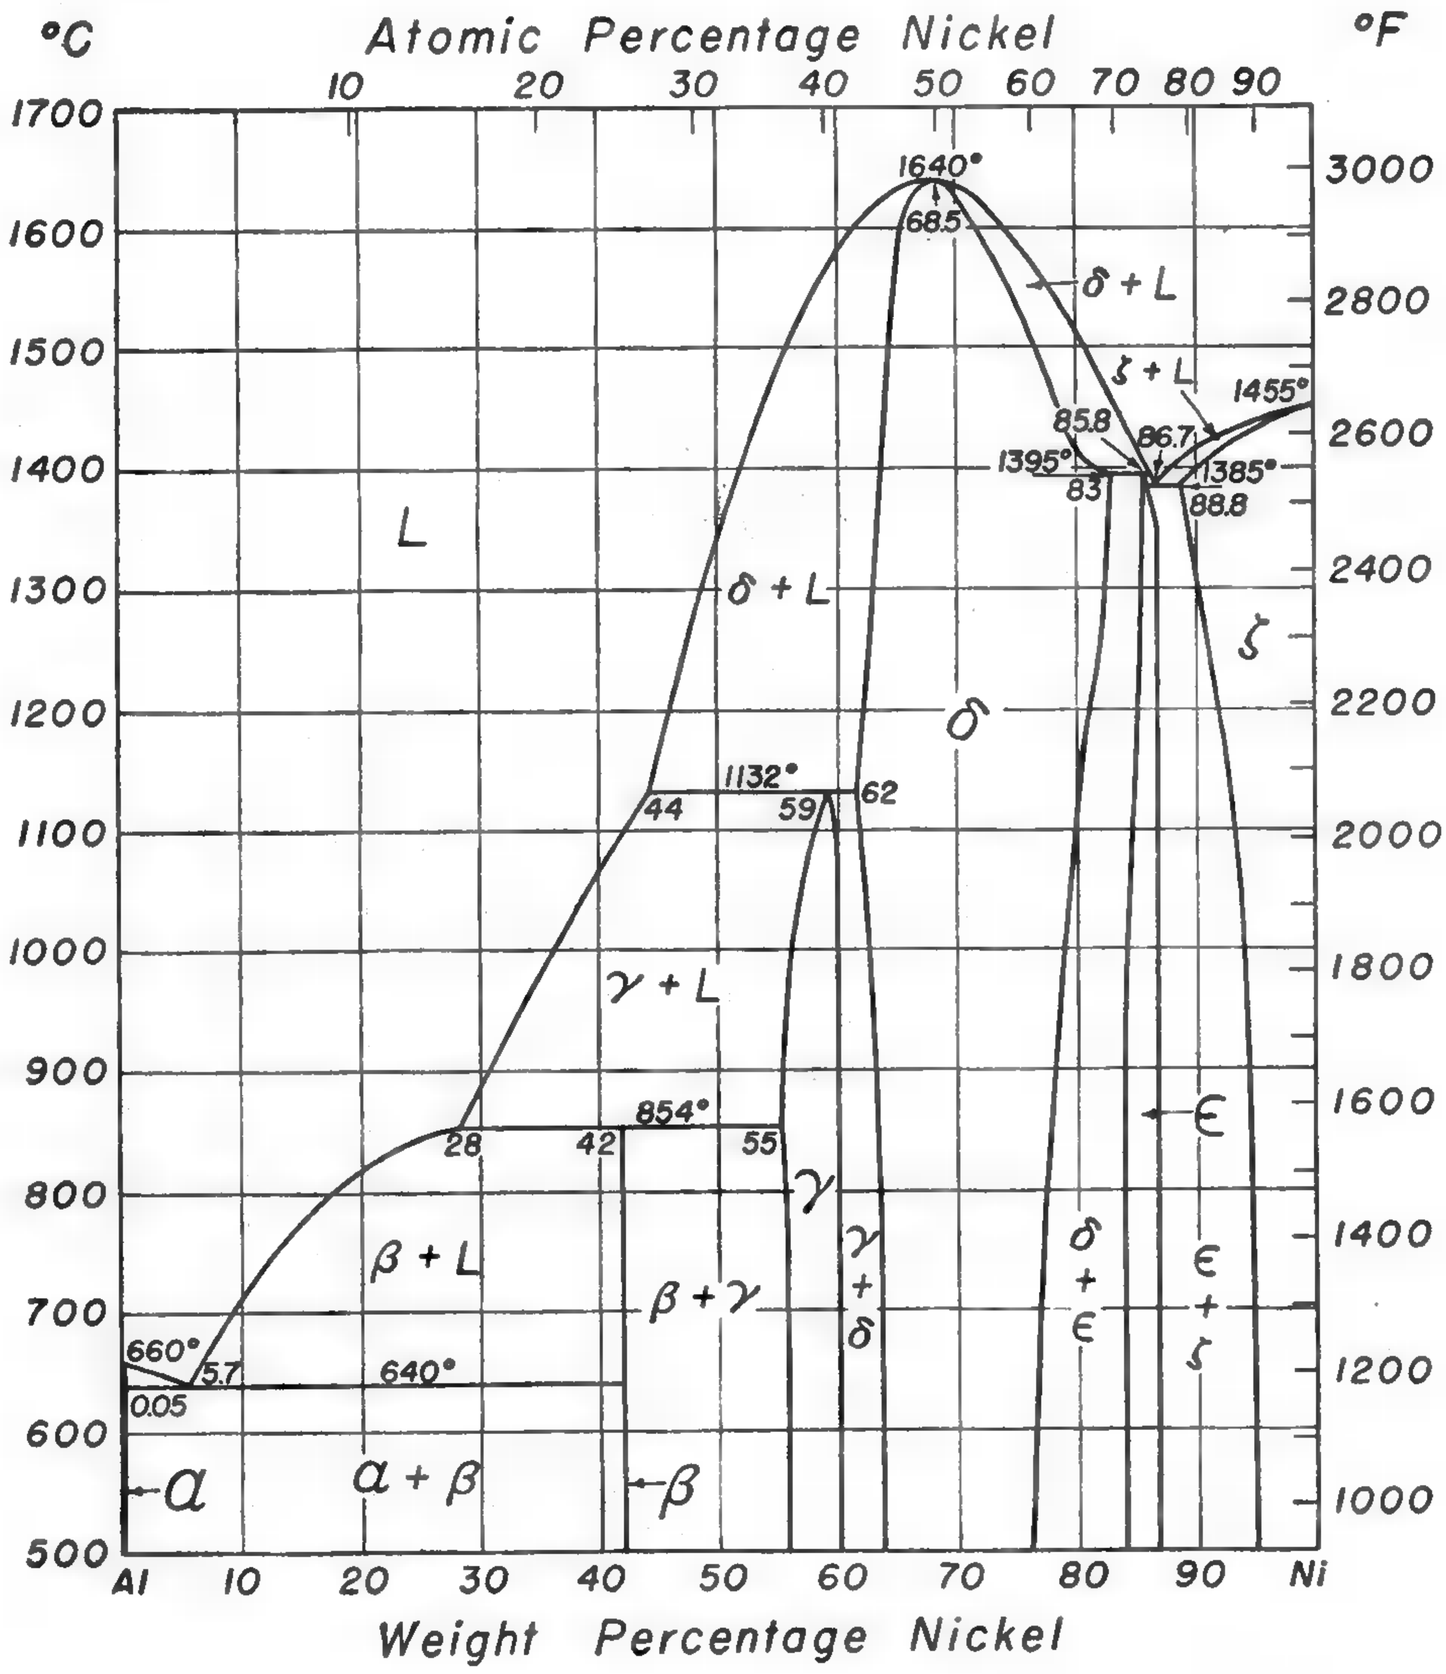
Al-Ni Aluminum-Nickel

By W. L. Fink* and L. A. Willey*



The diagram shown is from investigations by Alexander and Vaughan,[2] Schramm,[3] and Fink and Willey.[1]

The Curie temperature of nickel is decreased linearly from 360 to 70 C by the addition of 4.6% Al in solid solution.[3]

The solubility of nickel in solid aluminum is, as follows:[1] 0.040% at 625 C, 0.018 at 570, 0.006 at 505. The solubility of aluminum in solid nickel is:[3] 9.7% at 1300 C, 8.0 at 1200, 6.5 at 1080, 6.0 at 980, 5.0 at 700.

Nickel is used as an alloying element in a few commercial aluminum-base alloys, principally in aluminum-copper-magnesium alloys and aluminum-silicon-magnesium alloys. Nickel increases the strength of these alloys at elevated temperature and decreases the coefficient of thermal expansion, but usually decreases the resistance to corrosion.

At the other end of the system there are a few commercial alloys that are used principally for thermocouple wires.

β	Orthorhombic	6.598	7.352	4.802
γ	Trigonal	4.028	4.891	....
δ	Body-centered cubic	2.881	....	....
ε	Face-centered cubic	3.58	....	....

Al-Pb Aluminum-Lead

By W. L. Fink* and L. A. Willey*

The diagram shown is from investigations by Van Horn,[1] Campbell and Ashley,[2] and Dardel.[4] The system is of the monotectic type. The miscibility gap extends from 1.52% to greater than 99% Pb at the monotectic temperature (658.5 C).

The eutectic of this system has been reported at 99.98% Pb.[3, 4] The solubility of lead in solid aluminum does not exceed 0.2% at the monotectic temperature (658.5 C).[1] The solubility of lead in liquid aluminum is decreased slightly by the presence of about 5% Cu.[1]

Lead is used along with bismuth as a minor alloying element in a few commercial aluminum alloys to improve the machinability. The amounts added do not exceed about 0.5%. There are no other commercial applications of aluminum-lead alloys.

Al-Sb Aluminum-Antimony

By W. L. Fink* and L. A. Willey*

Aluminum and antimony form an intermetallic phase, β, at 50 atomic per cent. The melting point of β has not been definitely established but it is approximately 1050 C.

The solubility of antimony in solid aluminum has been found to be less than 0.1% at 645 C.[2] A determination of the solubility of aluminum in solid antimony has not been made; however, this solubility is probably less than 0.1% at the eutectic temperature.

The crystal structure of the β phase has been reported to be face-centered cubic.[1]

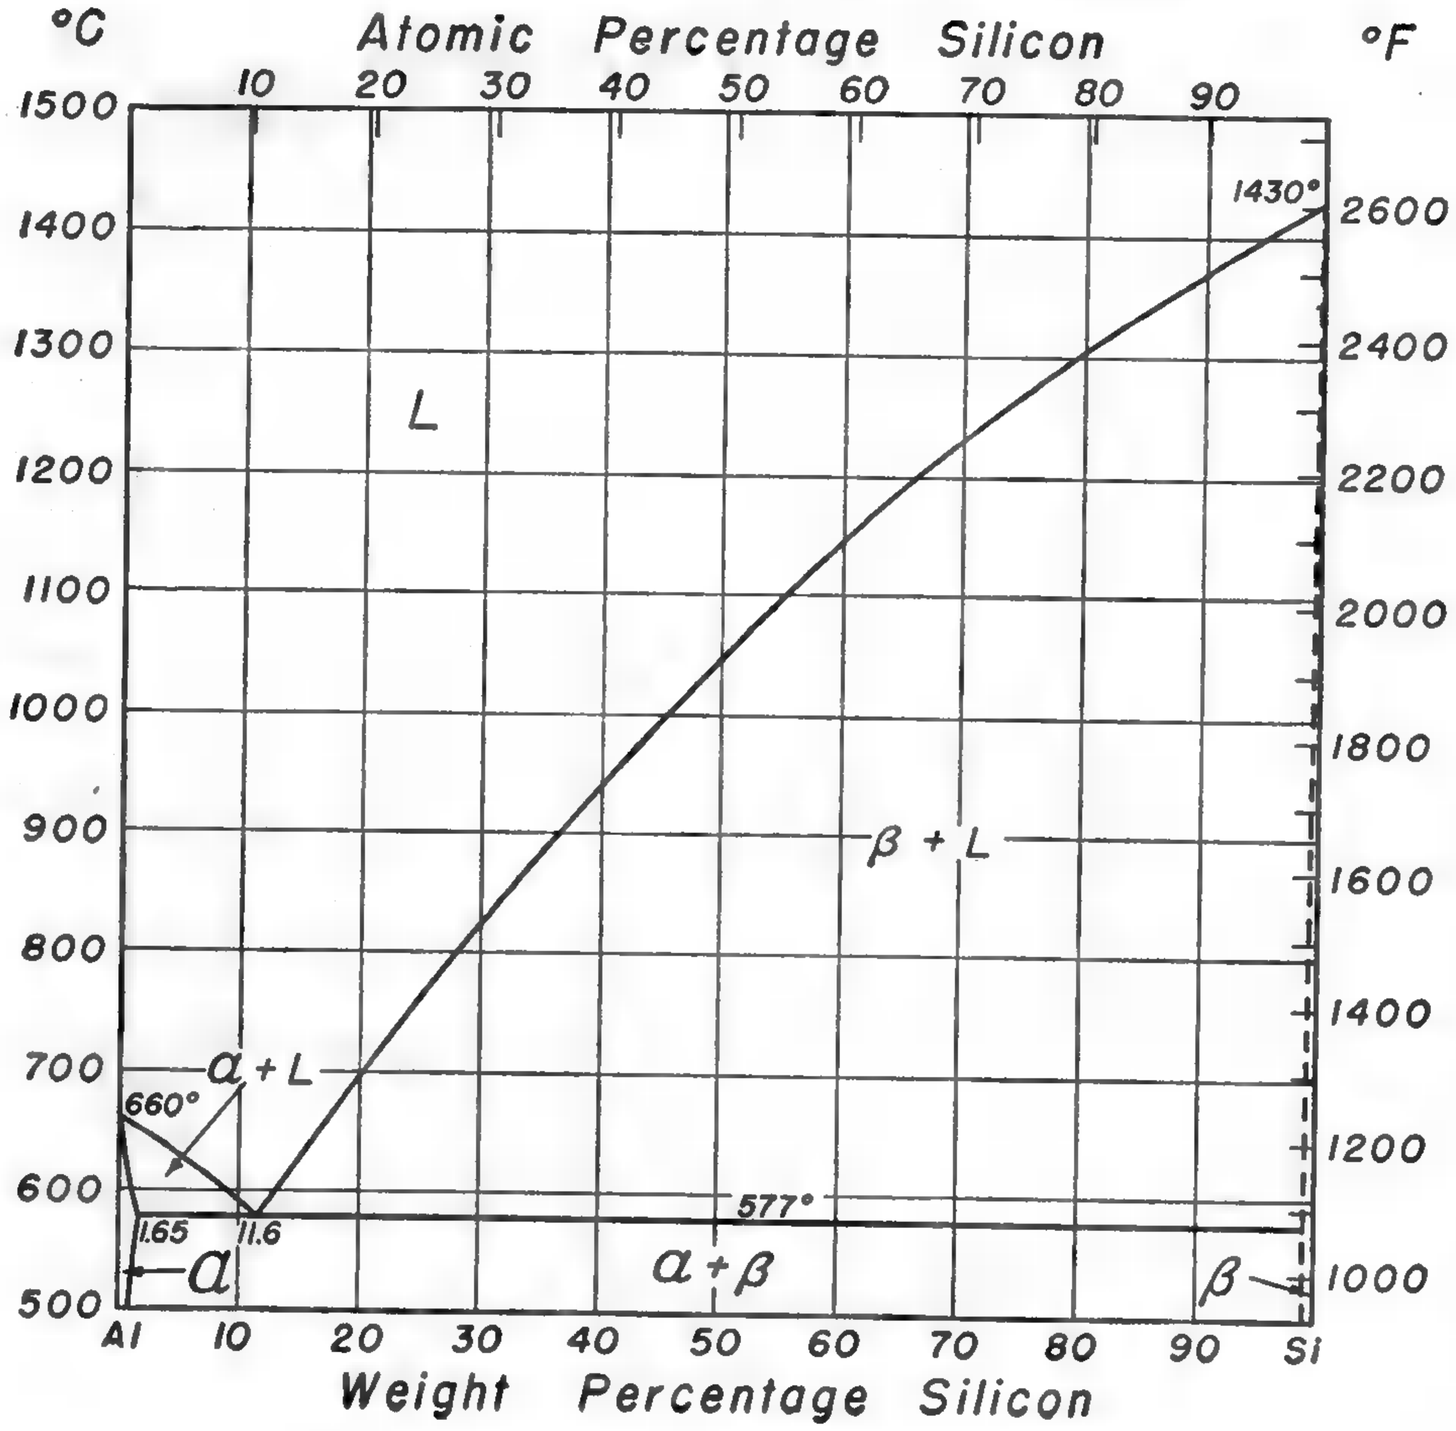
Al-Si Aluminum-Silicon

By W. L. Fink* and L. A. Willey*



The solubility of aluminum in solid silicon has never been thoroughly investigated; however it has been reported that silicon dissolves about 4% Al at the eutectic temperature.[4] From other evidence this value would appear to be excessive.[7]

The solubility of silicon in solid aluminum is, as follows:[8] 1.30% at 550 C, 0.80 at 500, 0.48 at 450, 0.29 at 400, 0.17 at 350, 0.10 at 300, 0.05 at 200.

Silicon inevitably occurs as an impurity in all commercial aluminum alloys and is used as an alloying element in many of the commercial casting alloys. Silicon is also used as an alloying element in wrought alloys that depend on magnesium silicide as the hardening agent. (*See* page 805.)

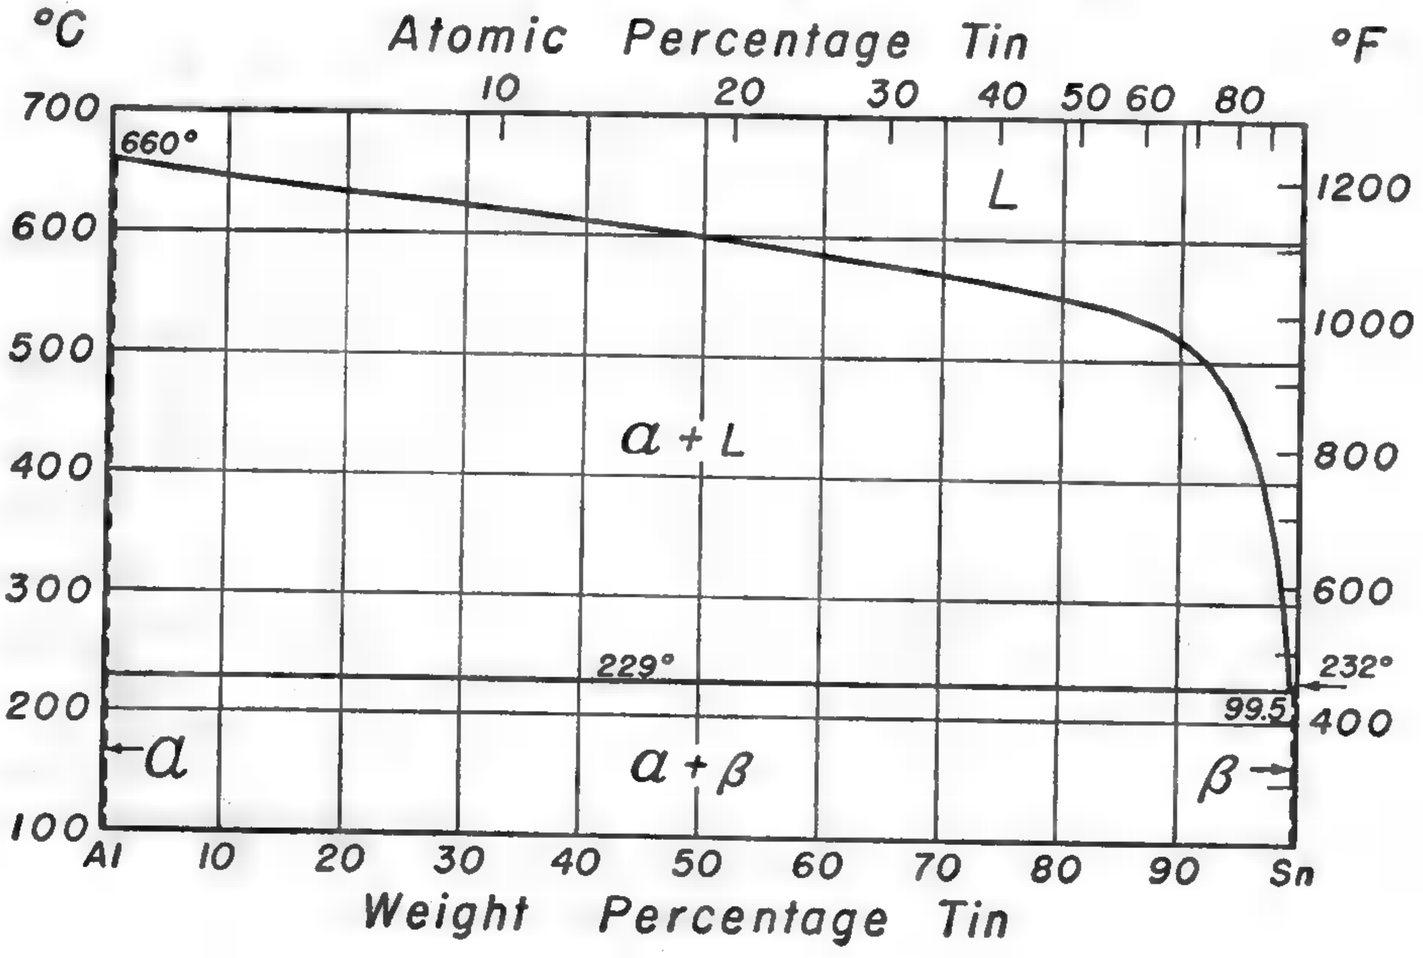
Al-Sn Aluminum-Tin

By H. P. Nielsen* and R. J. Nekervist†



Reported values for the solubility of tin in solid aluminum vary considerably.[1,3,5,10] Unpublished results by Wm. L. Fink indicate that the solubility is approximately 0.05% Sn at 500 C, and not more than a few thousandths per cent at the eutectic temperature (229 C). At still lower temperatures the solubility is nil.

Al-Ti Aluminum-Titanium

By W. L. Fink* and L. A. Willey*

Attempts to determine accurately the solid solubility of titanium in aluminum have not been successful, apparently because of the extremely slow rate of diffusion. A determination, however, has indicated a solubility of 0.24% Ti at 510 C. Calculations indicate a solid solubility at the peritectic temperature of between 1 and 1.5% Ti.

The β phase contains 37.2% Ti and therefore may be represented by the formula $TiAl_3$.[1] Nothing is known of the diagram beyond approximately 40% Ti.

The β phase is tetragonal with $a = 5.424$ kX and $c = 8.574$ kX.[1]

Al-Zn Aluminum-Zinc

By E. A. Anderson*

The diagram is that selected by Raynor.[1] Efforts to detect an alleged peritectic at 443 C previously reported[4] have been unsuccessful.[5] Heat effects at 443 C have not been explained convincingly. The existence of a two-phase region between 31.6 and 78% Zn above 275 C seems well established.[2,3] The two phases are face-centered cubic and have nearly the same lattice parameter.

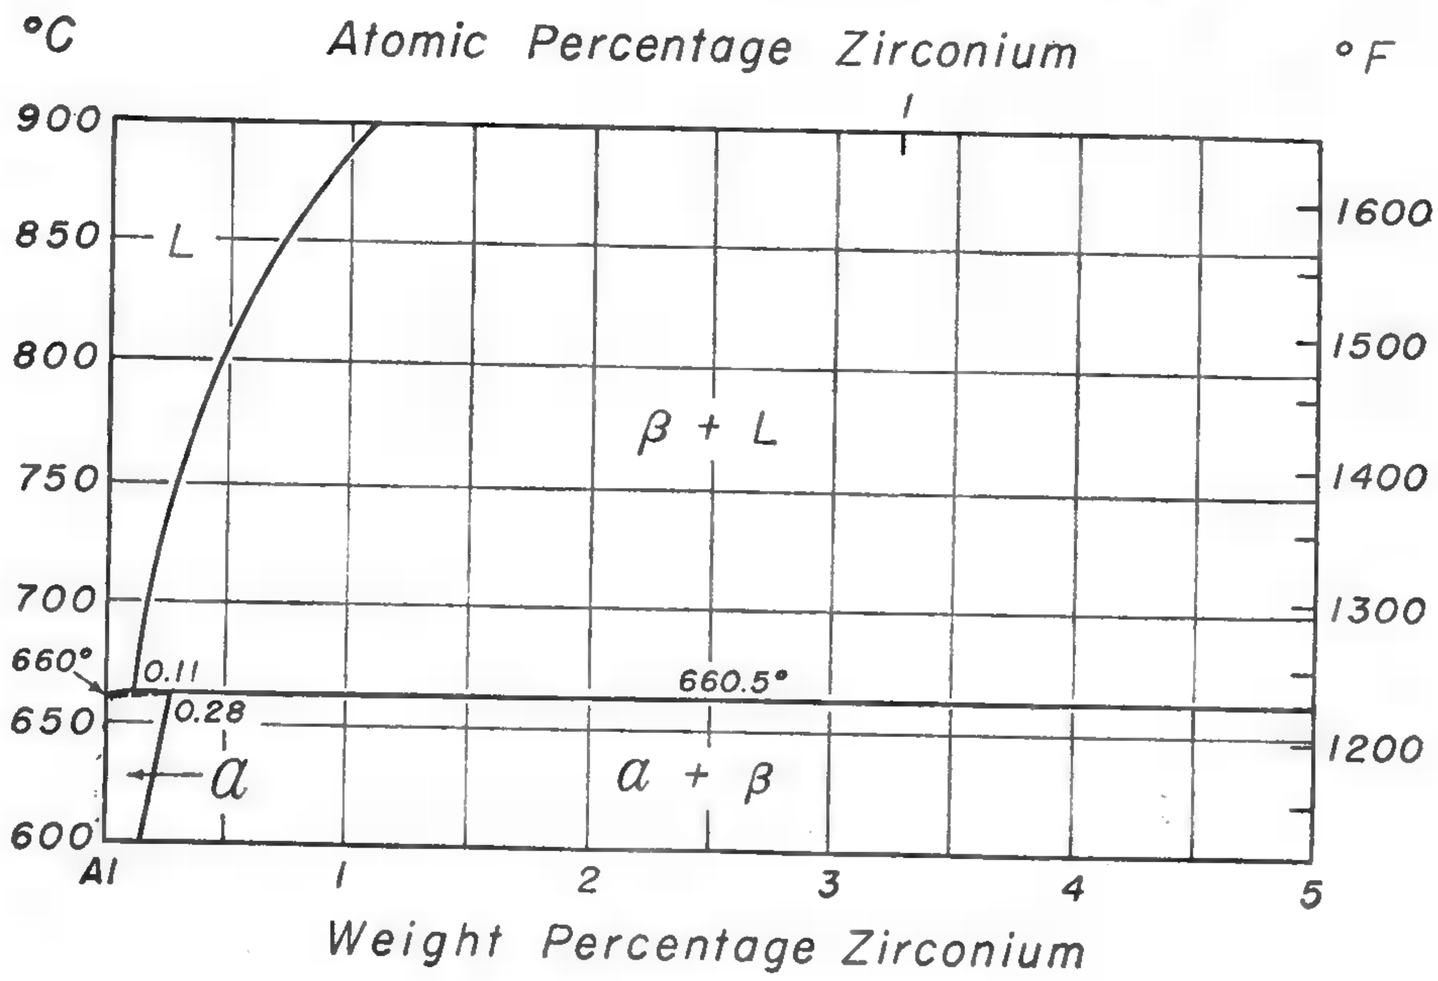
Al-Zr Aluminum-Zirconium

By W. L. Fink* and L. A. Willey*



The β phase (tetragonal) contains 53% Zr and therefore corresponds to the formula $ZrAl_3$. This constituent is not discolored or attacked by ordinary etching reagents. No investigations of the system at temperatures above 1000 C or beyond 53% Zr have been made. The solubility of zirconium in solid aluminum is as follows:

Temperature, deg Cent	Percentage Zirconium
660.5	0.28
640	0.23
600	0.15
550	0.084
500	0.050

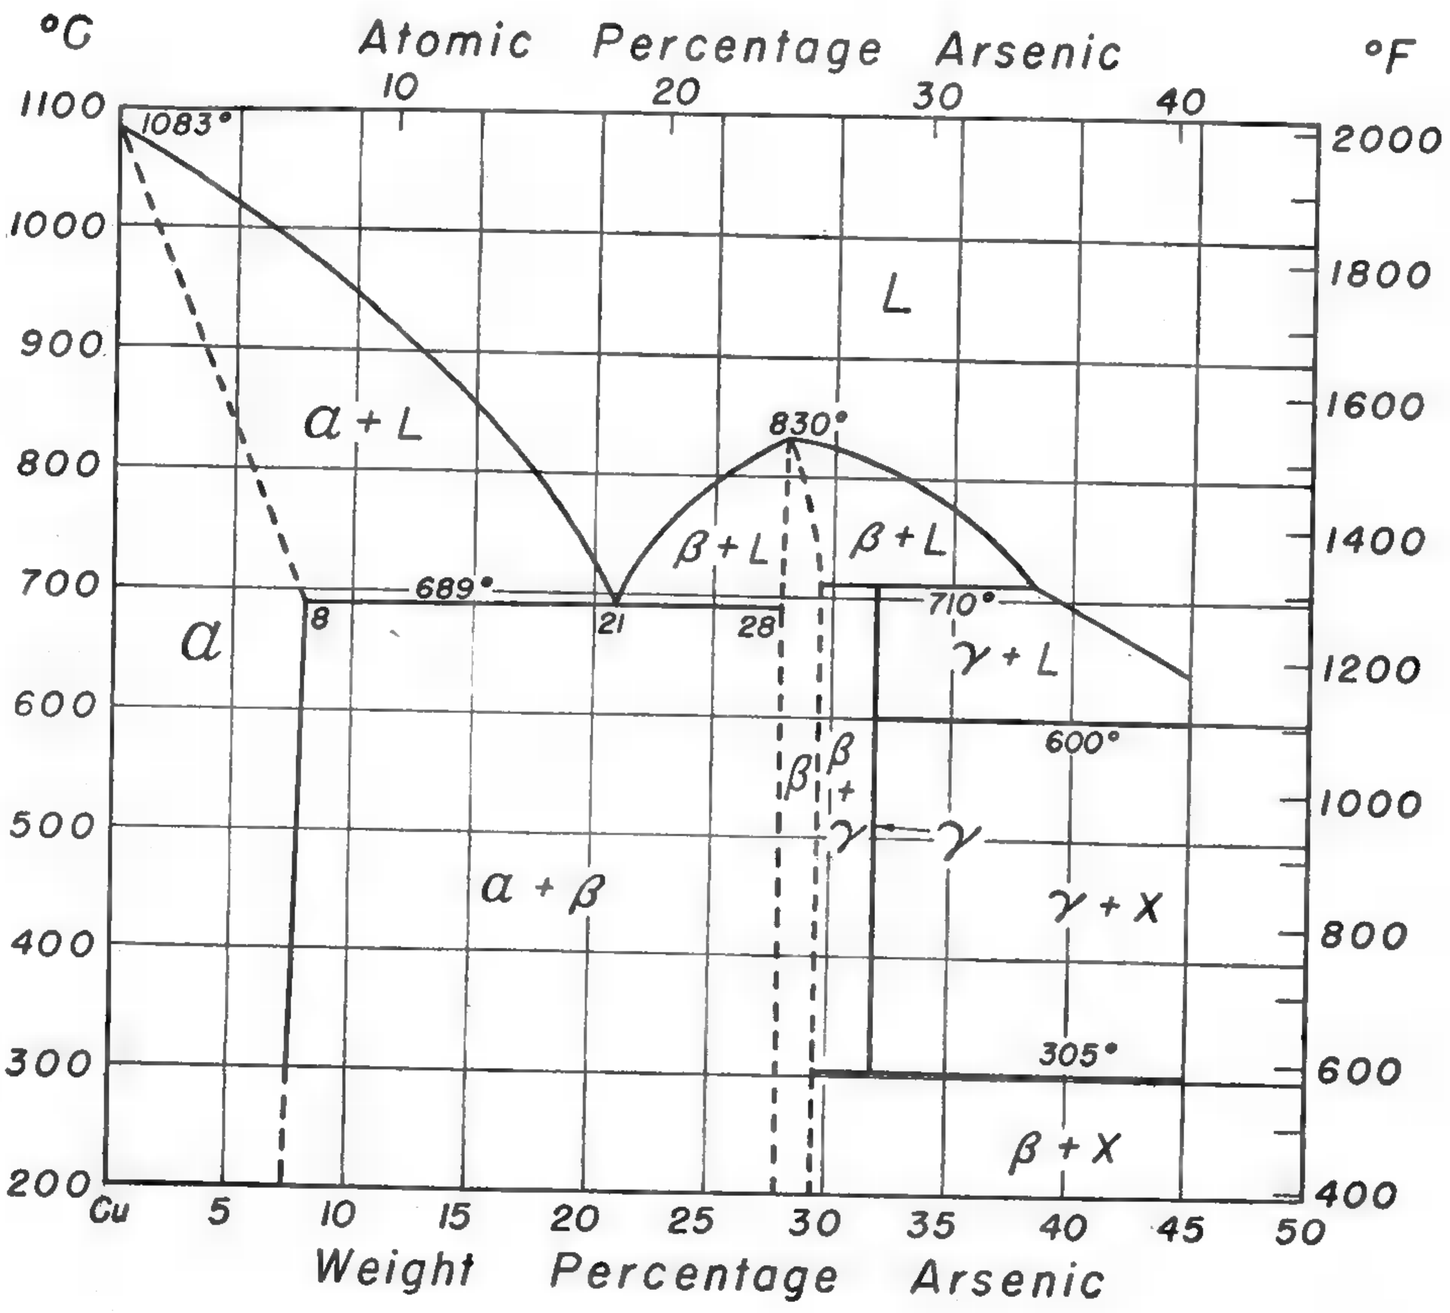
As-Cu Arsenic-Copper

By H. L. Burghoff*



This diagram is essentially as given by Hansen,[1] except that the alpha solid solubility boundary is as determined by Mertz and Mathewson.[5] The constitution of copper-arsenic alloys containing more than 28% As is uncertain, for the evidence concerning the existence of the γ phase (the compound Cu_5As_2) is contradictory. The β phase region includes the composition Cu_3As.

Alloys containing up to about 0.5% As are used commercially.

* Research Metallurgist, Chase Brass & Copper Co., Waterbury, Conn.

From a diffusion study, it was estimated that the limit of the γ loop is between 3½ and 4% As at 1150 C.[1]

The η phase (FeAs) crystallizes in a simple rhombic lattice.[2] The elementary cell contains four FeAs groups.[3] The ϵ phase (Fe_2As) has a simple tetragonal lattice with two Fe_2As groups per cell.[3]

Natural $FeAs_2$ (72.86% As) is isomorphous with marcasite (FeS_2) and with $FeSb_2$.[4,5]

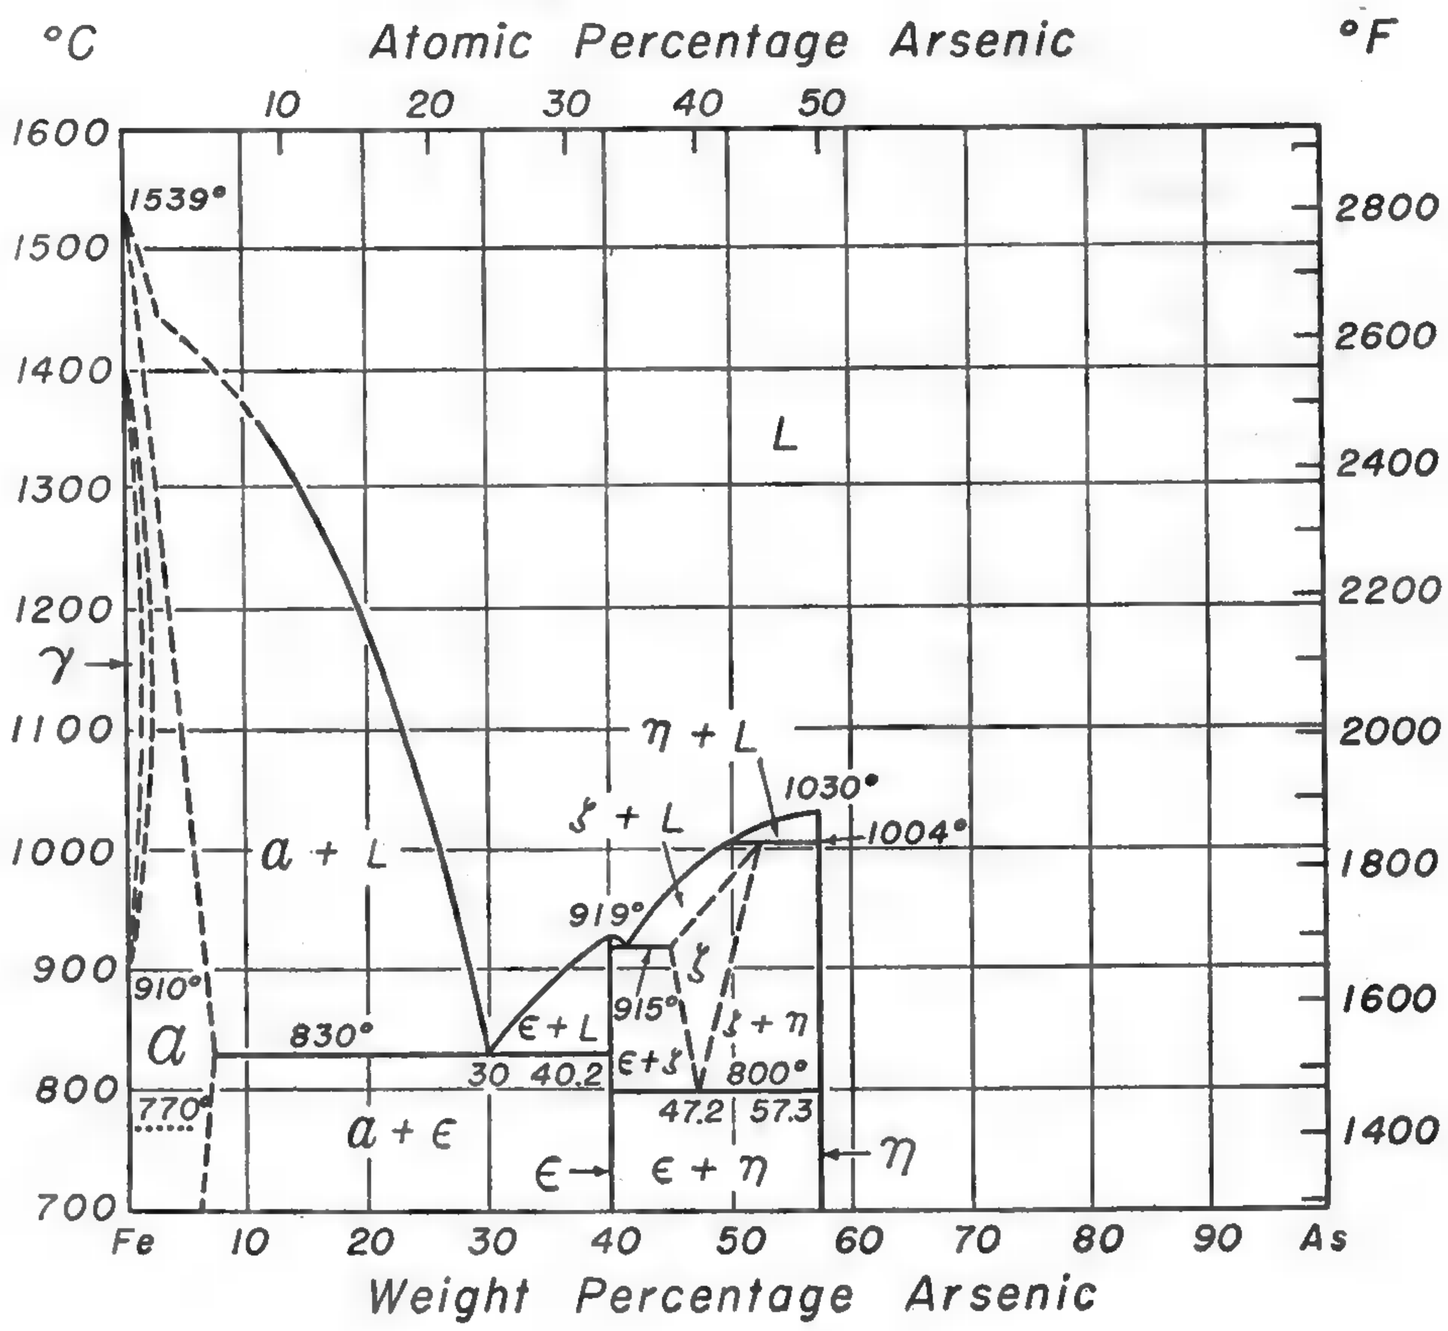
As-Fe Arsenic-Iron

By R. M. Parke*



As-Pb Arsenic-Lead

By A. A. Smith, Jr.*

Lead and arsenic form a simple eutectic system as determined by Heycock and Neville,[1] Heike,[2] and Bauer and Tonn.[3] No detailed study has been made on the arsenic end of the system, since arsenic sublimes under atmospheric pressure above 610 C.

Arsenic has but slight solubility in solid lead—approximately 0.05% at the eutectic temperature and probably less than 0.01% at 25 C.[3]

Au-Bi Gold-Bismuth

By W. Earl Lindlief*

The only known data for the liquidus and eutectic are those of Vogel.[1] The melting point of the bismuth used in his determinations was 266 C, which is 5.3 C lower than the melting point of pure bismuth. The liquidus and eutectic temperatures may therefore be somewhat in error.

Jurriaanse[2] found the solubility of bismuth in solid gold to be less than 0.2% by metallographic methods. His X-ray work indicated the solubility to be nil and this has been verified by the more recent work of Owen and Roberts.[3]

The β phase (Au_2Bi, 34.64 weight % Bi) is face-centered cubic with $a = 7.942$ kX units.[3]

Au-Cu Gold-Copper

By David Harker*

Lattice Parameters of Gold-Copper Alloys Quenched from 600 C
(Lattice parameters of the α' structure are within 0.005 kX of those of α)

Gold, wt %	0	10	20	30	40	50	60	70	80	90	100
Lattice constant, kX	3.608	3.631	3.655	3.680	3.709	3.743	3.785	3.837	3.894	3.969	4.070

Lattice Parameters of Gold-Copper Alloys Quenched from 200 C (Tetragonal α'')

Gold, wt %	65	70	75	80	85
a, kX units	3.846	3.914	3.956	3.978	3.950
c/a	0.976	0.934	0.926	0.933	0.981

* Research Laboratory, General Electric Company, Schenectady

Both α' and α'' are ordered states of the face-centered cubic α' phase; α' is cubic with the ideal formula $AuCu_3$; α'' is tetragonal with the ideal formula AuCu. There is also an orthorhombic structure at the equiatomic composition.[4,6] According to the results of Hultgren and Tarnopol[8] this structure is stable over a temperature range of nearly 50 C in the vicinity of 400 C. The b/a axial ratio of the orthorhombic crystals increases on standing six months at room temperature.[6]

There is some evidence for the existence of another ordered state with the ideal formula Au_2Cu_3. If it exists, there would be almost a smooth continuation of the α'' region.

Au-Fe Gold-Iron

By R. M. Parke*

Although the diagram of the gold-iron system given by Hansen[1] shows a compound $AuFe_3$, based on the work of Wever (reported by Nowack[2]), the data of Jette, Bruner, and Foote[3] and of Pan, Kaufmann, and Bitter[4] are convincing that no compound exists. The η solid solutions containing from 10 to 15% Fe are ferromagnetic.[3]

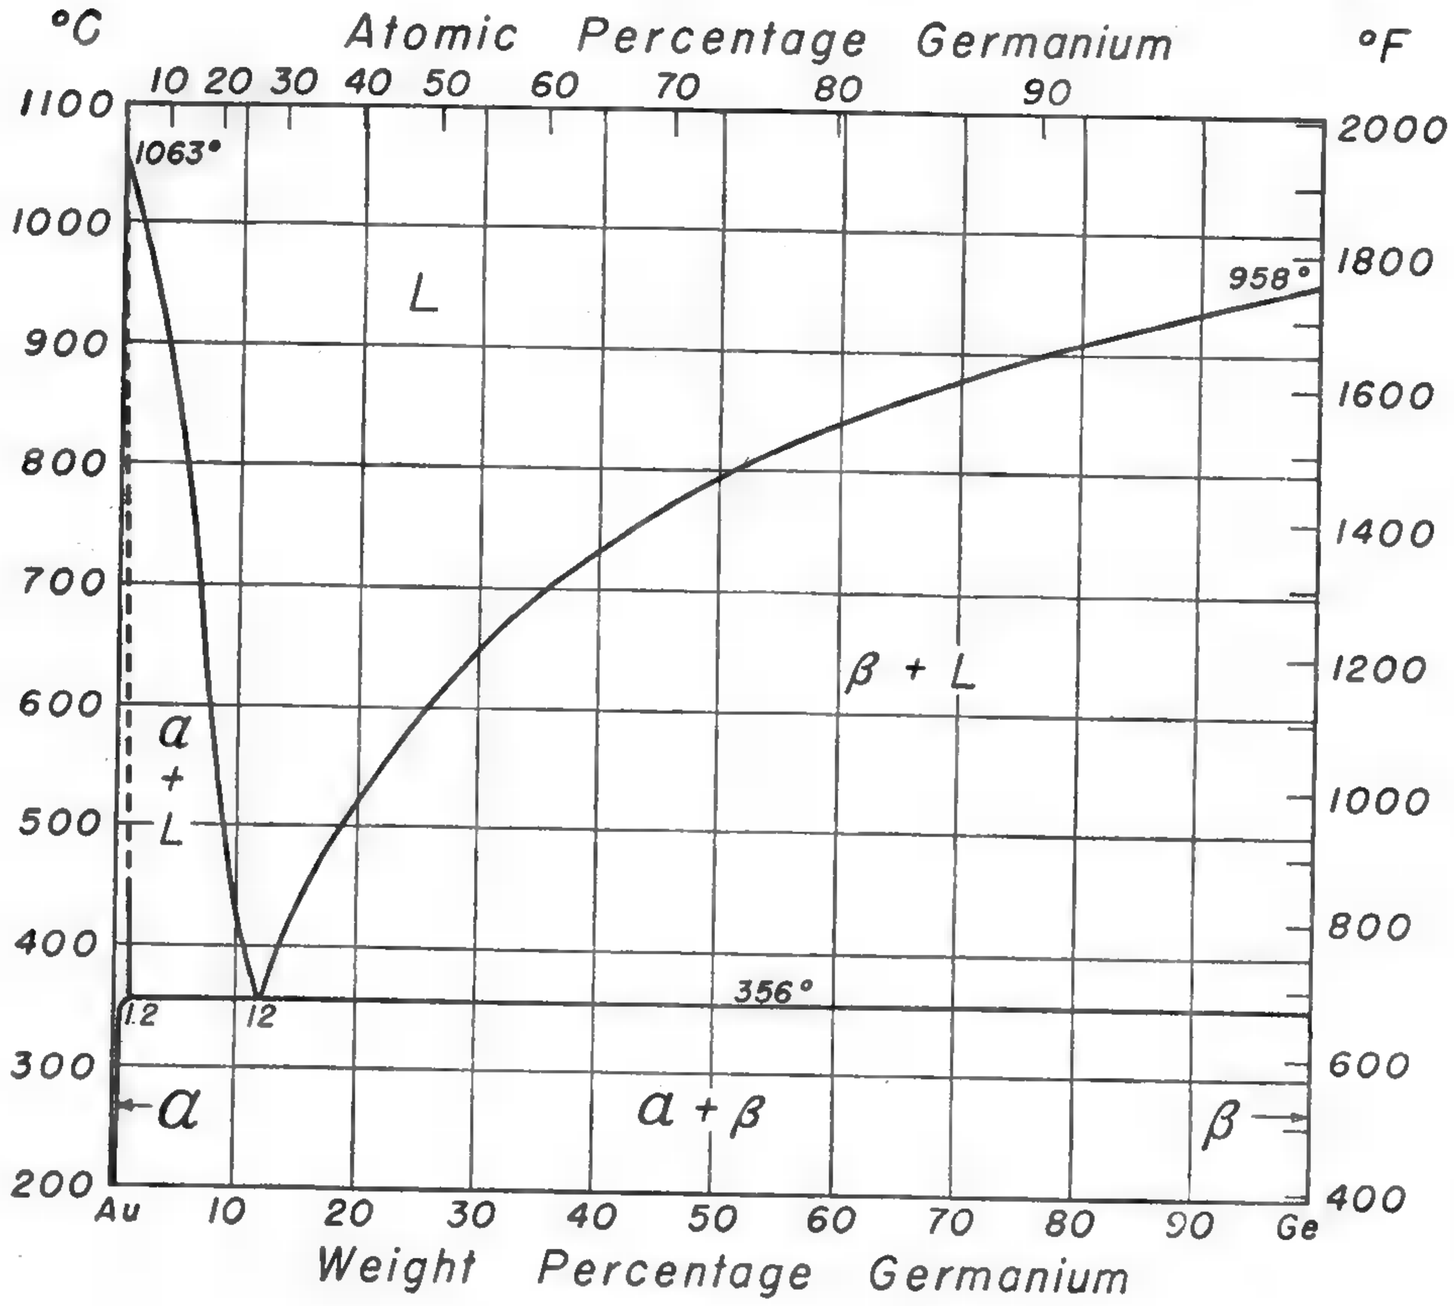
Au-Ge Gold-Germanium

By R. I. Jaffee* and Bruce W. Gonser*



The solubility of germanium in gold is 0.1% or less at room temperature.

The solubility of gold in germanium has not been investigated. Germanium[3] and the gold-germanium eutectic alloy[1] expand on solidification, resulting in so-called "sprouting" on the free surface of solidification. The alloys retain their gold color up to the eutectic composition.

The structure of the eutectic is extremely fine-grained at the eutectic composition, and on the gold side of the eutectic, but is quite coarse on the germanium side. Up to about 5% Ge the alloys are malleable. The hardness increases to about 200 Vickers at 12% Ge.

The addition of 1.16% Ge to gold increases the lattice parameter of the face-centered cubic solid solution from 4.0700 to 4.0724 kX.[2]

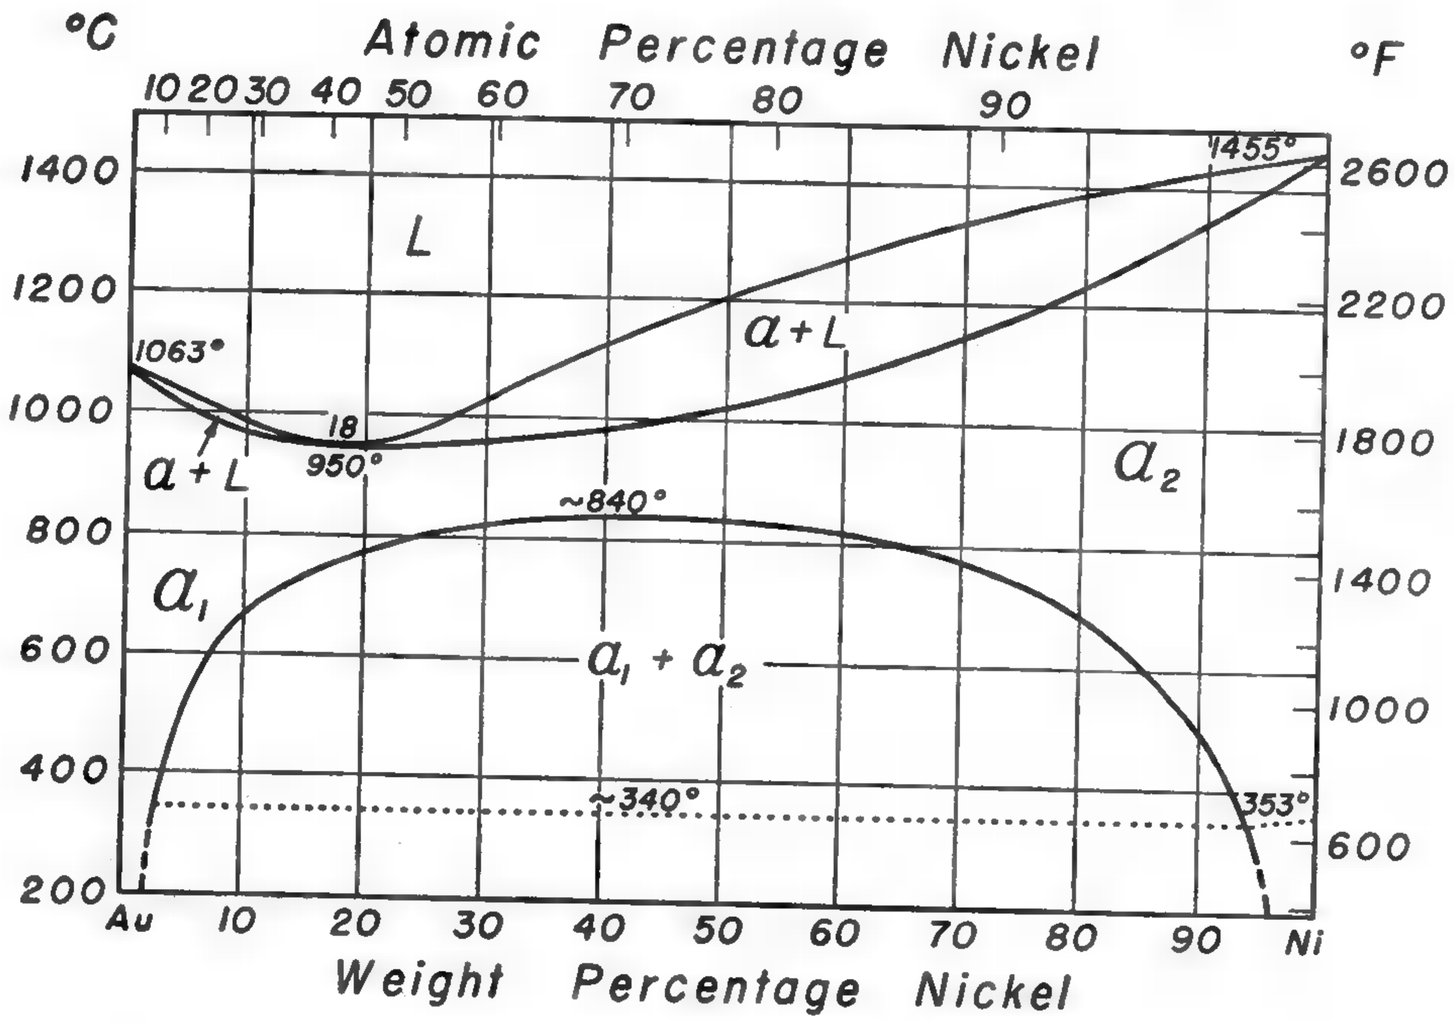
Au-Ni Gold-Nickel

By Louis A. Carapella*



At about 340 C, the α_2 phase in equilibrium with α_1 becomes ferromagnetic during cooling. A second magnetic change has also been detected at lower temperatures[4, 8] in alloys with approximately 40 to 95% Ni quenched from the single-phase range. This is not an equilibrium magnetic change.

Lattice parameters have been reported.[4]

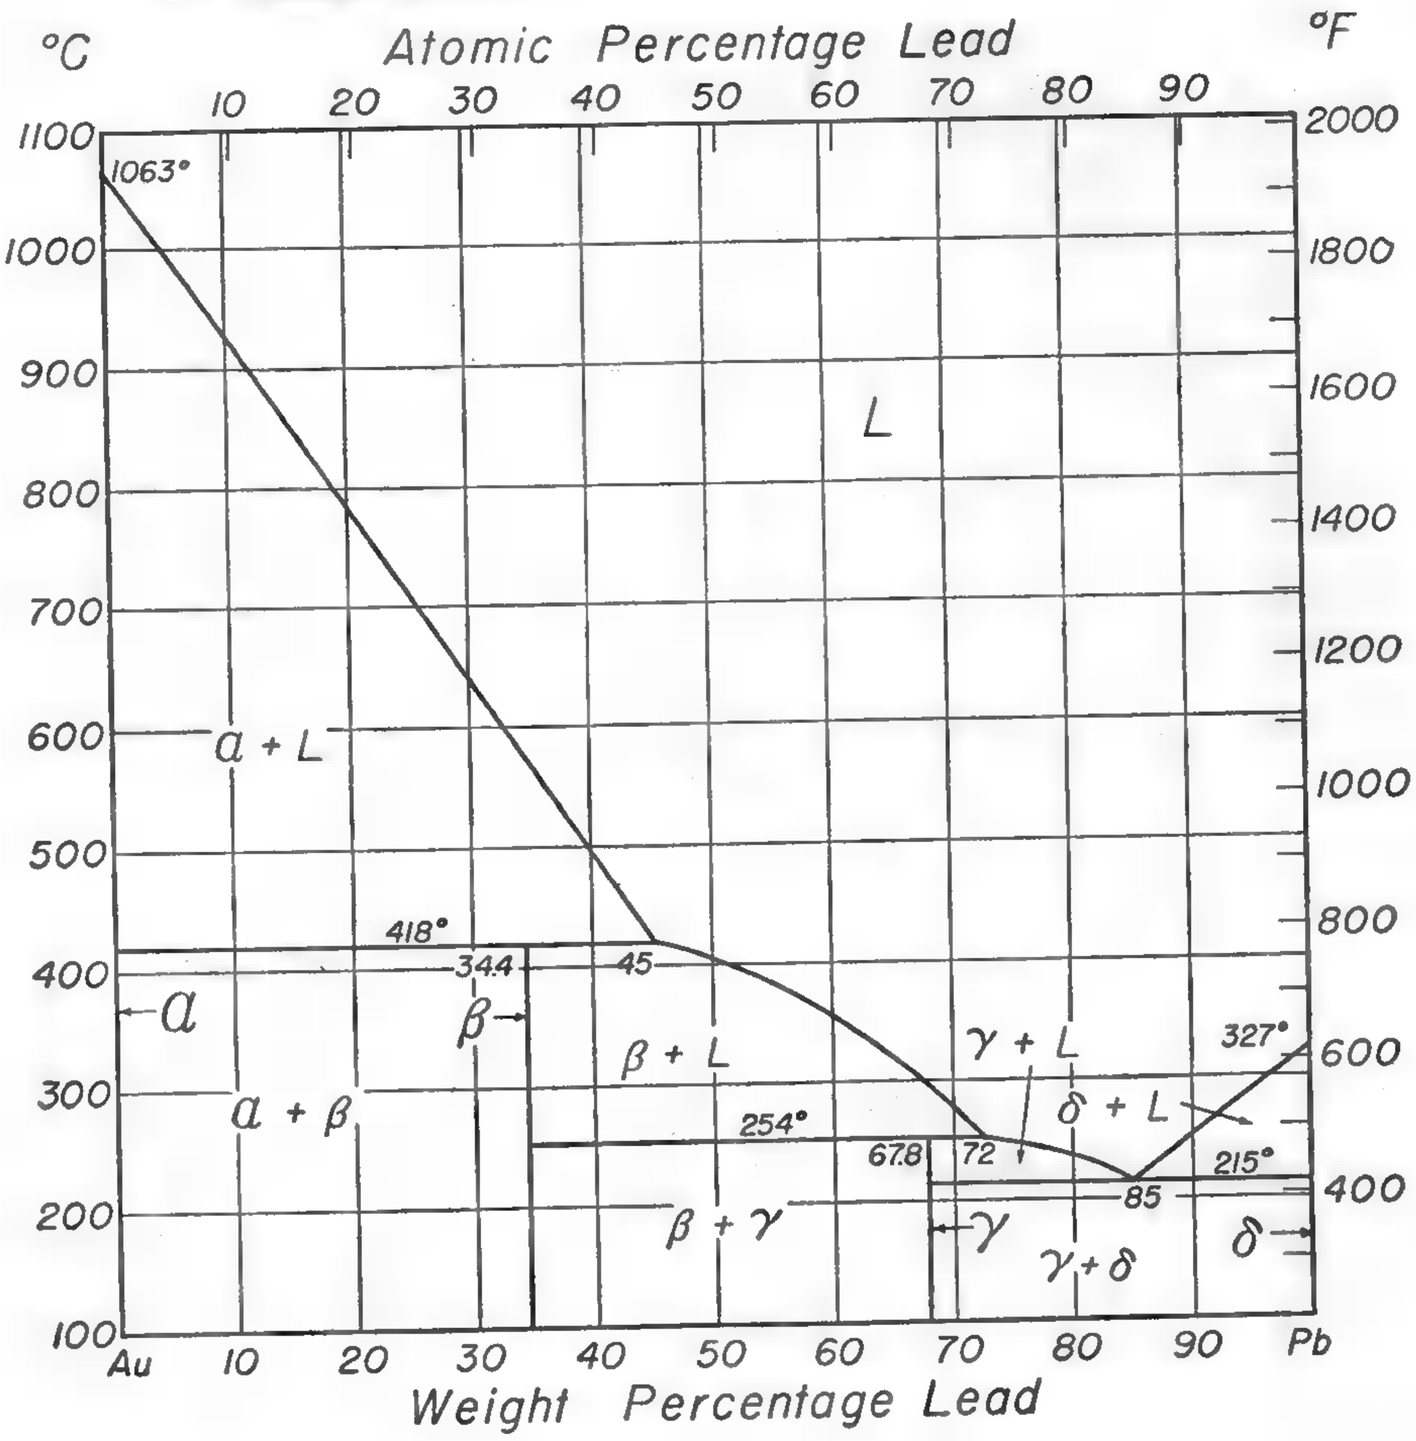
Au-Pb Gold-Lead

By Charles L. Gordon*



The phase diagram is based mainly on the work of Vogel.[1] The solubility of lead in solid gold is probably less than 0.005%.[2,3,8] The suggested solubility of gold in lead ranges from 0.09% near the eutectic temperature (215 C) to 0.03% at 170 C.[5]

The β phase (Au_2Pb) is face-centered cubic with 16 gold and 8 lead atoms in a unit cell that is identical with those of $MgCu_2$ and KBi_2. The lattice parameter is 7.910 kX units.[9] The γ phase ($AuPb_2$) is tetragonal[6] with $a = 7.319$ kX and $a/c = 1.297$.

Au-Pd Gold-Palladium

By E. M. Wise*

The liquidus has been drawn according to the results of Ruer[1] and of Fraenkel and Stern.[2] Measurements of the lattice parameter[4,5] indicate a nearly linear function of the composition expressed in atomic percentage.

The maximum electrical resistivity of about 27.5 microhm-cm occurs at about 50% Au.[6-10] The temperature coefficient of electrical resistivity has a minimum value of about 0.00034 per degree centigrade (0 to 100 C) at about 60% Au.[6,†] In the curves of these two electrical properties versus composition, peculiar changes in slope near 70% Au have not been explained.

Hardness and tensile strength are maximum at about 55% Au. The maximum values are 88 Bhn and 50,000 psi tensile strength for annealed material, and 160 Bhn and 83,000 psi for alloys reduced 66% in cold working.

Only the alloys containing less than about 15% Pd are yellow in color.

Palladium-gold alloys have been used in dentistry and for electrical contacts.

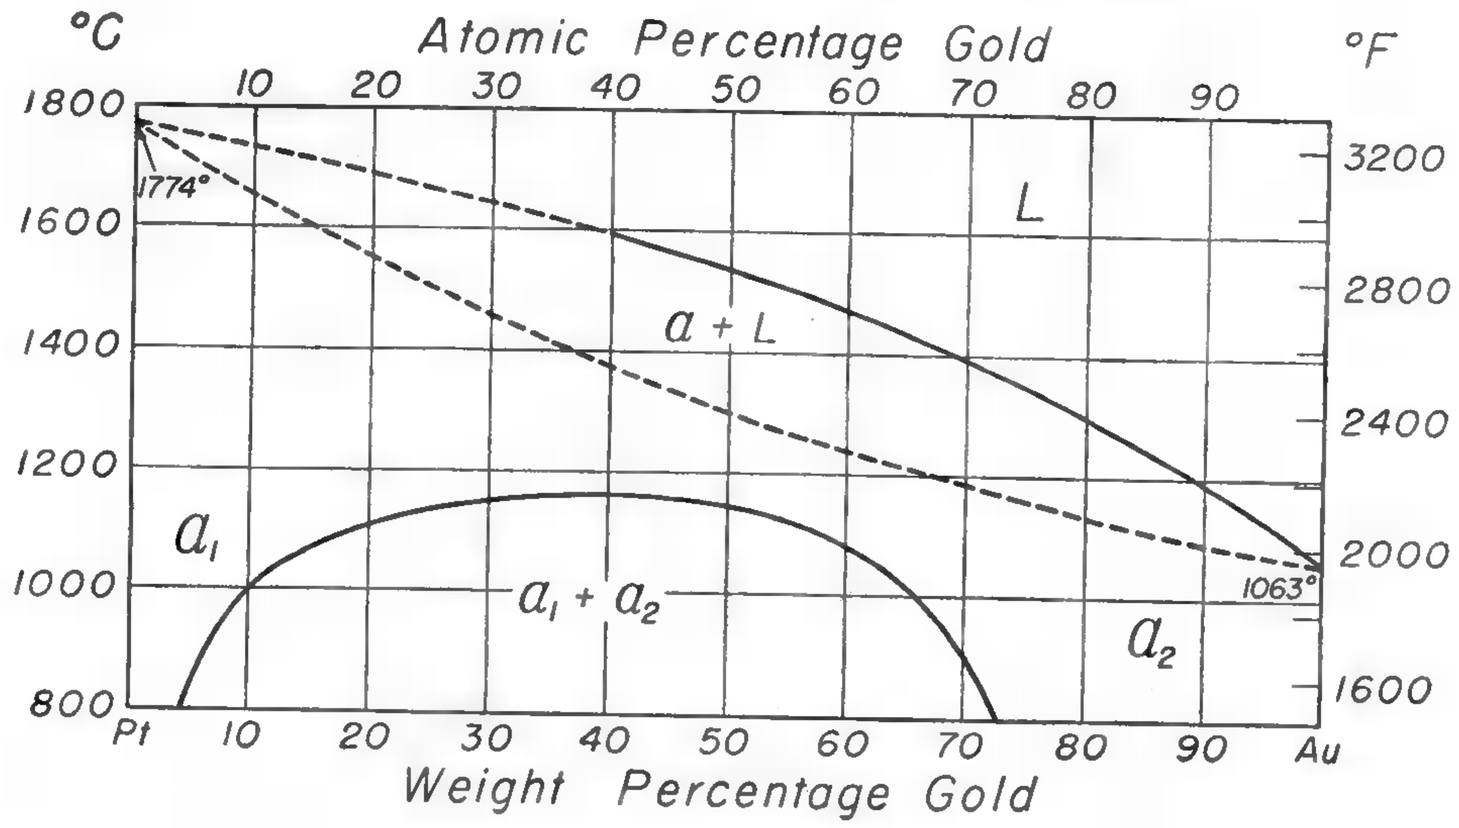
Au-Pt Gold-Platinum

By E. M. Wise*



The shape of the duplex $a_1 + a_2$ region is based on the closely agreeing work of Johansson and Linde[2] and Stenzel and Weerts.[3] It appears that at low temperature the domain of heterogeneity extends from 3% to 85 or 90% Au. At temperatures below about 600 C some additional transformations—perhaps involving ordering—may occur.

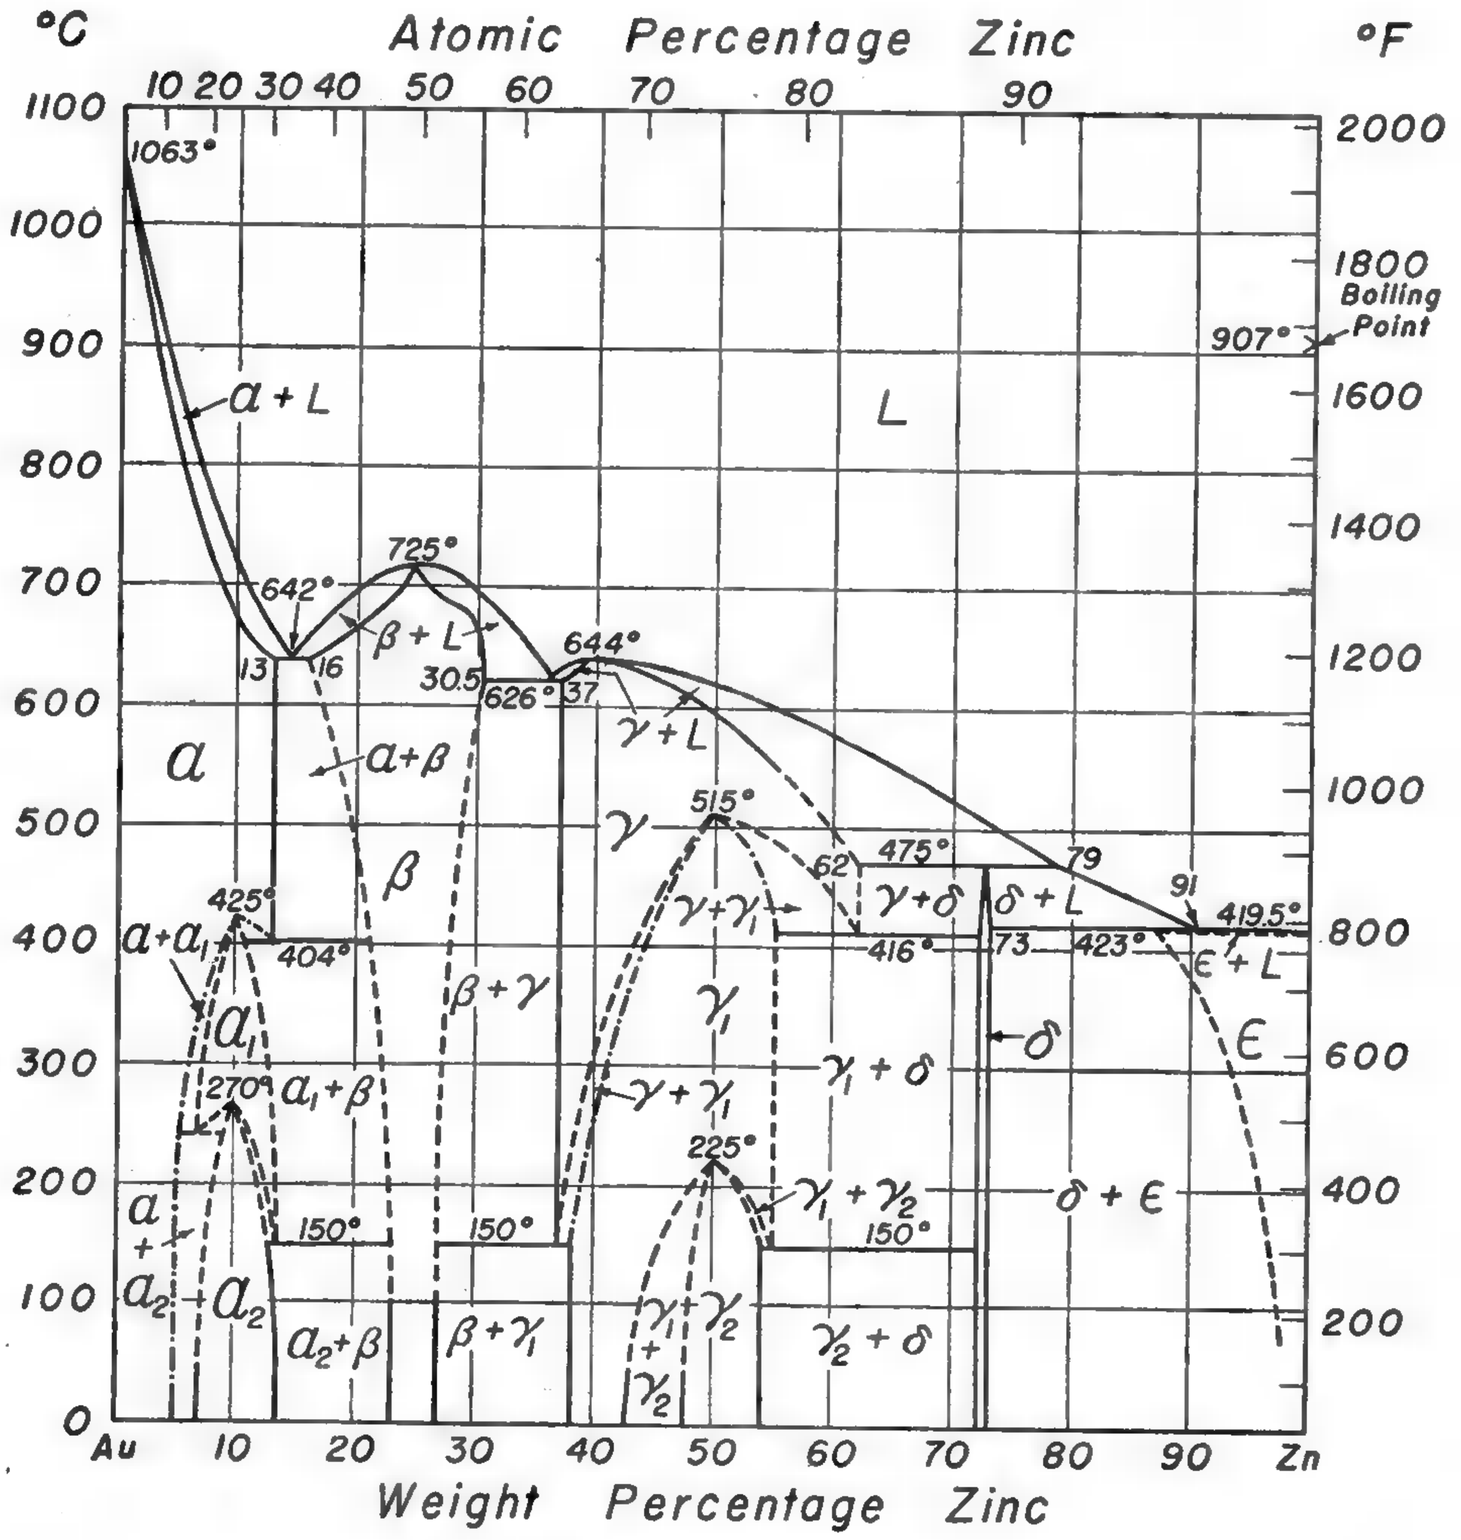
Au-Zn Gold-Zinc

By Fred M. Reinhart*



The gold-zinc system is analogous to copper-zinc but is complicated by the formation of several ordered phases at low temperature. There are five types of structure common to both systems.[1]

A superstructure is present in the β-phase alloys quenched from temperatures up to the melting point.[5]

The diagram is based on Hansen's[3] review of the work of Vogel[4] and of Soldau[2] and on more recent work by Ageew and Shoykhet.[6]

The β phase is body-centered cubic (CsCl type) with ■ = 3.146 kX at 30.2% Zn. γ is cubic with 52 atoms per unit cell; the lattice parameter is 9.223 kX at 41.1% Zn. γ_1 and γ_2 have complex cubic crystal structures that contain, respectively, 90 and 32 atoms per unit cell. The δ and ϵ phases are close-packed hexagonal with axial ratios of 1.55 to 1.60 and 1.80 to 1.90, respectively.

B-Fe Boron-Iron

By R. M. Parke*

Wever and Müller[1,2] determined that the compound Fe_2B has a body-centered tetragonal structure with four Fe_2B groups in the unit cell. Bjurstrom and Arnfelt[3] verified the structure of Fe_2B and also determined that the monoboride FeB has a rhombic structure with four FeB groups to the unit cell. Unlike carbon, boron forms substitutional solid solutions with alpha iron and probably with gamma iron.[4] The solubility of boron in delta iron is 0.15% at 1381 C. In gamma iron the maximum solubility is about 0.1%. The solubility of boron in alpha iron is less than 0.15% at 915 C.[4]

With five alloys containing 0.06 to 2.5% B, Wasmuht[8] studied precipitation hardening after quenching from 750 C. No hardening was observed, and it is concluded therefore that there is very little decrease in the solubility of boron in alpha iron as the temperature decreases below 750 C.

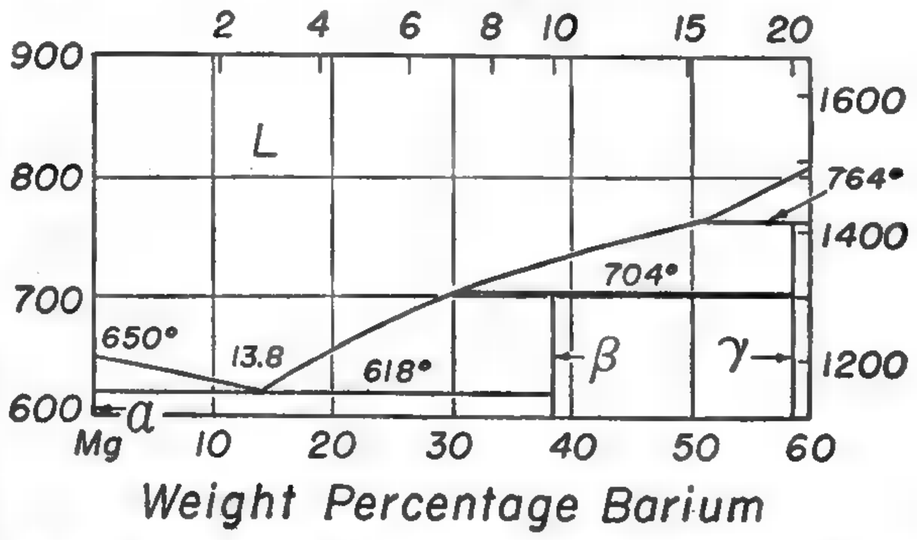
Ba-Mg Barium-Magnesium

By Louis A. Carapella*



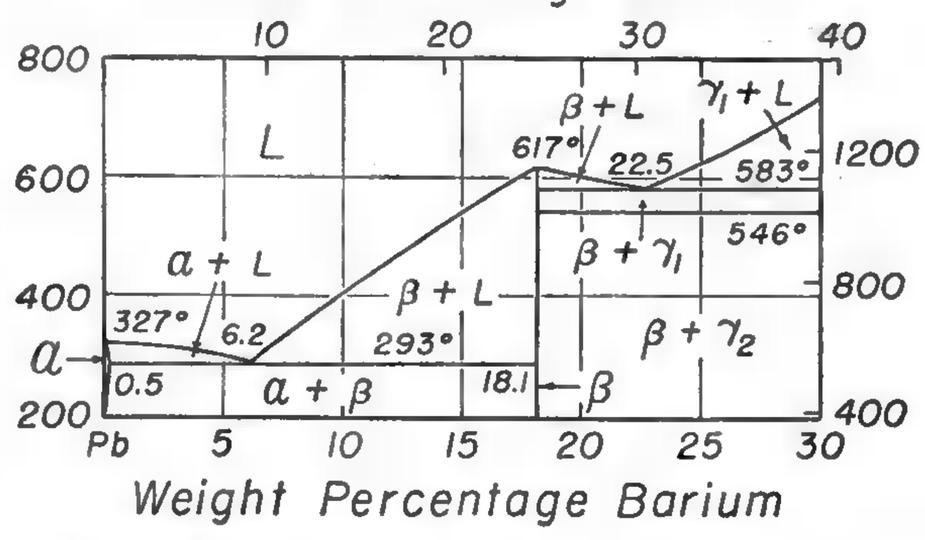
The diagram is based on the results of Grube and Dietrich [Z Elektrochem, 44, 755 (1938)], who investigated the range of composition up to approximately 80% Ba.

The β phase corresponds to the composition $BaMg_9$ (38.56% Ba); γ is $BaMg_4$ (58.54% Ba). The compound Ba_2Mg_5 (about 69% Ba) melts congruently at 855 C, and forms a eutectic with a barium-rich phase at 76.1% Ba (746 C).

* Mellon Institute of Industrial Research, Pittsburgh

Ba-Pb Barium-Lead

By Louis A. Carapella*



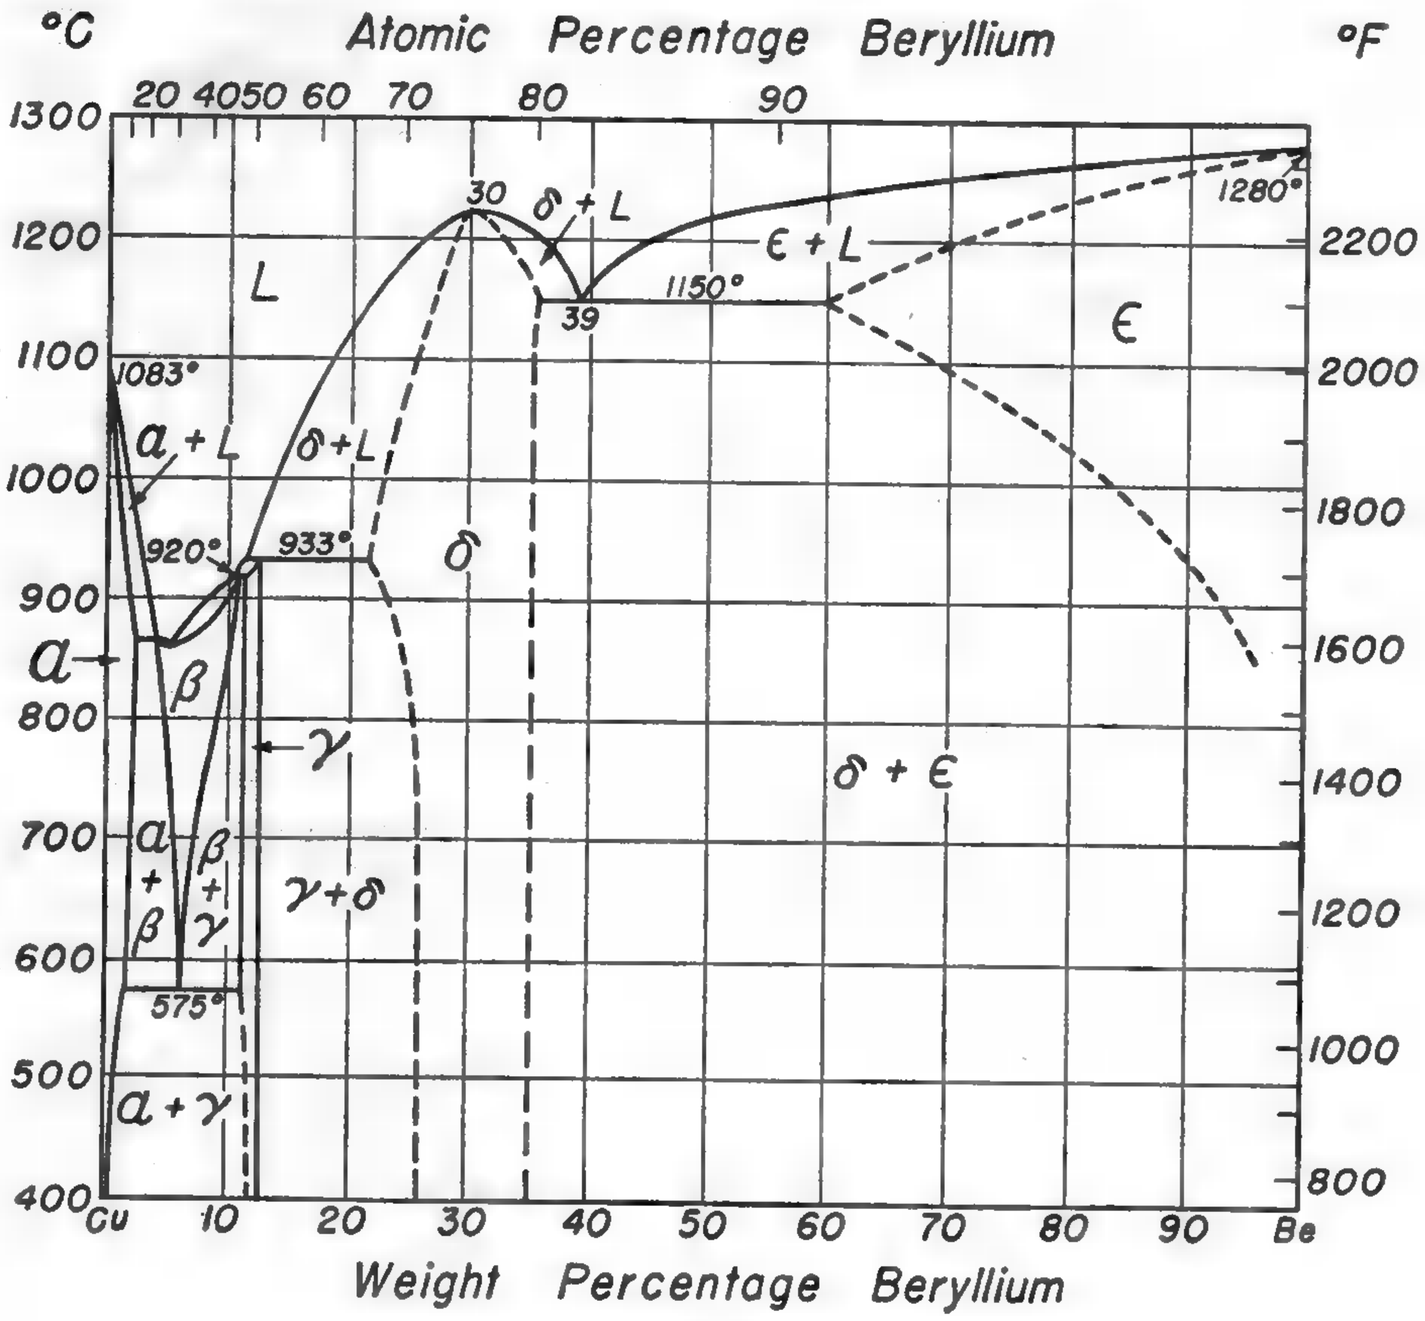
The diagram is based on the results of Grube and Dietrich [Z Elektrochem, 44, 755 (1938)], who investigated the entire range of composition in the barium-lead system.

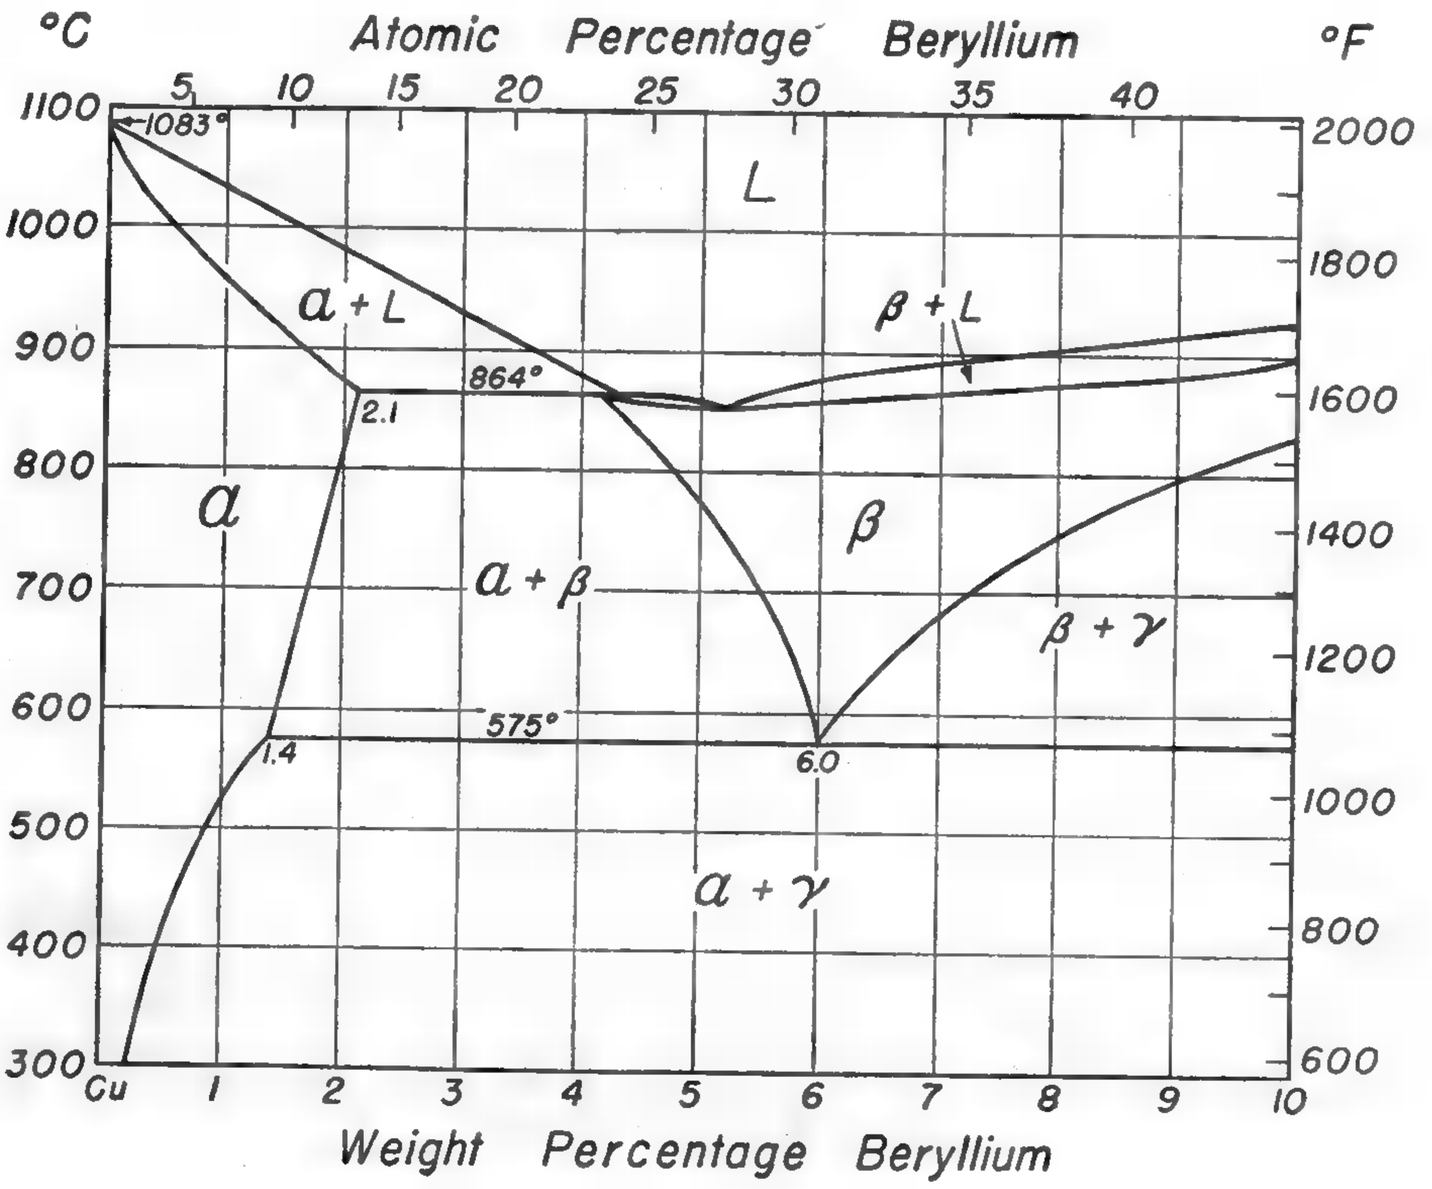
The β phase is $BaPb_3$. The γ phase (BaPb) undergoes allotropic transformation at 546 C, and melts peritectically at 850 C. The compound Ba_2Pb melts congruently at 928 C and forms a eutectic with barium at 75% Ba (595 C).

* Mellon Institute of Industrial Research, Pittsburgh

Be-Cu Beryllium-Copper

By H. F. Silliman*





The diagram is relatively well established except for the extent of δ phase and the solubility of copper in beryllium. The liquidus and the eutectic horizontal at 1150 C are based solely on the work of Losana and Venturello.[10] The high solubility of copper in solid beryllium, as suggested by these investigators, was based on thermal analysis alone; the values appear doubtful. Thermal arrests in high-beryllium alloys between 500 and 800 C indicate that the diagram is more complex than shown here.

The minimum in the liquidus curve for the β phase has been questioned[5] but the weight of evidence favors it. The α boundary is from the work of Tanimura and Wassermann.[4] The curvature of the boundary between the $\alpha + \gamma$ and γ fields, suggested by Iwasé and Okamoto,[5] gains some support from X-ray studies on aged samples.[6]

The γ phase corresponds to the composition CuBe. Although the maximum in the liquidus of the δ phase is at the composition $CuBe_3$, the structure is said to be of the same type as $CuMg_2$, and the phase is reported to include the composition $CuBe_2$.[7,10]

The lattice parameter of the face-centered cubic α phase is 3.566 kX at 2.1% Be.[4,6] The β phase is body-centered cubic, disordered, with $a = 2.79$ kX at 7.2% Be and 750 C.[9]

The γ phase is body-centered cubic with the CsCl type of ordering. The lattice parameter is 2.70 kX.[6,7] The cubic δ phase ($CuMg_2$-type) has a lattice parameter of 5.940 to 5.887 kX.[7,10]

Be-Fe Beryllium-Iron

By R. M. Parke*

Beryllium in iron closes the "gamma loop". The γ field does not extend beyond 0.4% Be.[1] The solubility of beryllium in α is 7.5 to 8% at 1150 C and 4.5 to 5% at low temperature. A eutectic is formed between the α phase and the hexagonal compound $FeBe_2$ at 10% Be and 1150 C.[2]

Be-Mg Beryllium-Magnesium

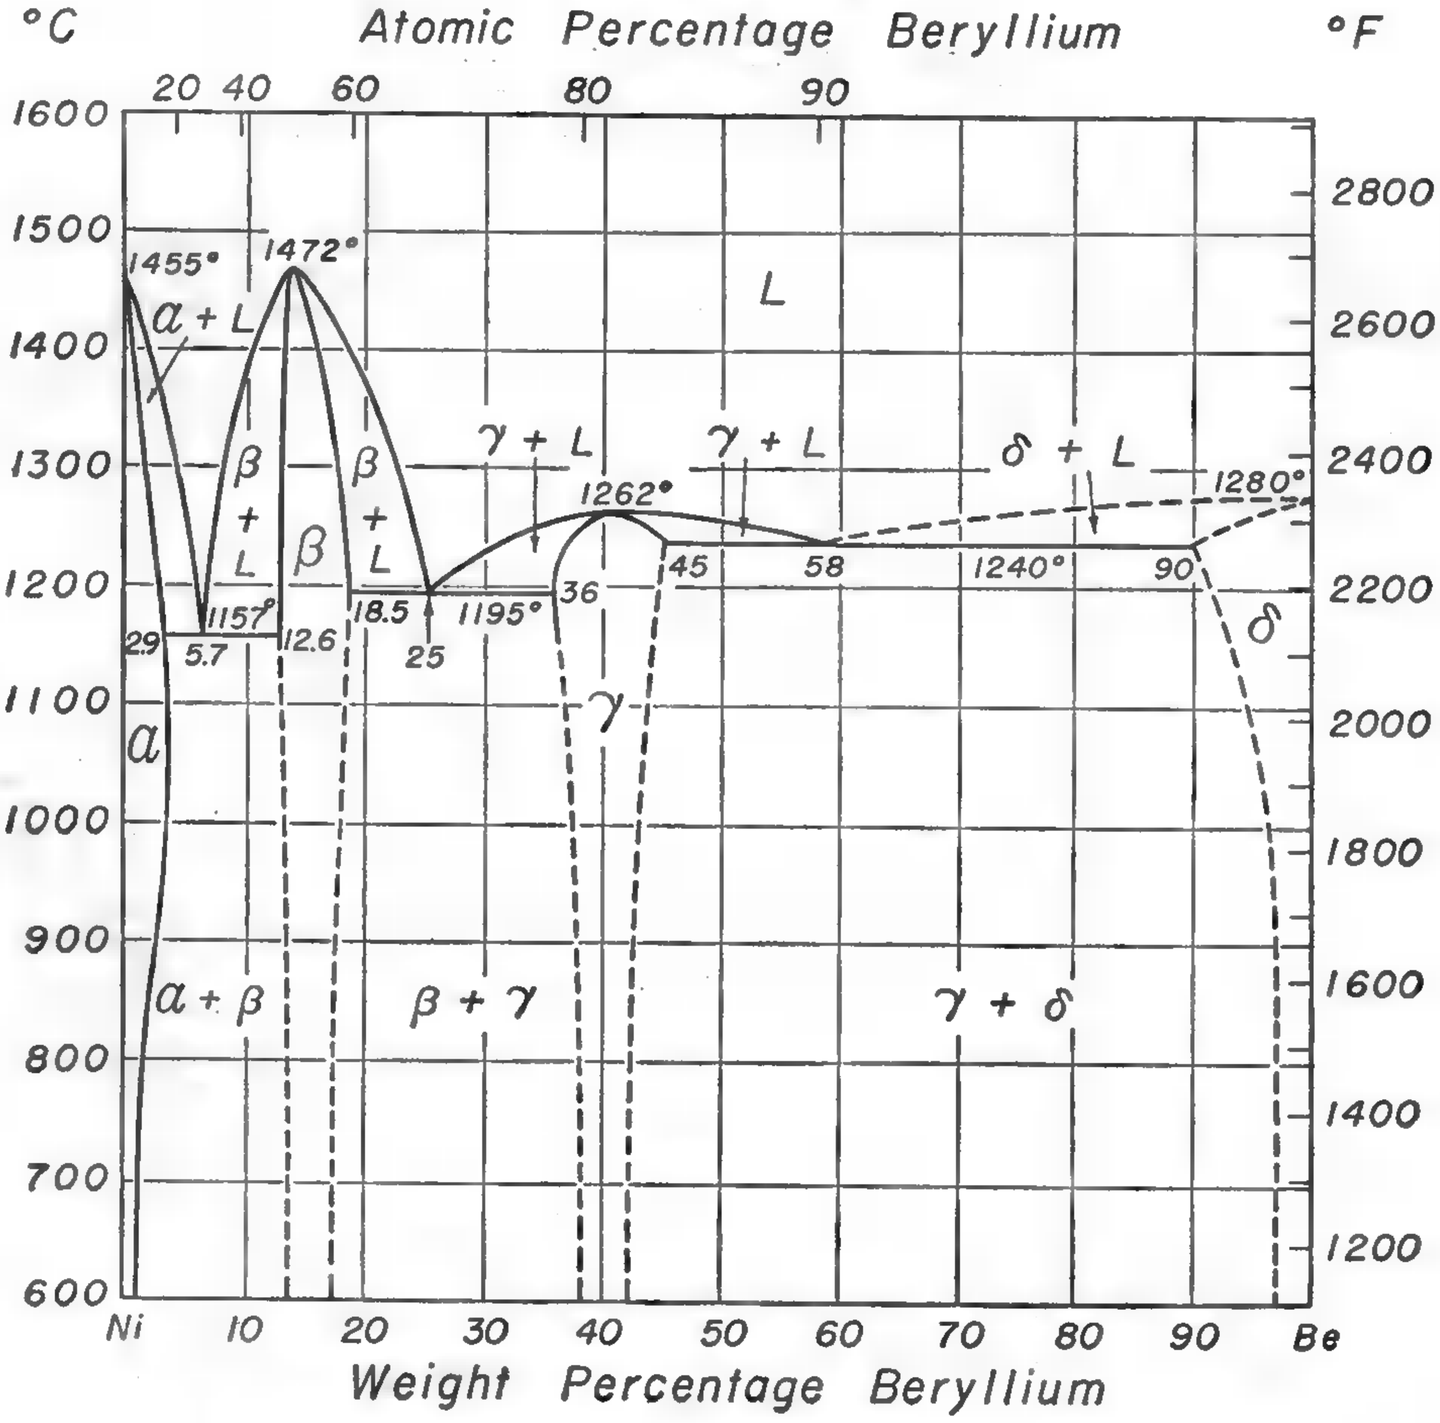
By Taylor Lyman*

It is impossible to produce magnesium-beryllium alloys by the usual methods because the boiling point of magnesium (1110 C) is below the melting point of beryllium (1280 C). A process has been described [*see* Met Abs, 7, 109 (1940)] for producing such alloys under a pressure of more than 100 atmospheres of hydrogen. Small amounts of beryllium, contained in an aluminum-beryllium master alloy, are sometimes added during the melting of commercial magnesium alloys that are to be wrought (*see* page 974). The solubility of beryllium in magnesium is very small.

* Editor, Metals Handbook

Be-Ni Beryllium-Nickel

By E. N. Skinner†



Interest in the constitution of beryllium-nickel alloys has been confined principally to the study of the nickel-rich α solid solution,[1,2] which exhibits exceptional precipitation hardening.

Losana and Goria[3] have investigated this system in the range from 10 to 100% Be. These investigators observed isothermal reactions at 1157, 1195 and 1240 C, involving intermetallic phases designated as β and γ. These phases include the compositions NiBe and Ni_5Be_{21} respectively. Both phases melt congruently — β at 1472 C and γ at 1262 C. Because of the experimental difficulties in the preparation of beryllium-nickel alloys, there is some uncertainty concerning the shapes of the liquidus, solidus and solvus curves shown for the beryllium-rich compositions.

† The International Nickel Company, Inc., New York.

Beryllium dissolved in high-purity nickel depresses the Curie temperature, as follows:[4]

Weight % Be	0	0.5	1.0	1.5	2.0	2.5
Curie temperature, °C	350	280	220	160	95	35

The β phase has the CsCl type of body-centered cubic structure with $a = 2.603 \pm 0.003$ kX.[5] The γ phase has a deformed gamma-brass type of cubic structure with a lattice parameter of 7.56 kX.

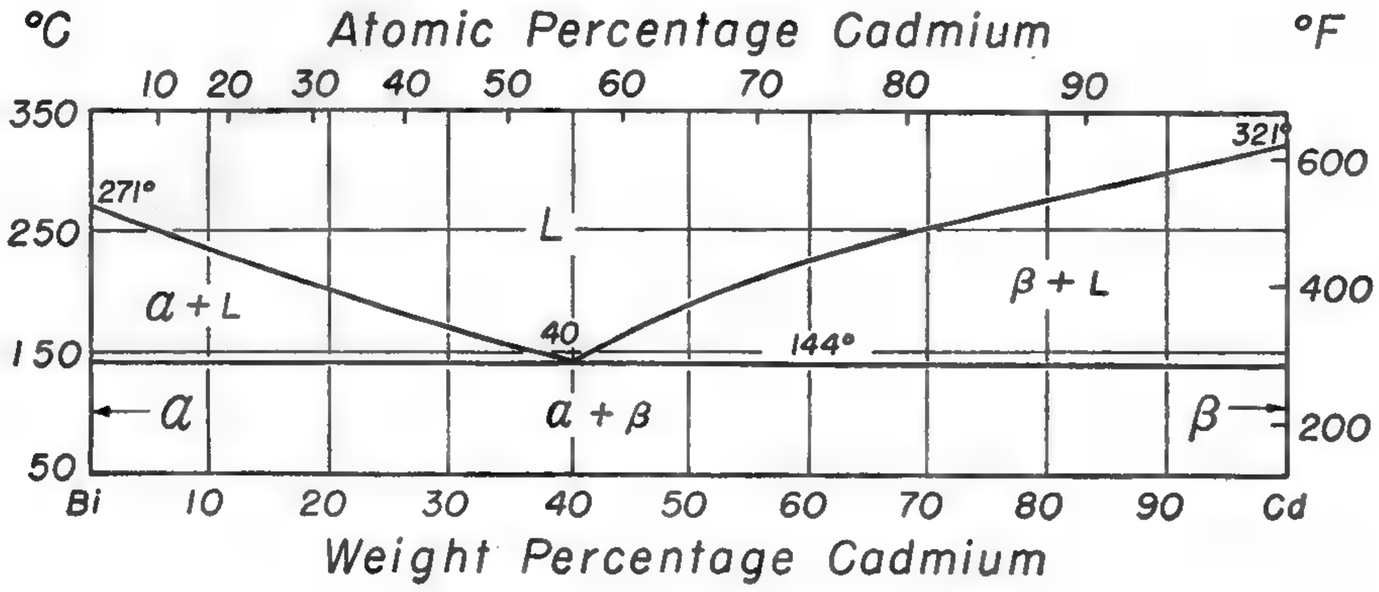
Bi-Cd Bismuth-Cadmium



The diagram has been taken without change from Hansen,[1] who states that the liquidus temperatures are accurate to less than 5 C. According to Tammann and Rocha,[2] the solubility of bismuth in cadmium is less than 0.05% at the eutectic temperature (144 ± 2 C[1]).

Bi-Cu Bismuth-Copper

By A. C. Vaughan*

The eutectic temperature is about one degree Centigrade lower than the melting point of bismuth.[3] Liquidus temperatures are reported in references 4, 5, 6, 7 and 8.

The solubility of bismuth in solid copper was determined by Hanson and Ford,[1] with microscopic methods, as about 0.001% after quenching from 980 C. Blazey[9] showed that the amount of bismuth necessary to cause hot shortness in arsenical deoxidized copper (and presumably closely related to the solubility) decreases from 0.006% at 725 C to less than 0.002% at 600 C. The practical insolubility of either metal in the other was indicated by measurements of the lattice parameter by Ehret and Fine.[2]

Bi-Fe Bismuth-Iron

By R. M. Parke*

According to Isaac and Tammann,[1] bismuth and iron are virtually insoluble in each other in the molten state, and this has been confirmed by Hägg.[2] Using a magnetic method, Tammann and Oelsen[3] determined that 0.0002 to 0.0004% Fe dissolved in bismuth heated to 400 and 1600 C under a hydrogen atmosphere.

Bi-Hg Bismuth-Mercury

By Louis A. Carapella†

A continuous liquidus curve with no evidence of compound formation has been established.[1,2] A eutectic point at 99.9% Hg has been suggested.[3] There is some indication of a solidus temperature at minus 39.2 C for mercury-rich alloys.[3,4,5] Data are lacking for the bismuth-rich alloys.

Bi-Mg Bismuth-Magnesium

By G. F. Sager* and B. J Nelson*

The extent of the $\beta + \gamma$ field has not been firmly established.

The solubility of bismuth in magnesium is, as follows:

Temperature, °C	553	525	500	450
% Bi	9.05	6.56	4.95	2.81
Temperature, °C	400	350	300	250
% Bi	1.53	0.79	0.33	0.1

The γ phase is hexagonal with $a = 4.666$ kX, $c = 7.401$ kX.[3]

Bismuth has little effect on the mechanical properties of magnesium. There are no magnesium-bismuth alloys of commercial importance.

Bi-Pb Bismuth-Lead

By G. O. Hiers*

The diagram is based on the references listed and on unpublished data of W. C. Smith concerning the eutectic.

The solubility of bismuth in lead is 21.5% at 184 C and 18.8% at 20 C.

The β phasé has been reported to be hexagonal with $a = 3.507$ kX and $c/a = 1.646$.

Bismuth-lead compositions are used as "low-melting alloys" (*see* page 744).

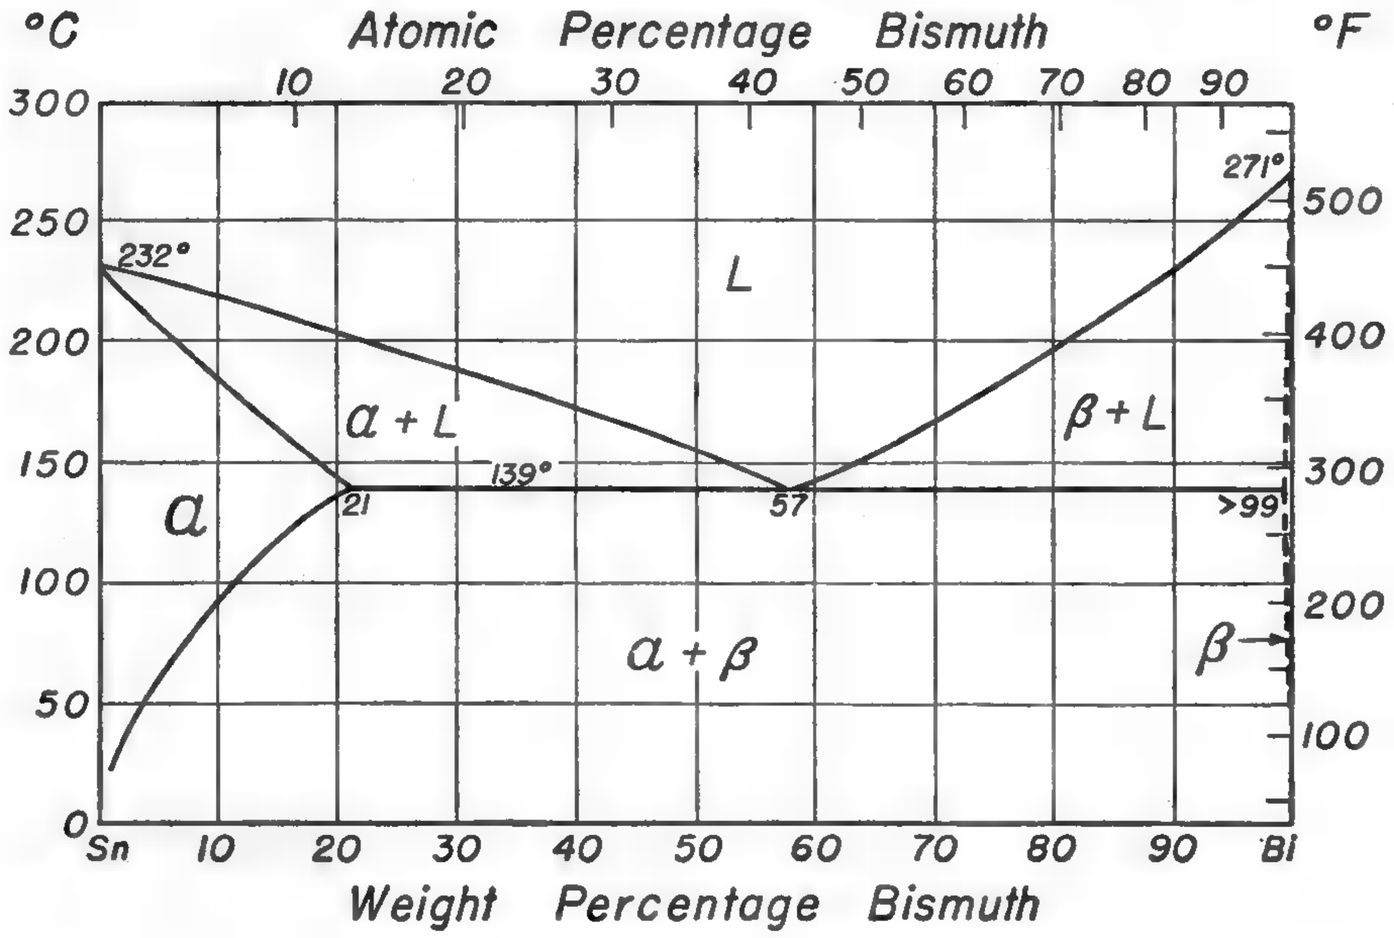
Bi-Sn Bismuth-Tin

By R. I. Jaffee* and Bruce W. Gonser*



Long annealing at the eutectic temperature is required for attainment of the maximum solubility of bismuth in α. Chill-cast specimens containing as little as 8% Bi show some eutectic.[2] The maximum solubility of tin in β is probably about 0.1%.

An alleged eutectoid transformation at 95 C is now generally discredited, and thermal arrests at that temperature are believed to be the result of precipitation of β from the supersaturated α solid solution.

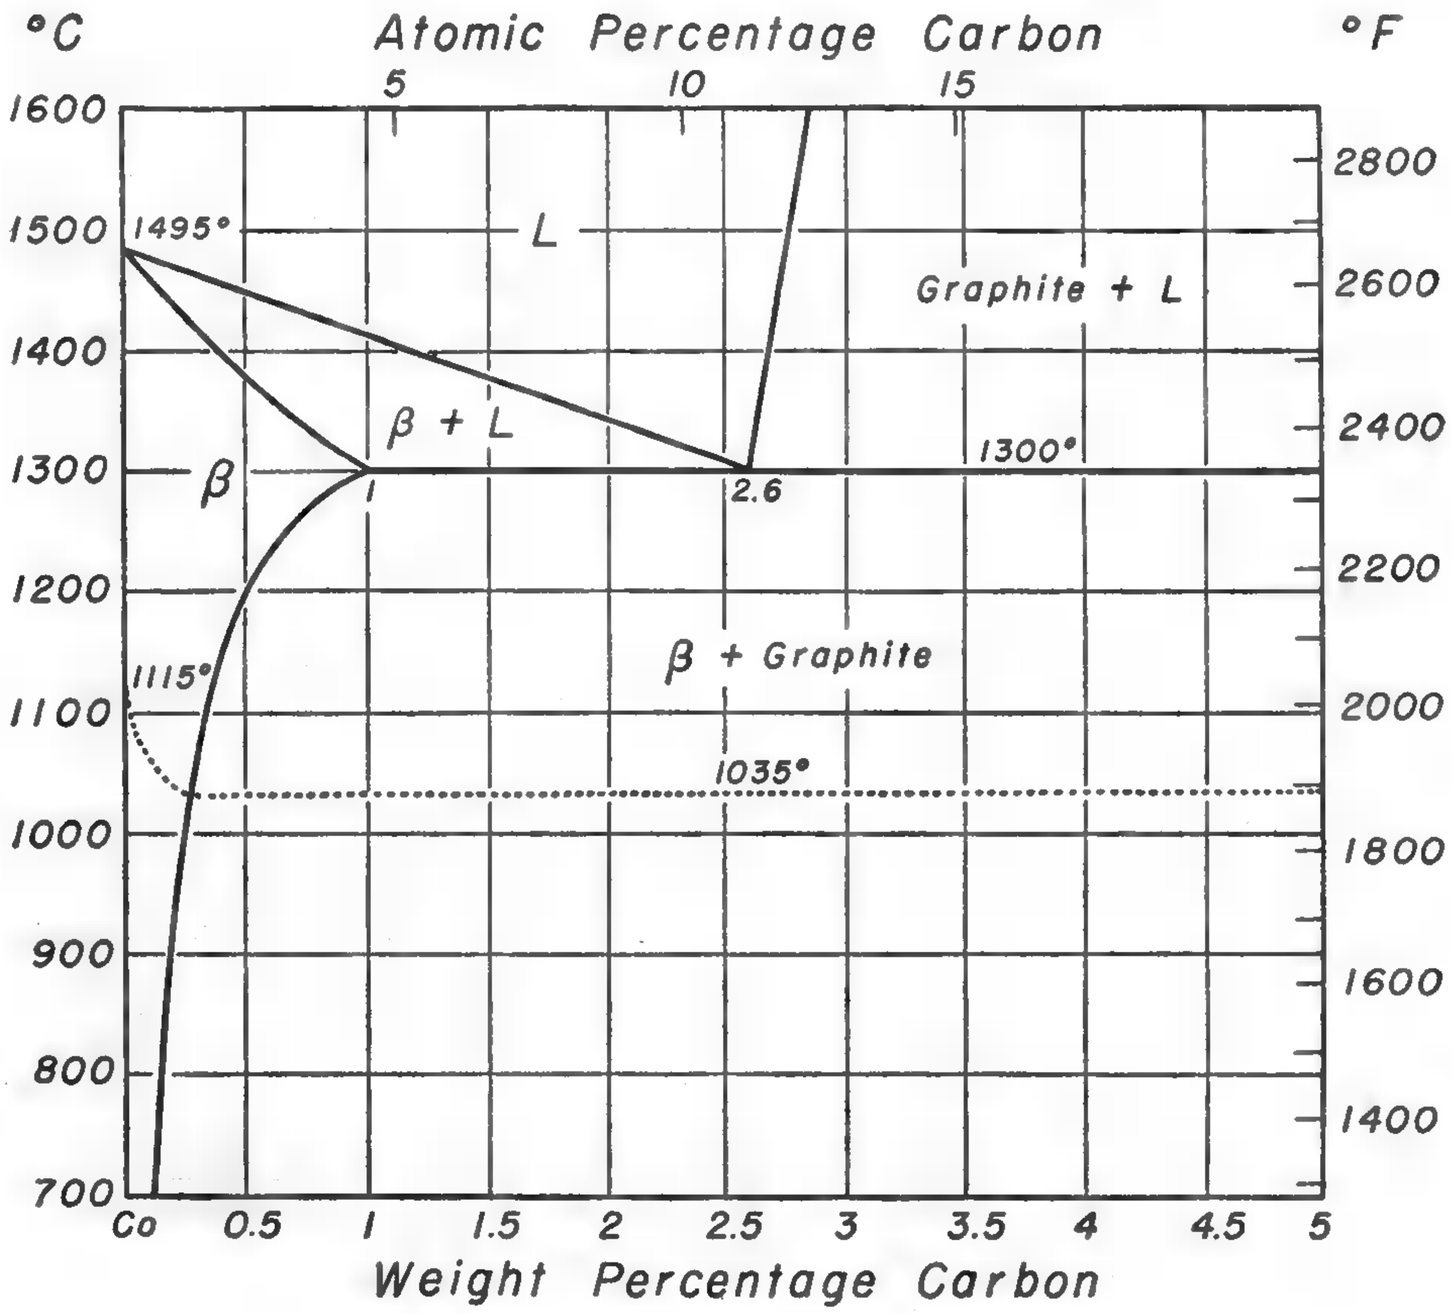
C-Co Carbon-Cobalt

By W. P. Sykes*



The accompanying diagram is based on the extremely meager amount of data appearing in the literature.[1,2] One investigator[2] thinks it likely that a carbide, Co_3C, forms the second solid phase of the eutectic, but that this carbide decomposes so readily that it can be retained only by a most drastic quench from the molten state.

As indicated by the dotted line on the diagram, carbon in solution in β cobalt lowers the magnetic transformation temperature from 1115 to 1035 C.

Recently a new cobalt carbide, described as Co_2C (9.3% C), has been prepared by reacting carbon monoxide with cobalt at 230 C.[3] The stability of this phase with respect to α cobalt and graphite is not known. Measurements of the lattice parameter of carburized α cobalt give no evidence of any solid solubility of carbon in α cobalt.[3]

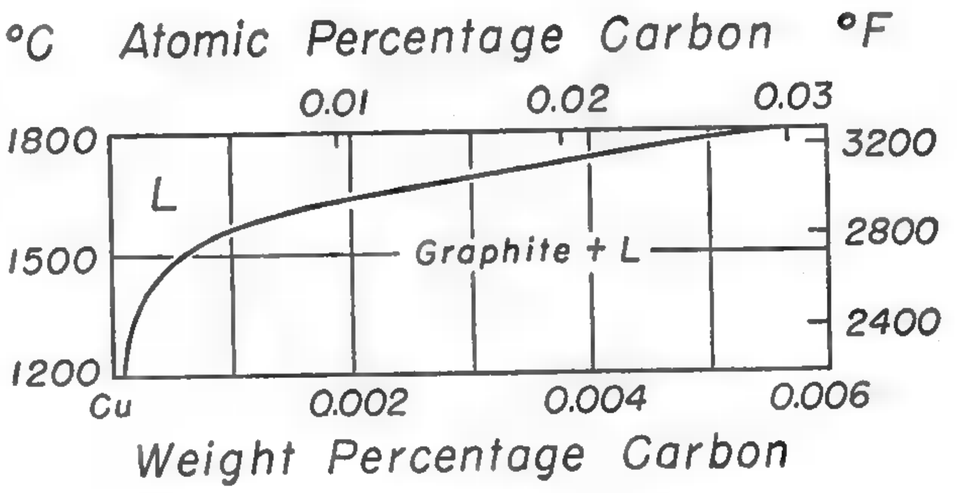
C-Cu Carbon-Copper

The solubility of carbon in liquid copper is shown in the adjoining diagram according to the results of Bever and Floe [Trans AIME, 166, 128 (1946)]. These investigators reported also that the solubility of carbon in molten tin bronzes is approximately the same as in pure copper. It is not known whether the carbon-copper system is of the eutectic or peritectic type.

This system is of interest principally because of the relation between the solubility of carbon and the formation of insoluble carbonaceous gases when the carbon-bearing copper is exposed to oxidizing conditions.



C-Fe Carbon-Iron

By J. B. Austin*

The common names for the alpha, gamma and Fe_3C phases are, respectively, ferrite, austenite and cementite. Cementite is unstable with respect to graphite and the iron solutions. The dashed lines on the diagram represent equilibriums in the stable system iron-graphite; the solid lines represent the metastable iron-cementite system.

Ferrite dissolves 0.025% C at the eutectoid temperature;[6] the solubility is undoubtedly less at lower temperatures.

The crystal structures and lattice parameters of the phases are, as follows: α, body-centered cubic, $a = 2.8610$ kX at 20 C; γ, face-centered cubic, $a = 3.64$ at 910 C; δ, body-centered cubic, $a = 2.92$ at 1400 C; Fe_3C, orthorhombic, $a = 4.5155$, $b = 5.0773$, $c = 6.7265$ at 25 C; graphite, hexagonal, $a = 2.46$, $c = 6.78$ at 20 C.

The variation of the lattice parameter of austenite with carbon content in the range 750 to 1100 C, can be expressed approximately by the relation:

$$Increase\ in\ parameter = 0.0027 \times (\%C \times 10)^3$$

C-Mn Carbon-Manganese

By W. P. Sykes*

The available data on this system do not warrant the construction of a phase diagram. However two carbides of manganese have been isolated and identified.[1,2] These were prepared by dissolving carbon in molten manganese, and are isomorphous with $Cr_{23}C_6$ and Cr_7C_3. The following lattice dimensions are reported: $Mn_{23}C_6$, cubic, $a = 10.564$ kX; Mn_7C_3, trigonal, $a = 13.87$ kX, $c = 4.53$ kX.

C-Mo Carbon-Molybdenum

By W. P. Sykes*

Solid molybdenum dissolves about 0.1% C at 2000 to 2100 C.[1] The β phase appears to be a solid solution dissolving carbon interstitially in a close-packed hexagonal lattice.[1,2,3] The limiting composition on the carbon-rich side is probably 5.88% C, represented by the formula Mo_2C.

The higher-carbon intermediate γ phase appears to form most readily at temperatures above 2400 C, but the homogeneity range and the crystal structure of this phase have not been determined.[1]

C-Ni Carbon-Nickel

By T. E. Kihlgren* and J. T. Eash*

The system presented is based principally on the work of Ruff and others, and Kasé. The solid solubility of carbon in nickel between 1300 and 995 C is represented according to unpublished results obtained by R. H. Schaefer. The solid solubility of carbon at 500 C is estimated to be about 0.03%.

The compound Ni_3C containing 6.42% C has been reported to exist between 1500 and 2500 C, but it is endothermic and very unstable.[2,4]

The Curie temperature of nickel (353 C) is not affected appreciably by carbon.

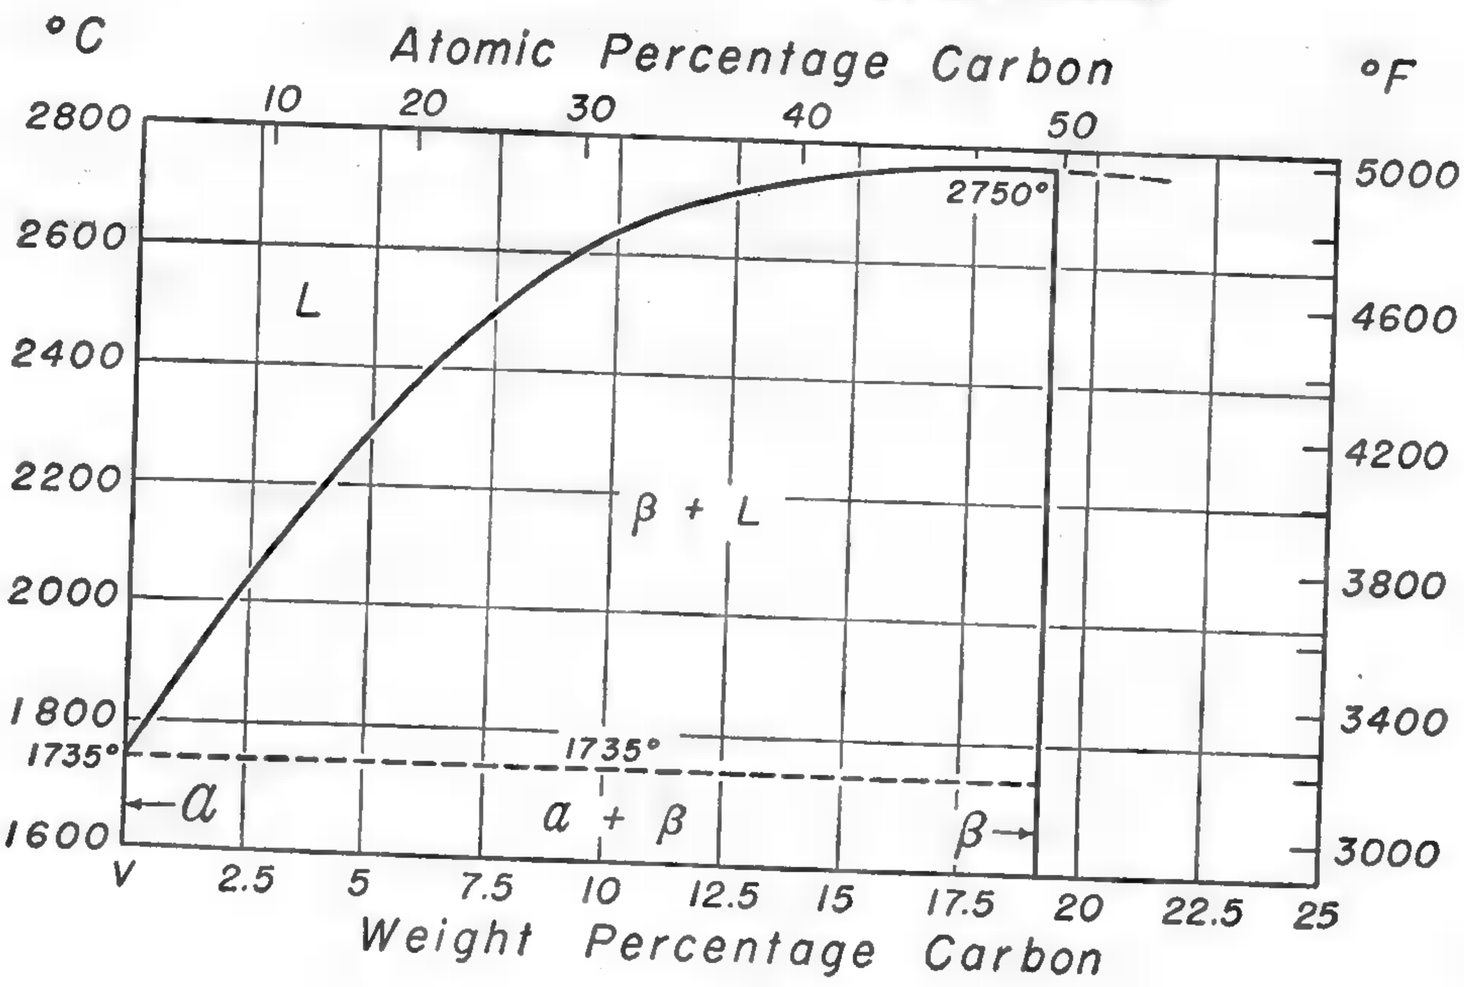
C-V Carbon-Vanadium

By W. P. Sykes*



Carbon is soluble to a very limited extent in solid vanadium.[1] No quantitative data regarding such solubility have been reported. The solidus and liquidus temperatures are shown in the diagram as determined by Ruff and Martin.[2]

The β phase is apparently the carbide VC, having a theoretical carbon content of 19.1%.[2,3,4] Phases corresponding to the formulae V_5C, V_4C_3 and V_2C have been reported,[2,5] but the existence of these phases has not been confirmed. The β phase is cubic (NaCl type) with $a = 4.30$ kX.

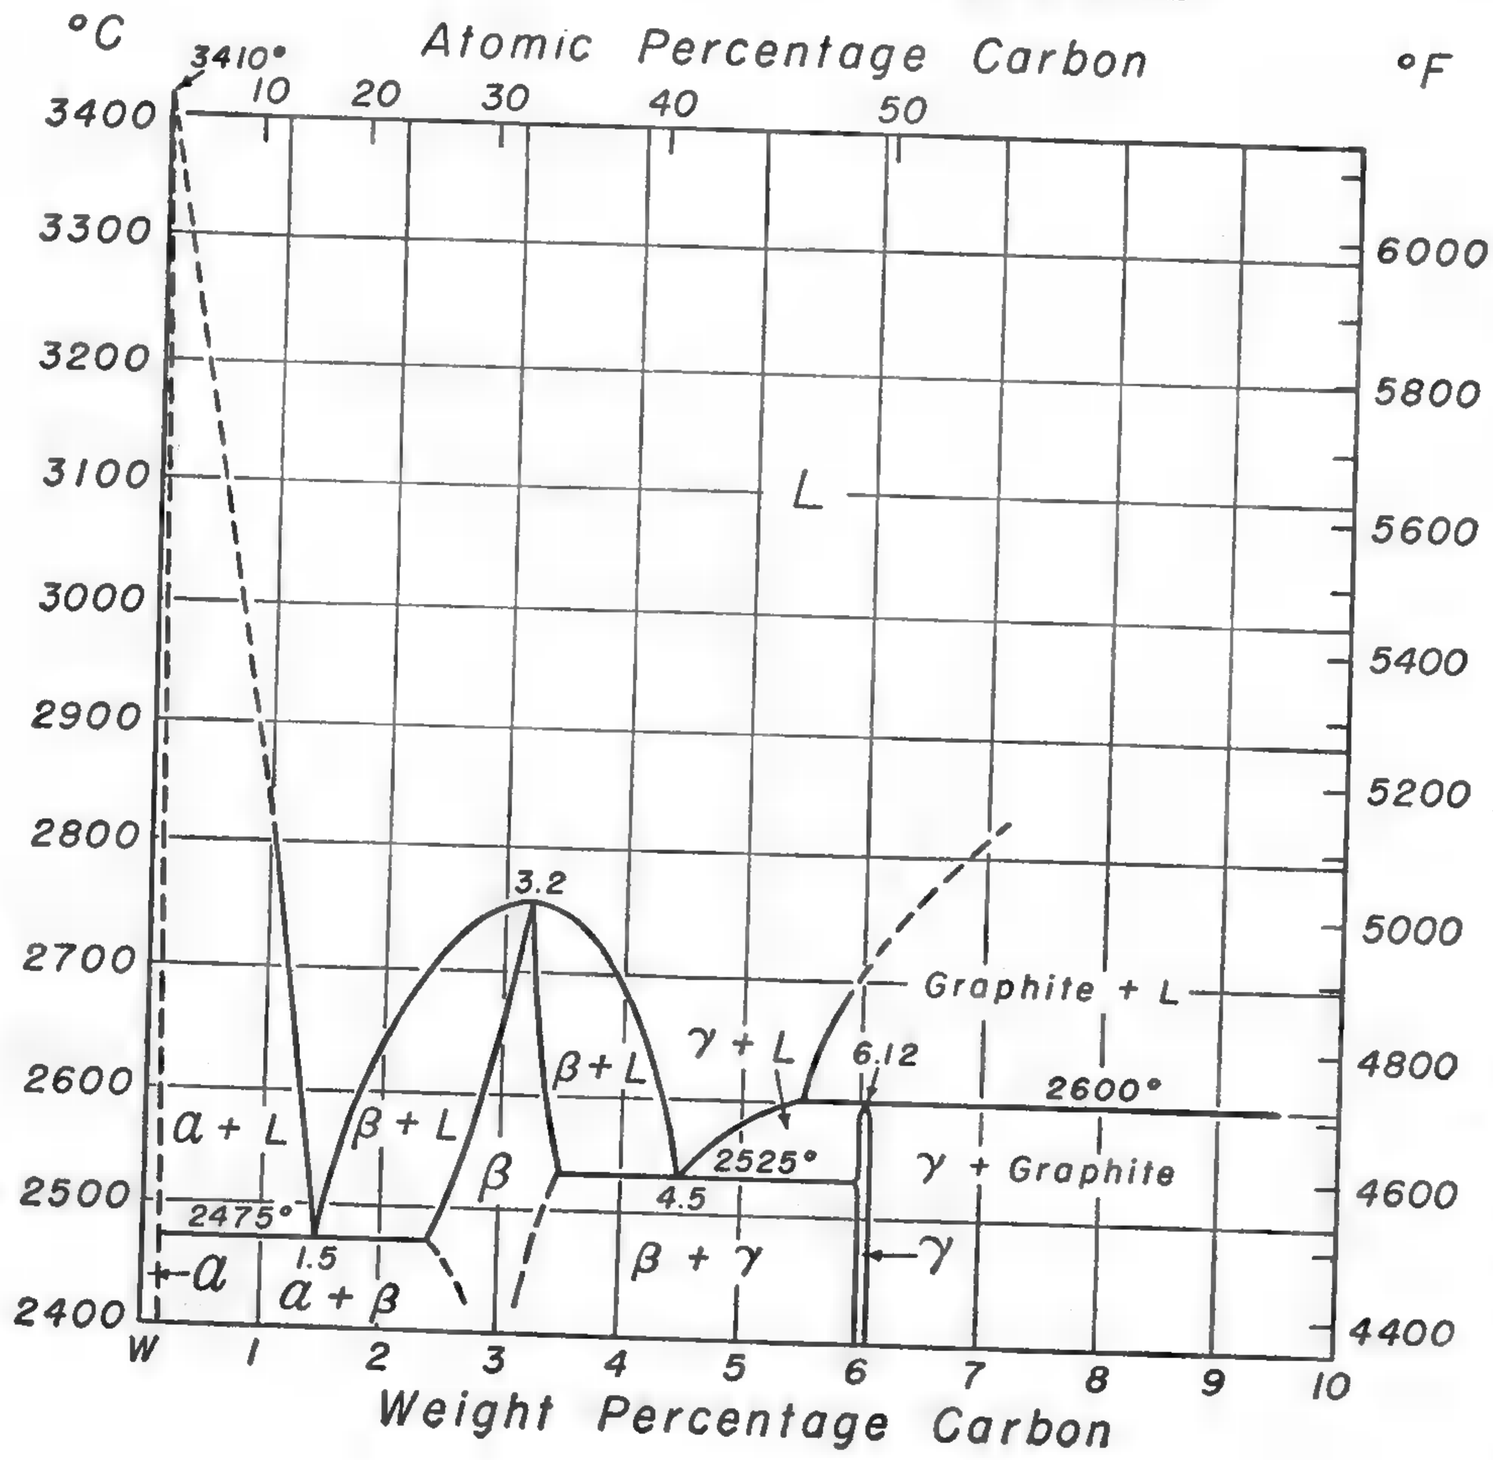
C-W Carbon-Tungsten

By W. P. Sykes*



The solubility of carbon in solid tungsten is less than 0.1% at the eutectic temperature.[1,2] The β phase, corresponding to the formula W_2C, has been reported[3] to undergo an allotropic transformation at about 2400 C but this observation has not been confirmed.

Upon heating to 2600 C the γ phase, corresponding to WC in composition, decomposes into graphite and liquid.

Although both W_2C and WC are rated on the Mohs hardness scale as 9+ it was reported that W_2C is less effective than WC as an abrasive.[4]

The β phase is close-packed hexagonal with $a = 2.99$ kX, $c = 4.71$, $c/a = 1.57$; γ is hexagonal with $a = 2.90$, $c = 2.83$, $c/a = 0.97$.

Ca-Cu Calcium-Copper

By A. C. Vaughan*

The diagram is essentially that of Baar[1] and indicates some uncertainties. Copper is appreciably soluble in calcium but the boundaries of this terminal solid solution (γ) have been extrapolated from determined eutectic points at 560 C.

The compound β found by Baar to be $CaCu_4$, using thermal and microscopic methods, has been revised by Haucke[2] and Nowotny,[3] using X-ray methods, to $CaCu_5$ (88.8% Cu) and is so shown in the diagram. The compound is hexagonal with unit cell dimensions by Haucke, $a = 5.082$ kX, $c = 4.078$ kX; by Nowotny $a = 5.097$ kX, $c/a = 1.579$. The diagram shows eutectic mixtures of β and γ at 38% Ca and 560 C, and of α and β at 94% Cu and 910 C.

Baar observed weak thermal effects at 482 C on the cooling curves of alloys containing 10 to 76.5% Cu, which Hansen[4] states have not been explained satisfactorily.

Solid copper dissolves less than 0.1% Ca.[5]

Ca-Mg Calcium-Magnesium

By G. F. Sager† and B. J Nelson†

The solubility of magnesium in solid calcium has not been determined. The solubilities of calcium in solid magnesium have been reported, as follows: 1.8% at 517 C, 1.2 at 500, 0.8 at 300, 0.5 at 250.

The β phase ($CaMg_2$) is hexagonal with $a = 6.22$ kX and $c = 10.10$ kX.[7]

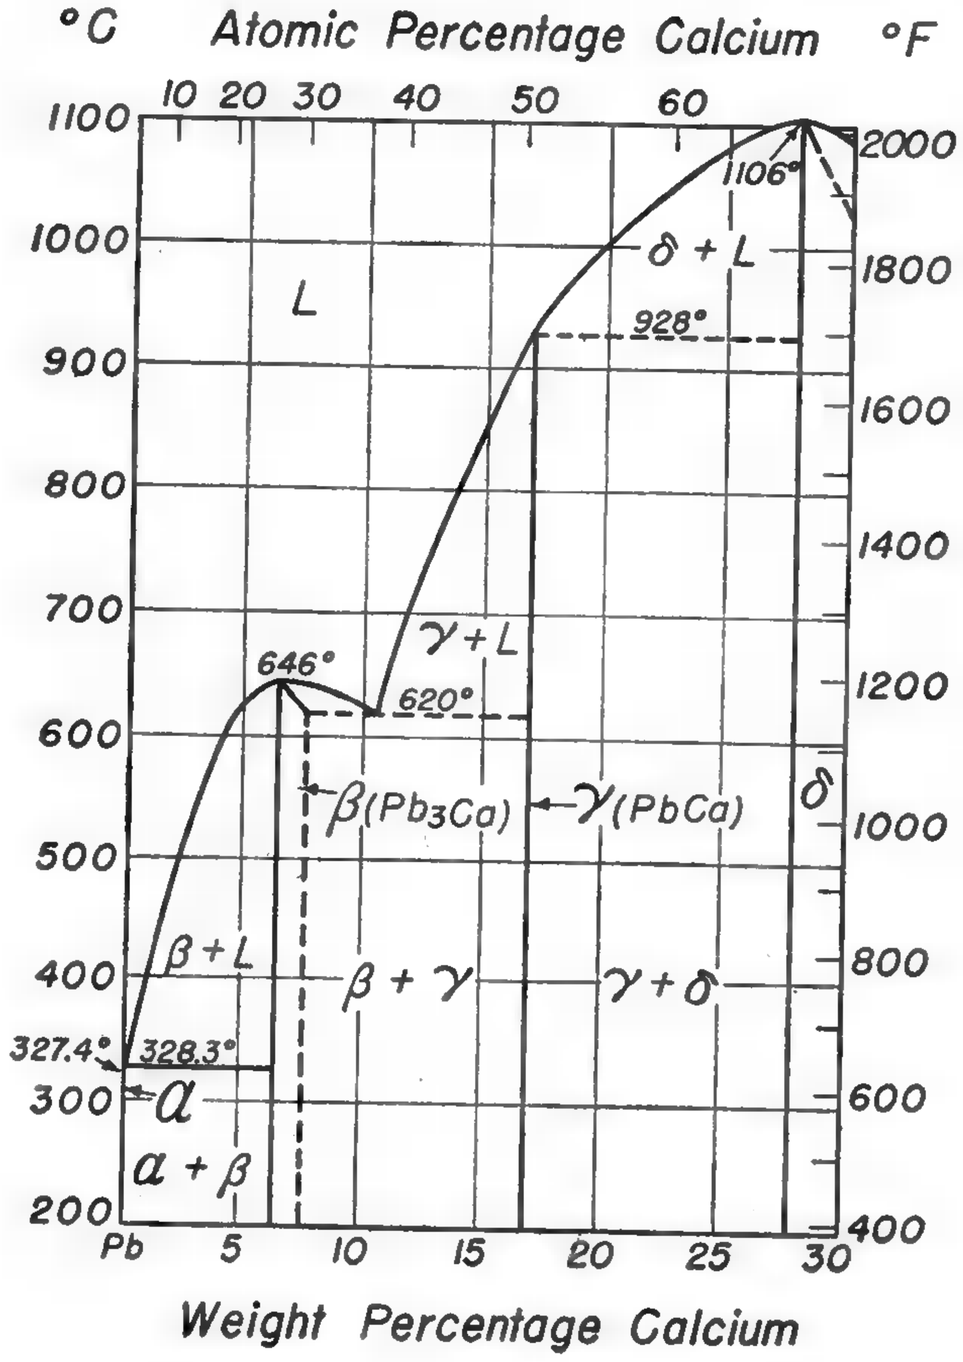
Ca-Pb Calcium-Lead

By E. E. Schumacher* and G. M. Bouton*



The γ and δ phases disintegrate rapidly in moist air. The β phase is not rapidly affected. The rate at which β precipitates from supersaturated α is greatly affected by the cooling rate; slowly cooled alloys with 0.03% Ca may not show precipitation for a year, but agglomeration is rapid at 220 C in alloys that contain 0.01 to 0.1% Ca.

In the calcium-rich portion of the system, there is a eutectic reaction at about 700 C involving δ (about 38% Ca), liquid (about 58% Ca), and calcium.

β, γ and δ are Pb_3Ca, PbCa and $PbCa_2$ respectively.

Cb-Ni Columbium-Nickel*

The β phase (Ni_3Cb) may exist over a range of composition of about 5%.[1] The γ phase, apparently based on NiCb, forms by peritectic reaction of liquid and δ.[1] The δ phase, not shown in the accompanying diagram, may be the terminal solid solution of nickel in columbium. The system has not been investigated beyond 65% Cb.

The solubility of columbium in solid nickel is from the X-ray diffraction results of Grube, Kubaschewski and Zwiauer.[2] Pogodin and Selikmann[1] reported a solid solubility somewhat greater than this at the lower temperatures.

Cd-Cu Cadmium-Copper

By Cyril Stanley Smith*

The liquidus is based on the works of Sahmen[1] and Jenkins and Hanson,[2] which are in excellent agreement. The γ phase (Cd_3Cu_4) does not form on solidification but appears only after prolonged annealing near 500 C. On solidification, even at a very slow rate, a metastable eutectic between δ and β forms at 540 C and 61.3% Cu. According to lattice parameter measurements[5] cadmium has a maximum solubility in copper of 3.0% at 549 C, decreasing to 0.5% at 300 C. The data could be reinterpreted to show appreciably greater maximum solubility. The solubility of copper in cadmium is between 0.005 and 0.10% at 270 C.[3]

The phases β and ϵ correspond exactly to Cu_2Cd and $CuCd_3$ respectively, and seem to have extremely narrow ranges of solid solubility. X-ray diffraction patterns[5] confirm this, though the crystal structures of these phases are not known. The δ phase is of gamma-brass structure,[4] cubic with 52 atoms (4 groups of Cu_5Cd_8) per unit cell; $a = 9.635$ kX.

Cd-Fe Cadmium-Iron†

Cadmium is insoluble in solid iron. Tammann and Oelsen[1] determined the solubility of iron in molten cadmium in the range 400 to 700 C to be 0.0002 to 0.0003%. According to Daniels[2] a compound, Cd_2Fe, exists. This high-melting compound is magnetic, and is less dense than cadmium.[2]

Cd-Hg Cadmium-Mercury‡

The only intermediate phase is tetragonal and extends from about 7 to 60% Cd. Near minus 10 C most compositions of this phase undergo a transition without a change in crystal structure. Two peritectic reactions exist: at minus 34 C (about 1 to 7% Cd) and at 188 C (about 50 to 65% Cd).

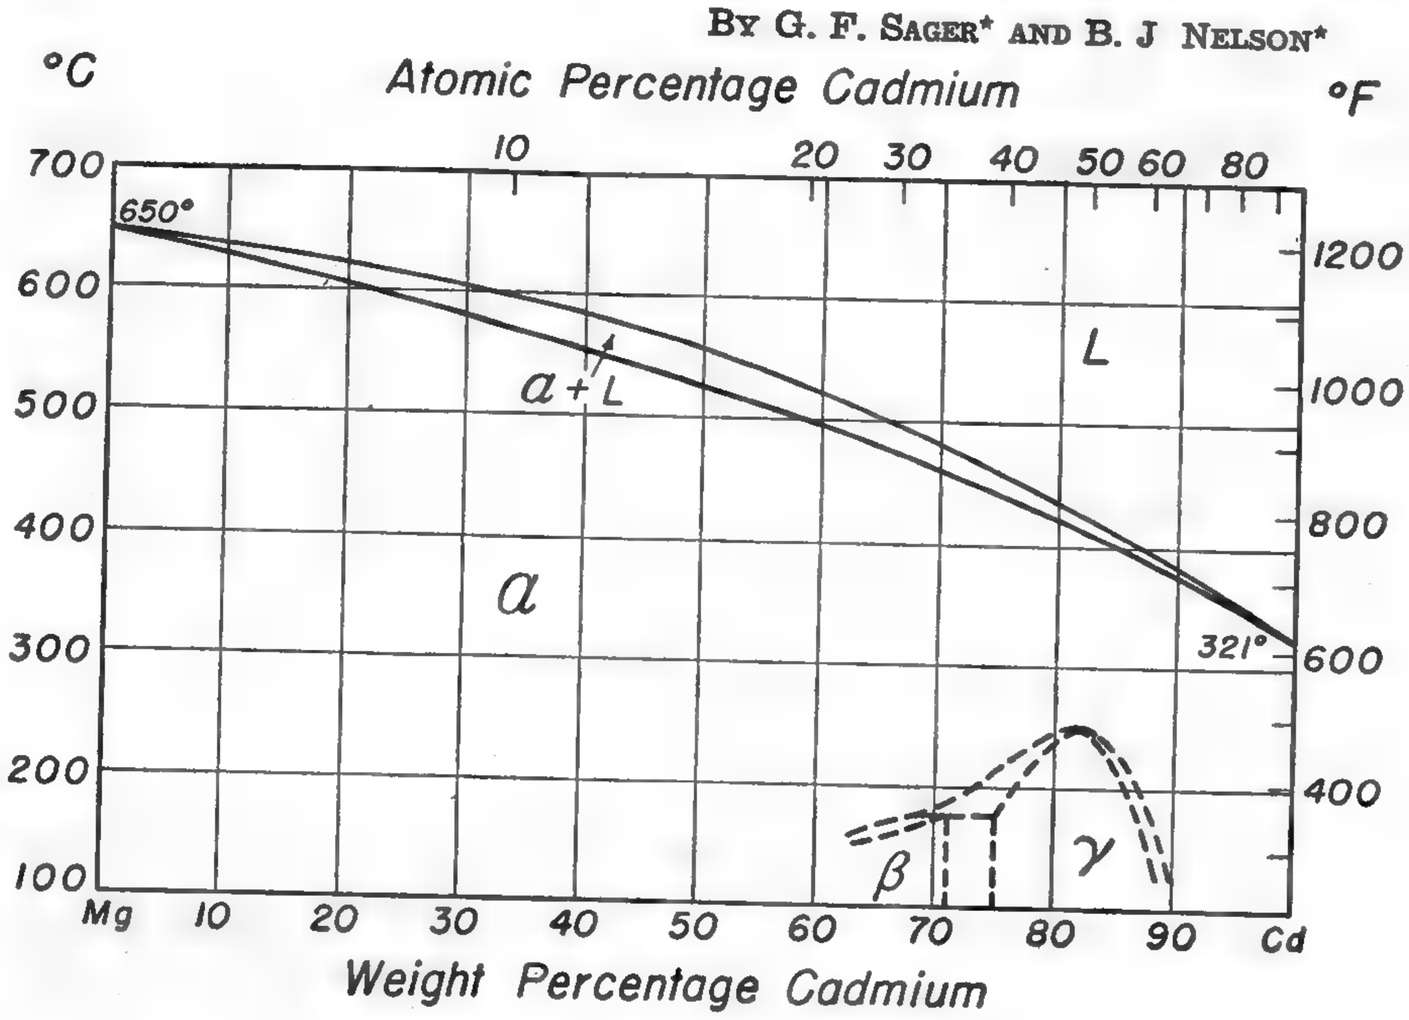
Cd-Mg Cadmium-Magnesium

By G. F. Sager* and B. J Nelson*



Cadmium and magnesium form a complete series of solid solutions with superstructures occurring below 250 C, at compositions corresponding to the formulas Cd_3Mg, CdMg and $CdMg_3$. The superstructure based on Cd_3Mg exists below 100 C,[3,4] but the equilibrium relations of this structure with alpha and gamma are not established.

Cadmium lowers appreciably the boiling point of magnesium alloys, and has a small beneficial effect on mechanical properties.

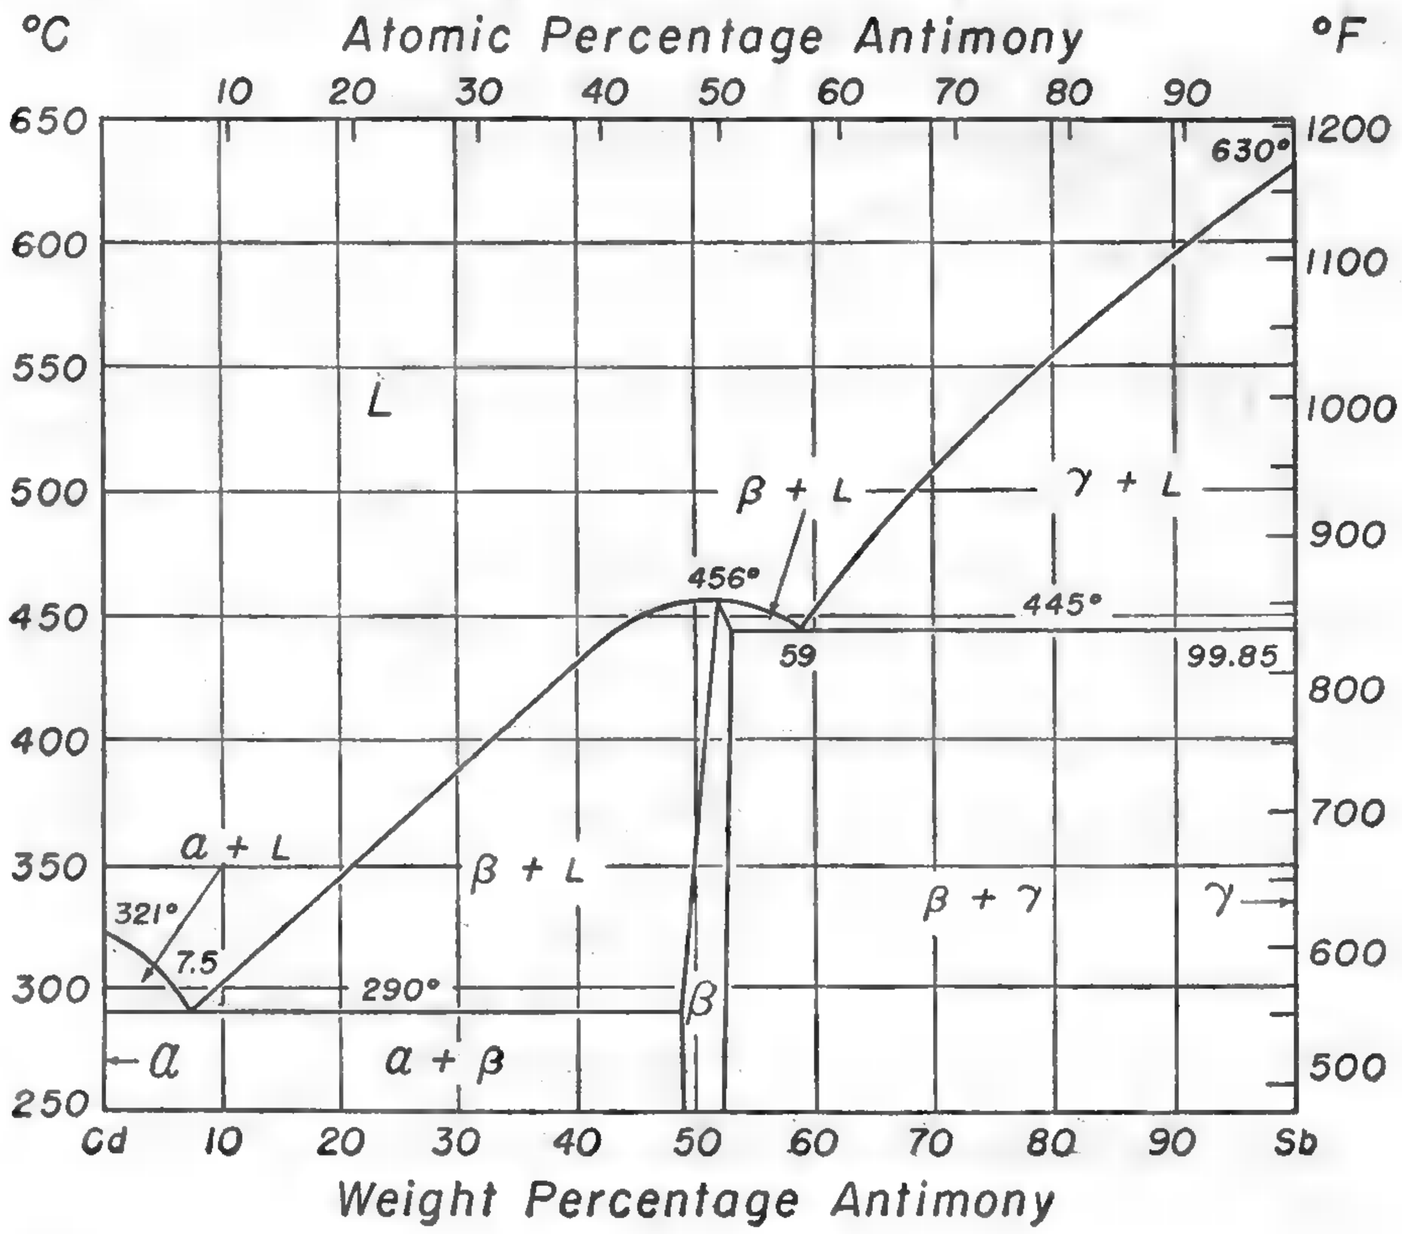
Cd-Sb Cadmium-Antimony

By Louis A. Carapella*



The phase designated here as β is usually referred to as CdSb. Under certain conditions of cooling, a metastable phase based on Cd_3Sb_2 forms instead of CdSb.[1,2,3] The metastable Cd_3Sb_2 phase (44% Sb) melts congruently at 420 C, and transforms eutectoidally at about 250 C.[1] In the metastable system, Cd_3Sb_2 forms a eutectic with cadmium at 8% Sb (285 C), and another eutectic with antimony at 54% Sb (395 C).[1]

The solubility of cadmium in antimony has been reported as 0.15% at 445 C.[1] Apparently the solubility of antimony in solid cadmium is slight.

The crystal structure of CdSb is orthorhombic;[4] Cd_3Sb_2 is monoclinic.[5]

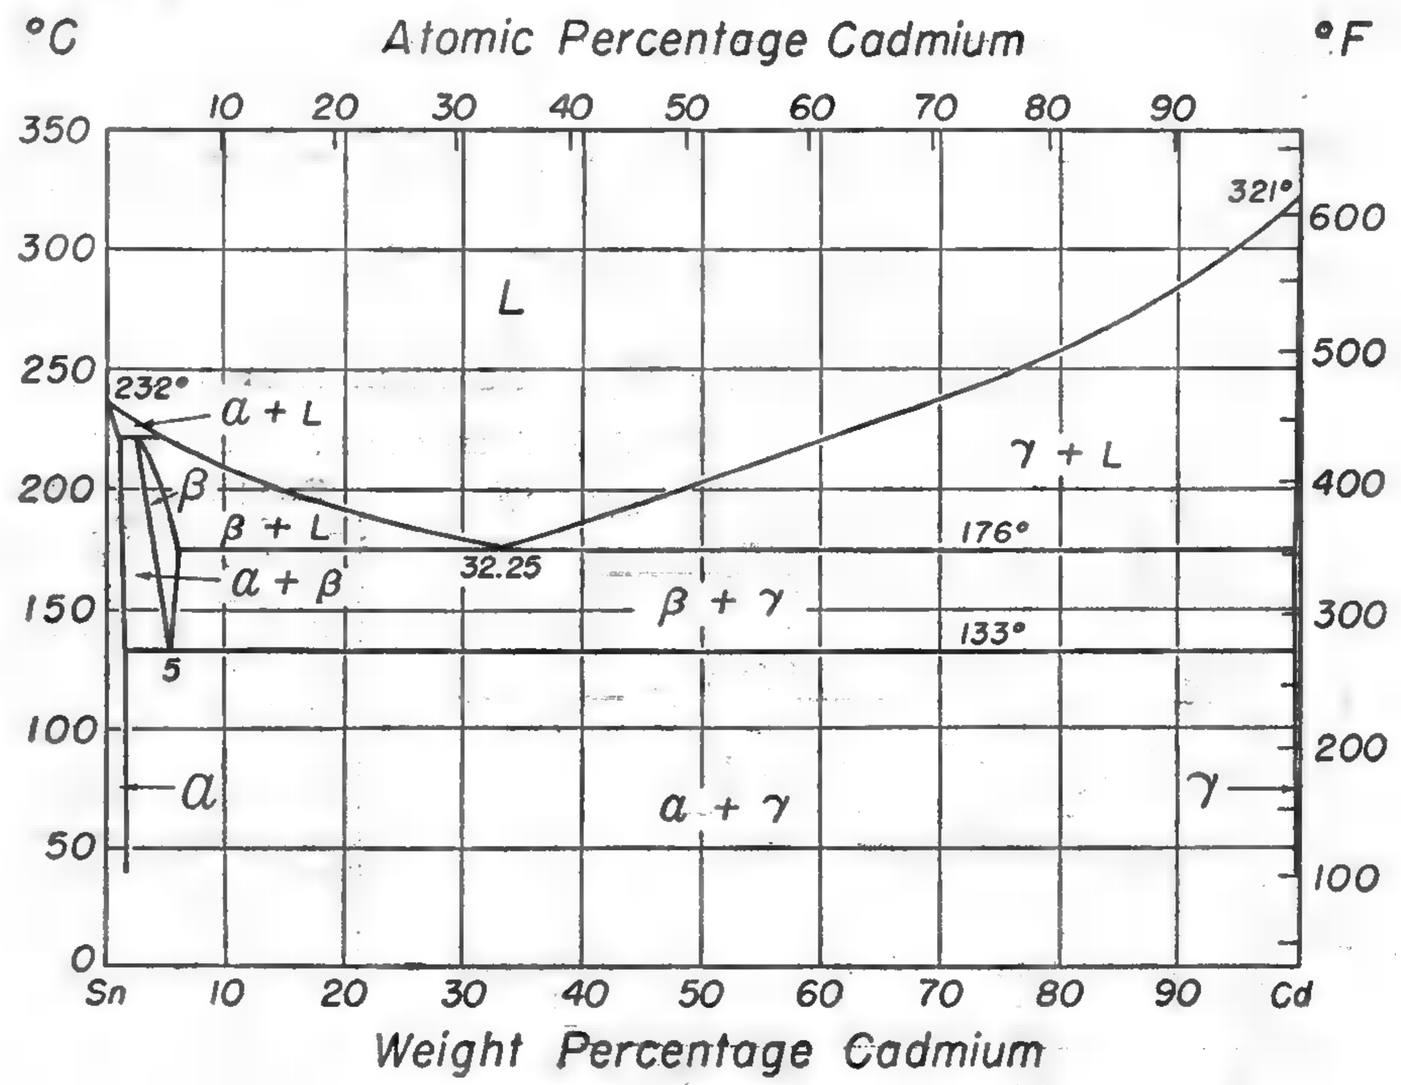
Cd-Sn Cadmium-Tin

By W. T. Pell-Walpole*



The peritectic reaction is readily suppressed by rapid cooling, but the β phase is then formed by direct deposition from the liquid below some (undetermined) temperature between 223 and 176 C.

The eutectoid decomposition of β occurs at 133 C under conditions of stable equilibrium. On cooling, the temperature of the eutectoid change is lowered to between 122 and 132 C; on heating, it is raised to between 135 and 140 C, depending on the rates of cooling or heating employed.

The sudden change in the solubility of tin in cadmium at 170 C causes a slight thermal arrest at this temperature in all alloys that contain the γ phase.

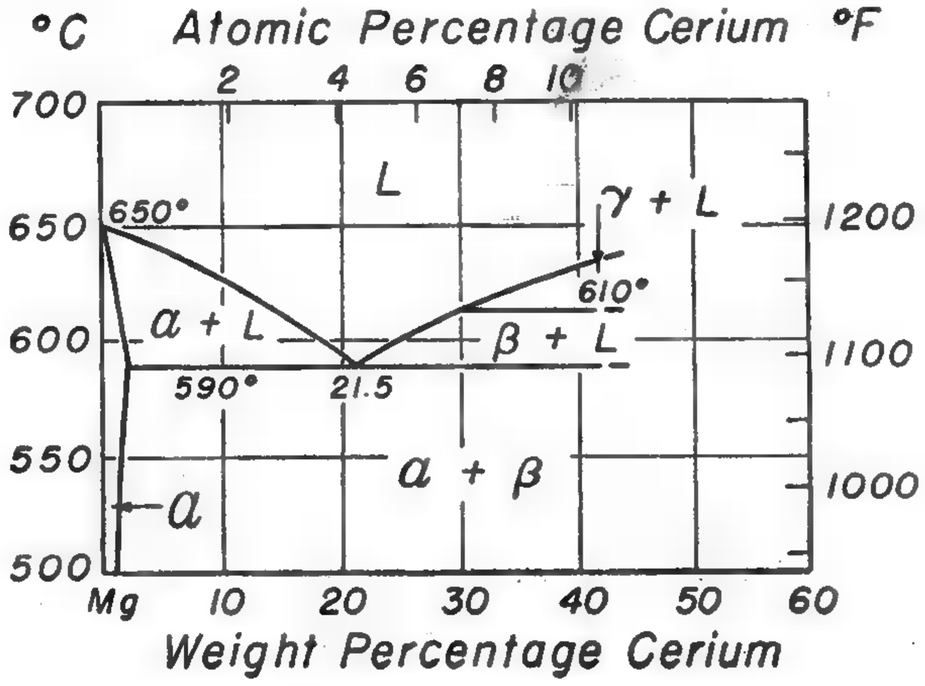
Ce-Mg Cerium-Magnesium

By G. F. Sager* and B. J Nelson*



The partial diagram is based on alloys made with cerium having a purity of 97.7%.[1] The results of other investigators have not been accepted because the purity of the cerium used was not reported, or because mischmetal was employed instead of cerium.

The solubility of cerium in magnesium is, as follows: 1.6% at 590 C, 1.0 at 550, 0.5 at 500, 0.15 at 337.

Cerium in magnesium alloys greatly increases the hardness and tensile strength of wrought alloys. Cerium-containing alloys retain a considerable part of their strength and hardness at temperatures up to 260 C. Cerium also gives exceptional creep resistance to magnesium alloys.[2] Magnesium-cerium alloys were used for supercharger impellers, cam-follower guides, and housings on a German aircraft engine during World War II.

Co-Cu Cobalt-Copper

By Cyril Stanley Smith*

Though Konstantinov[1] showed a two-liquid field extending from 32 to 72% Cu and Jitsuka[2] also found this, Sahmen[3] found no liquid segregation and his data are to be preferred. By analogy with the diagram for the copper-iron system, which also shows a nearly flat liquidus, it is expected that very small amounts of impurities will cause segregation into two liquids between 32 and 72% Cu.

The solubility of cobalt in copper has been established by both magnetic[5] and microscopic[4] examination. The solubility of copper in cobalt is placed at 10% as a result of Sahmen's thermal analysis data and his measurements of the temperature of the magnetic transformation of copper-cobalt alloys. Nothing is known concerning the effect of copper on the α-β transformation of cobalt at about 420 C.

Co-Fe Cobalt-Iron

By W. C. Ellis* and E. S. Greiner*

There is good agreement among investigators concerning the location of the α-γ transformation except for the steeply descending portion in the region of 80% Co. The data used in constructing this portion of the diagram are from X-ray diffraction measurements.[14] The magnetic change[7] coincides with the γ boundary from about 13 to 73% Co. The α solid solutions in the region of equal atom ratios of iron and cobalt undergo ordering.

There is no general agreement on the temperature of the ϵ-γ transformation of cobalt, which has been located at 420 C.[3-8,12,15] The two phases often coexist below 420 C.

* Bell Telephone Laboratories, Inc., Murray Hill, N.J.

Crystal Structures and Lattice Parameters of Cobalt-Iron Alloys[14,16]

Co-Pt Cobalt-Platinum

By R. I. Jaffee*

On freezing, cobalt-platinum alloys form a complete series of face-centered cubic solid solutions. The liquidus curve has a rather flat minimum at 1450 C and 50% Co. A face-centered tetragonal superstructure forms at the composition corresponding to PtCo (23% Co) during annealing below 800 C, as reported by Gebhardt and Köster[1] and by Hultgren and Jaffee.[2] The latter also found evidence of a body-centered cubic phase at this composition, in specimens annealed at 400 C; Jellinghaus[3] also reported that this phase was present in a cast 23% Co alloy. The ordered PtCo alloy has stronger permanent-magnet properties than any other known material.

Cr-Cu Chromium-Copper

By Cyril Stanley Smith*

The liquidus and solidus shown are essentially those of Siedschlag,[2] but the liquidus has been modified to show the melting point of chromium at 1800 C instead of 1550 C, which was the melting point of the impure chromium that he used. Obviously, other parts of the diagram must also be affected by impurities. The extent of the two-liquid field is particularly uncertain.

The values shown for the solubility of chromium in copper are those of Alexander[3] but his extrapolation to the eutectic temperature is not accepted. The values given by Corson[4] are somewhat higher than these—0.8 to 0.25% Cr at 1000 C and 500 C, respectively. The alloys must be quenched from about 1000 C if they are to be subsequently age hardened.

Cr-Fe Chromium-Iron

By E. C. Bain* and R. H. Aborn*

Sigma is a brittle nonmagnetic phase,[1] having the properties of an intermetallic compound approximating FeCr, but capable of dissolving a few per cent of either iron or chromium. Sigma forms from alpha at an extremely slow rate in pure alloys that have not been cold worked. The boundary between α and $\alpha + \sigma$ (from 60 to 67% Cr) is indicated as a shaded band because of uncertainty as to the exact location, owing to possible segregation in the alloys.[2]

The crystal structure of σ has not been determined with certainty but this phase appears to have a complex body-centered cubic structure.[3] The lines of the diffraction pattern are reported[3] to be not always identical, from which it has been suggested that two modifications can occur—one stable and the other a transitional structure.

The brittle phase σ is doubtless responsible for a marked embrittlement that occurs under certain conditions in the alloys with more than about 25% Cr.

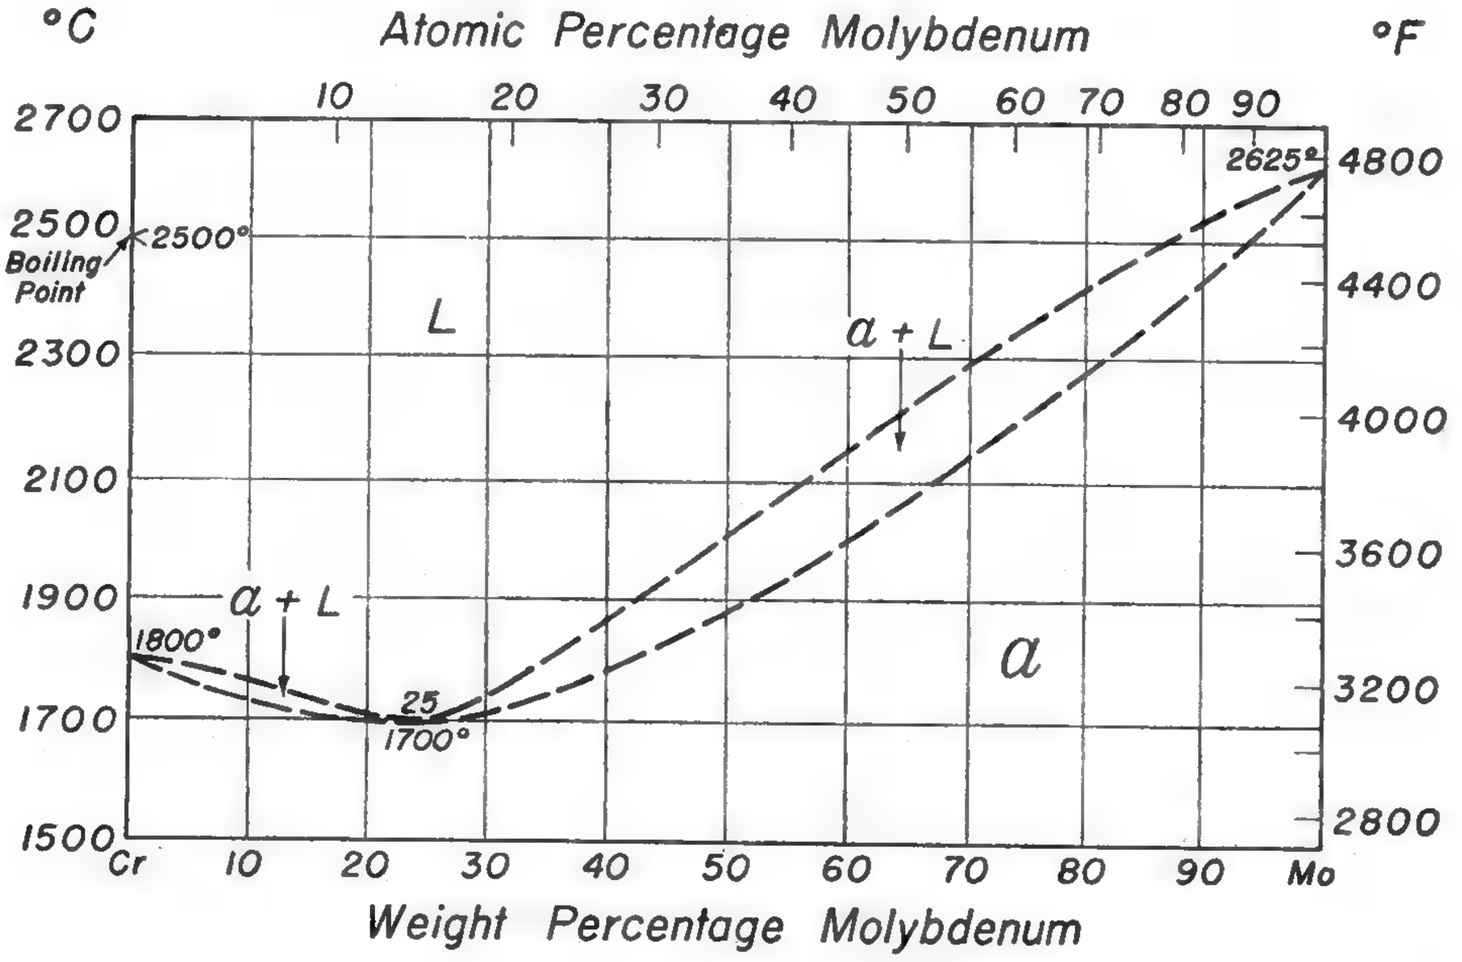
Cr-Mo Chromium-Molybdenum

By W. P. Sykes†



Published X-ray results[1] indicate that chromium and molybdenum are completely soluble in all proportions in the solid state. More recent unpublished data obtained by R. M. Parke and A. J. Herzig confirm the conclusion that there is only one solid phase in this system. The liquidus and solidus have not been determined accurately.

Cr-Ni Chromium-Nickel

By E. M. Wise* and J. T. Eash*

The Curie temperature of nickel is lowered rapidly by the addition of chromium in solid solution. The results of Marian[1] are as follows:

Weight Percentage Chromium	Curie Temperature, deg Cent
0	353
1	310
2	270
3	225
4	170
5	115
6	60
7	10

Cr-Pb Chromium-Lead

According to the results of Hindrichs [Z anorg allgem Chem, 59, 428 (1908)], the phase diagram for the chromium-lead system is similar to those for the copper-lead and chromium-copper systems. The chromium used in this investigation contained 1.20% Fe and 0.32% Si, and the melting point of this impure metal was 1550 C — 250 C lower than the melting point of pure chromium. Obviously other parts of the diagram must be affected by impurities. The monotectic point was reported as 1470 C and 28% Pb, and the monotectic horizontal was reported as extending to between 75 and 100% Pb. No effect of chromium on the melting point of lead was noted.

Cr-Si Chromium-Silicon

Kurnakov [Compt rend (Doklady) Acad Sci URSS, 34, 110 (1942)] investigated the entire system using alloys prepared from pure metals. Chromium dissolves about 7.5% Si. There are five intermediate phases. Cr_3Si (15.54% Si) melts at 1750 C, Cr_2Si (about 20% Si) at 1606 C, Cr_3Si_2 (about 25% Si) at 1550 C, CrSi (about 35% Si) at 1630 C, and $CrSi_2$ (about 53% Si) at 1500 C. There are five eutectics: α and Cr_3Si at 1515 C and 11.93% Si, Cr_3Si and Cr_2Si at 1593 C and 15.98% Si, Cr_2Si and CrSi [*sic*] at 1400 C and 28.1% Si, CrSi and $CrSi_2$ at 1445 C and 42.04% Si, and $CrSi_2$ and silicon at 1304 C and 76.1% Si. The preceding data are from an abstract [Met Abs, 10, 243 (1943)].

Cr-Pd Chromium-Palladium

The constitution of chromium-palladium alloys was investigated by Grube and Knabe [Z Elektrochem, 42, 793 (1936)], by means of thermal, microscopic, X-ray, hardness and electrical measurements. A face-centered cubic intermediate phase, Pd_2Cr_3, was reported, with melting point at 1398 C (42% Cr). There is a minimum in the liquidus curve of the palladium-rich solid solution at 1300 C and 38% Cr. Pd_2Cr_3 and the chromium solid solution form a eutectic at 1320 C and 59.5% Cr. The solubility of palladium in chromium is about 10% at the eutectic temperature. The phase diagram of Grube and Knabe shows no equilibrium between the palladium-rich solid solution and Pd_2Cr_3.

Cr-W Chromium-Tungsten

According to the results of Kubaschewski and Schneider [Z Elektrochem, 48, 671 (1942)], chromium and tungsten form a continuous series of solid solutions, with a minimum melting point at 30% W and 1720 C. Trzebiatowski, Ploszek and Lobzowski [Analytical Chemistry, 19, 93 (1947)] have confirmed the unlimited solid solubility at 1700 C, by means of X-ray measurements. However, they found a miscibility gap at lower temperatures, with solubilities as follow: at 1000 C, 16% W in chromium and 4.5% Cr in tungsten; at 1200 C, 21% W in chromium and 4.5% Cr in tungsten; at 1430 C, 65% W in chromium and 12% Cr in tungsten. The critical temperature was not determined.

Cr-Pt Chromium-Platinum

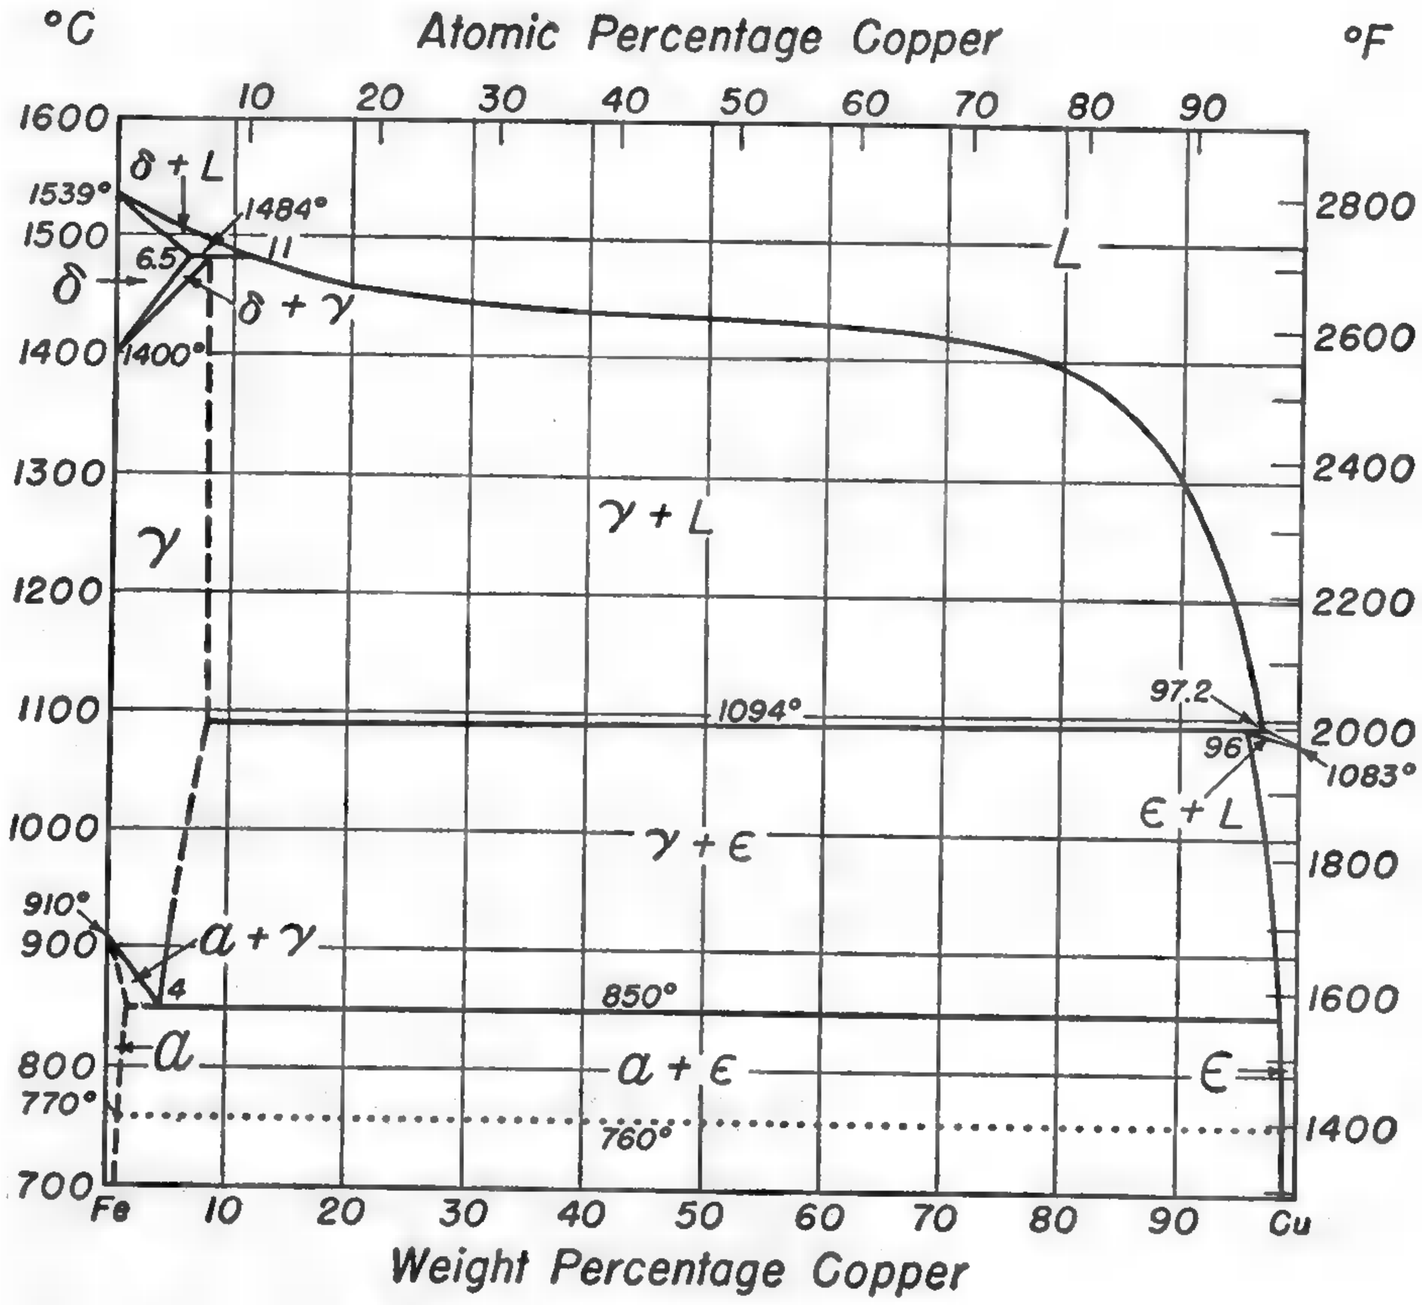
The liquidus descends from the melting point of platinum to about 1400 C at about 50% Cr. Compounds based on $PtCr_3$, PtCr and Pt_3Cr probably exist at low temperature. Ordered face-centered cubic alloys with about 6 to 17.5% Cr are ferromagnetic. (R. F. Vines, "Platinum Metals and Alloys")

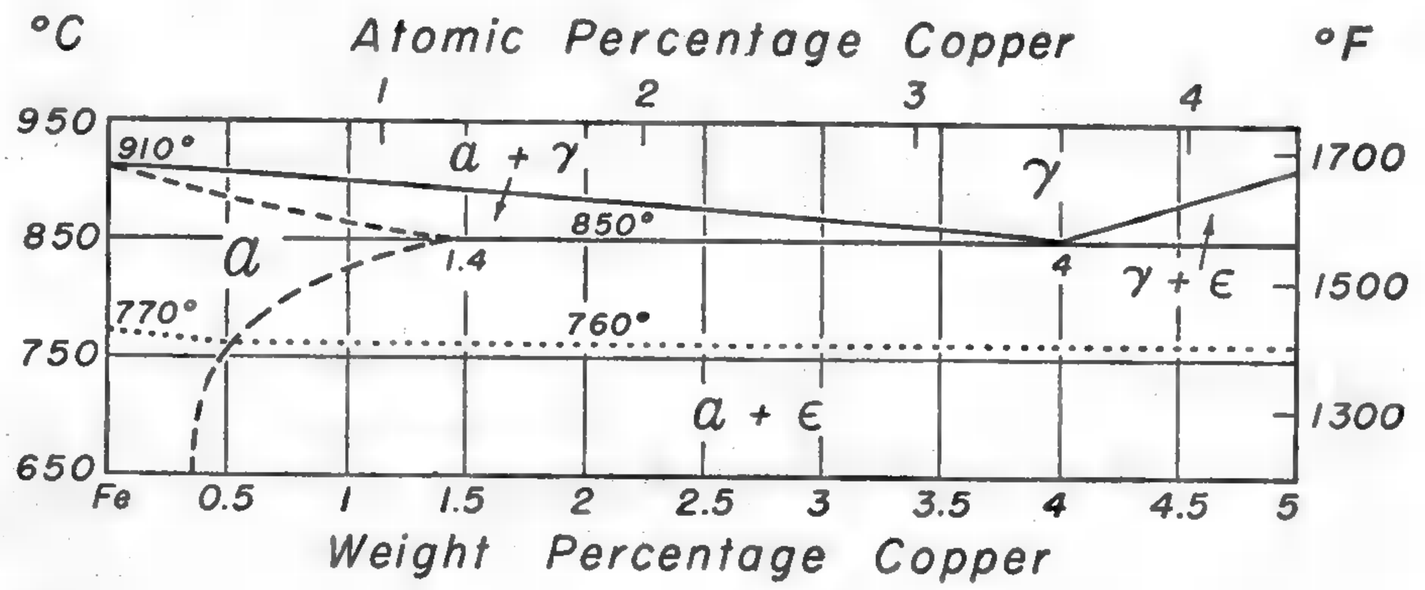
Cs-Fe Cesium-Iron

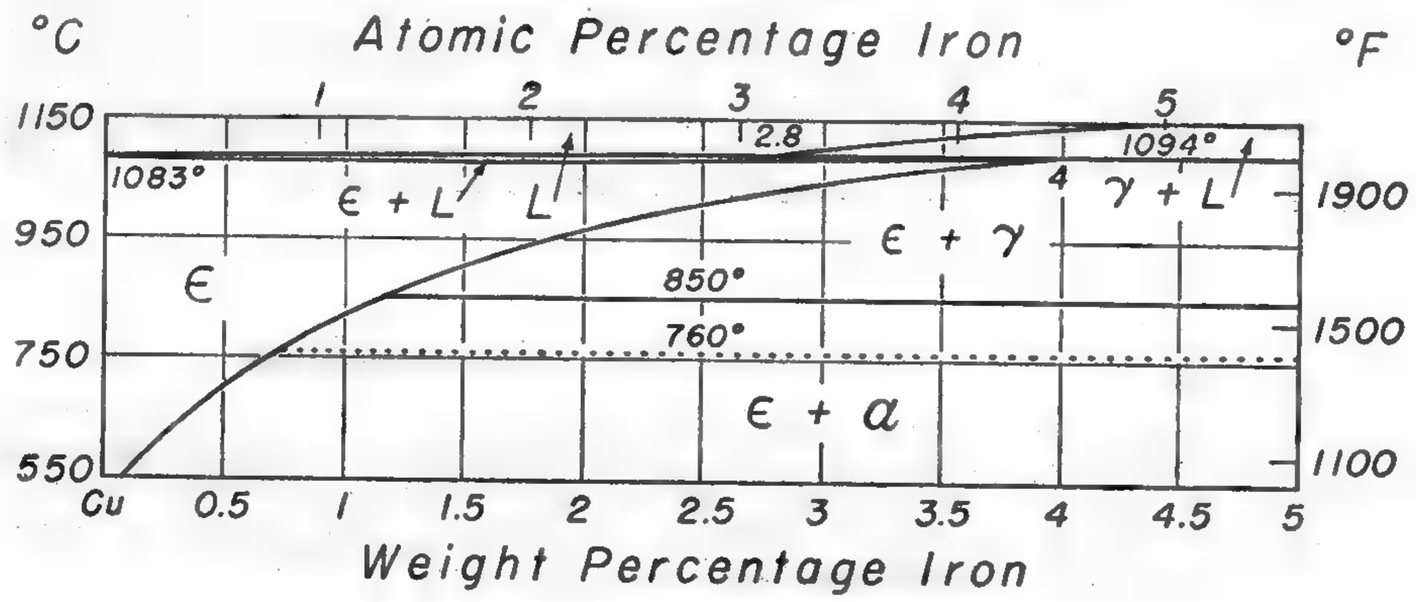
Iron is insoluble in liquid cesium. Cesium is insoluble in solid iron. Although the solubility of cesium in liquid iron is not known, the formation of iron-cesium alloys is considered improbable. (M. Hansen, "Der Aufbau der Zweistofflegierungen", J. Springer, Berlin, 1936)

Cu-Fe Copper-Iron

By B. N. Daniloff*







The boundaries separating the γ from the $\gamma + L$ and $\gamma + \epsilon$ fields have not been accurately determined. The maximum copper concentration of the γ solid solution has been variously reported to be from 8 to 10%[1,2,3,4] at 1484 C, and from 7.5 to 9%[1,2,3,4] at 1094 C. Experiments on sintered compacts of iron and copper showed that the solubility of copper in gamma iron between the peritectic and eutectoid temperatures may be considerably lower than indicated on the diagram, and that the copper solubility lines in gamma and alpha iron may form a nearly continuous curve.*

The solubility of copper in alpha iron at the eutectoid temperature is shown at 1.4% as determined by X-ray diffraction methods.[5] Earlier reports placed the solubility at 3.5% Cu.[6]

The line indicating the solubility of iron in copper has been fairly accurately established.[7,8] The iron-rich phase precipitated from ϵ solid solution remains in a nonmagnetic face-centered cubic form unless cold worked.[9,10,11]

X-Ray Data

Cu-Ga Copper-Gallium

In connection with the theory of alloys, the copper-gallium system is of interest because of its place in the series of systems involving copper with the elements of the B groups (Zn, Ga, Ge, As; Cd, In, Sn, Sb). When plotted on a scale of atomic percentage, the liquidus, solidus and alpha solid solubility curves of the copper-gallium system are at larger copper contents than those of the copper-zinc system, and at smaller copper contents than those of the copper-germanium system.

Cu-Ge Copper-Germanium

Like the copper-gallium system (*see* left-hand column), the copper-germanium alloys are of interest in building a theory of the structure of alloys. The liquidus, solidus and alpha solid solubility curves of copper-germanium alloys are at larger atomic percentages of copper than those of copper-gallium alloys, and at smaller copper contents than those of copper-arsenic alloys. The first intermediate phase in the copper-germanium system is hexagonal, and forms by peritectic reaction at 822.5 C.

Cu-Li Copper-Lithium

By A. C. Vaughan*

Thermal and X-ray methods were used for the investigation of copper-lithium alloys containing from 0.18 to 63.1% Li. No solid solubility of either metal in the other was detected.

The eutectic composition is very close to 100% Li; and the eutectic temperature, indicated here as 186 C, is apparently only slightly lower than the melting point of lithium.

Cu-Mg Copper-Magnesium

By G. F. Sager* and B. J Nelson*

The solubility of magnesium in solid copper is, as follows: approximately 2.6% at 700 C, 2.5 at 600 C, 1.9 at 470 C, 1.2 at 400 C.

The solubility of copper in solid magnesium is 0.55% at 480 C, 0.30 at 400, 0.20 at 300.

The β phase is hexagonal with $a = 5.281$ kX, $c = 3.464$ kX;[2] γ is face-centered cubic with $a = 6.99$ kX.[7]

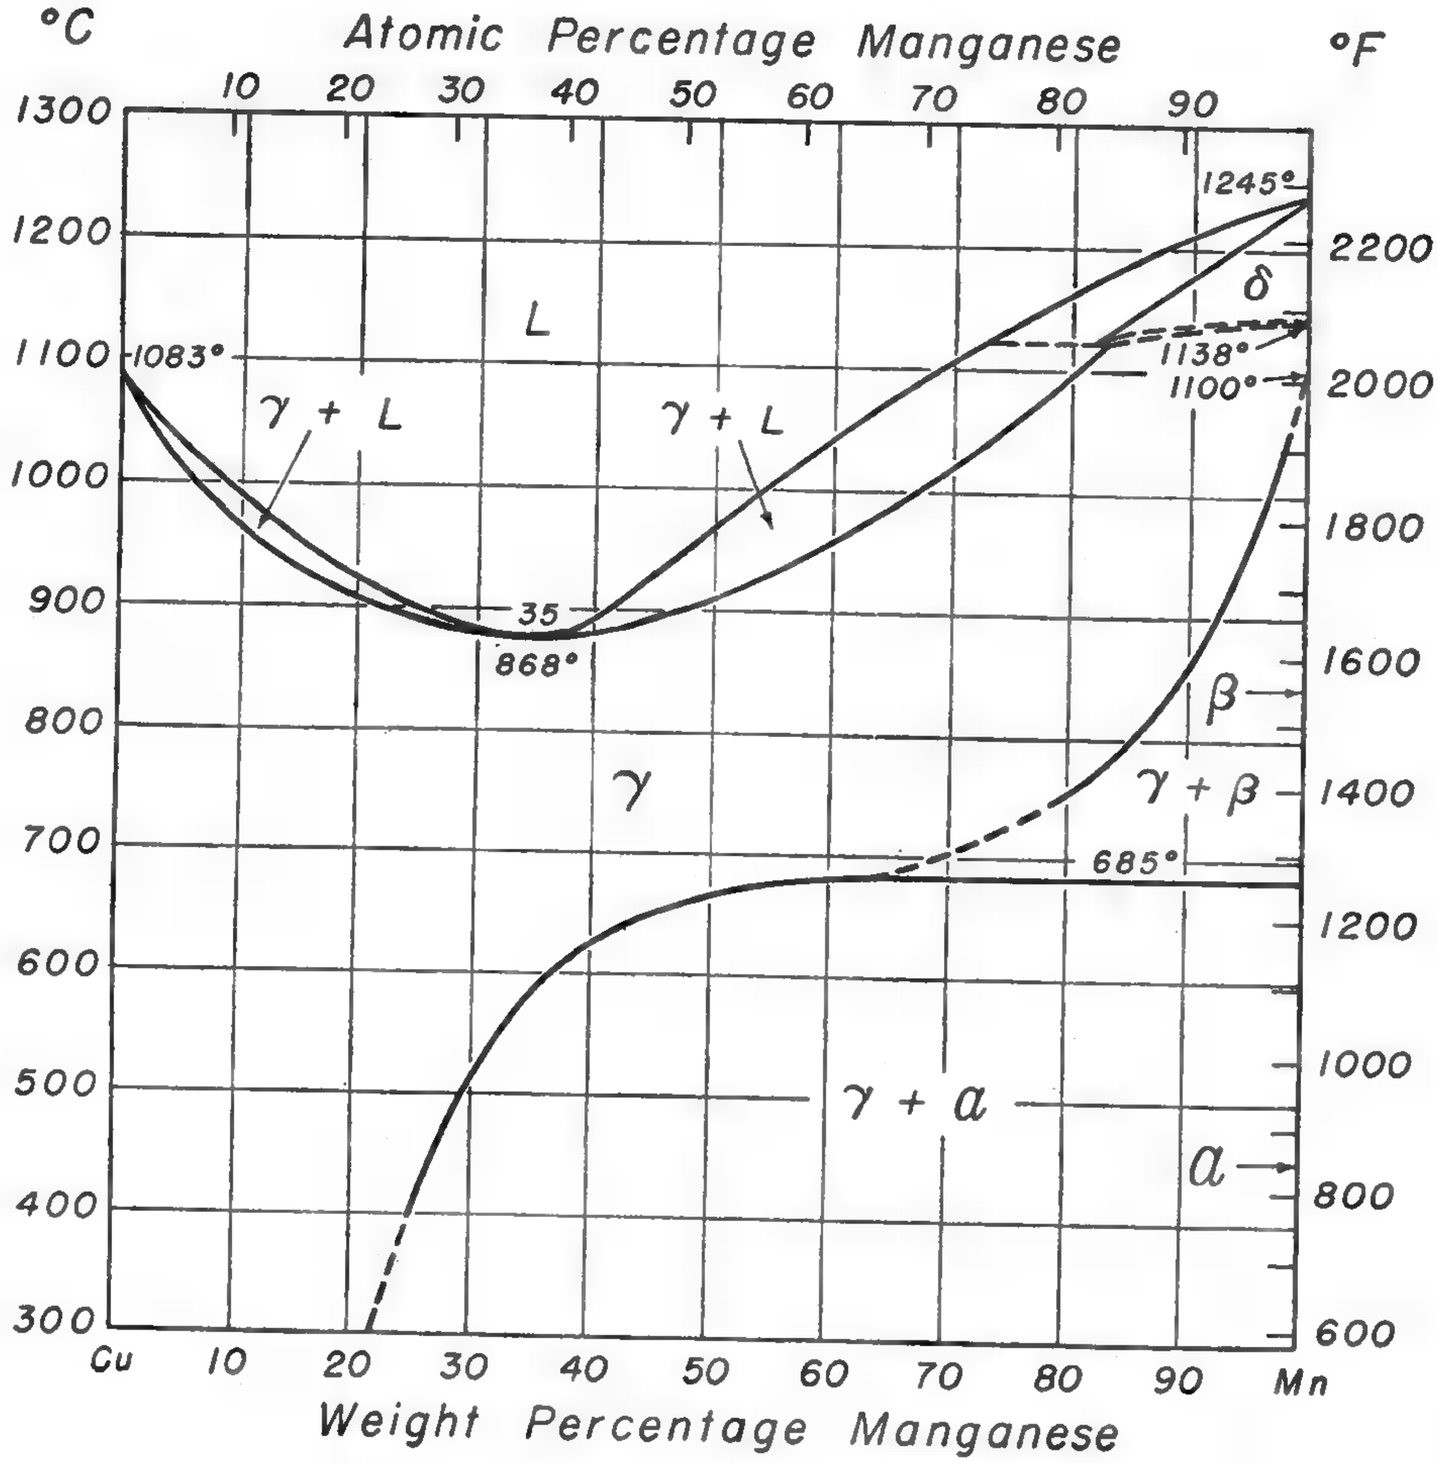
Cu-Mn Copper-Manganese

By Blake M. Loring*



The phase diagram is based on the data of Persson,[1,2] Grube[3] and Dean,[4] except for the transformation temperatures of pure manganese, which were taken to be 685 C, 1100 C and 1138 C.

A reaction involving δ, γ and liquid has been established,[3,4] although the precise location of the phase boundaries is in doubt.

Gamma that contains less than 82% Mn is face-centered cubic. Gamma that contains from [illegible] to 100% Mn is tetragonal; the axial ratio of quenched alloys varies from 1.000 (at 82% Mn) to 0.937 (at 100% Mn).[2,3,4]

Neither alpha nor beta manganese dissolves an appreciable percentage of copper.

Studies of heat content[5] have essentially substantiated the form of the diagram in the temperature range from 25 to 850 C.

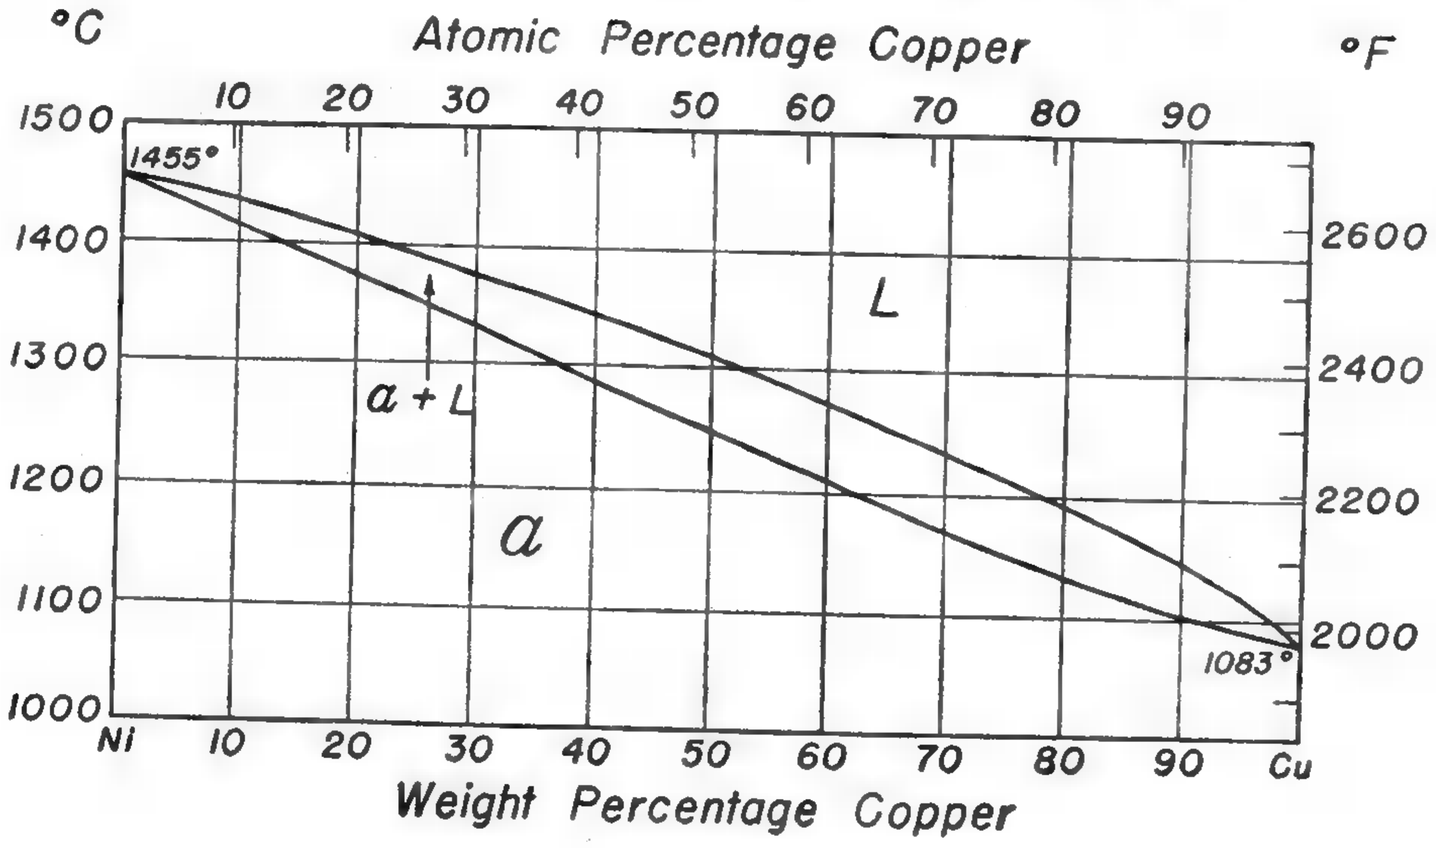
Cu-Ni Copper-Nickel

By N. B. Pilling* and T. E. Kihlgren*



The alloys are face-centered cubic. The lattice parameter varies linearly with atomic concentration, from 3.60 kX for copper to 3.54 kX for nickel.

The Curie temperature varies linearly with weight percentage nickel, from 353 C for pure nickel to 25 C for the alloy containing 30% Cu. The magnetic change occurs near minus 170 C at 50% Ni.[3,4]

Cu-O Copper-Oxygen

By F. N. Rhines*

The β phase is Cu_2O; γ is CuO.

At some temperature above 1400 C, the liquid (L_2), approximating the composition of Cu_2O, probably decomposes, leaving liquid copper saturated with oxygen in equilibrium with the gas phase.

Of the several determinations of the solubility of oxygen in solid copper, the one by Phillips and Skinner,[4] giving the lowest values of all, has been selected for the construction of the phase diagram.

The pressure-temperature diagram is largely an approximation. The triple point of copper, point T, is estimated from the data collected by Randall, Nielson, and West;[6] the quadruple points, Q_1 and Q_2, are estimated from the data of Roberts and Smyth,[3] but if the data of Slade and Farrow[2] had been used, the point Q_2 would have fallen at a pressure of 10^{-3} atmospheres; there are no measurements available for locating Q_3 except the knowledge of the temperatures of the equilibriums CuO, Cu_2O, L_2, and G, CuO, L_2 at one atmosphere. Cuprous oxide, Cu_2O, is assumed to have a minimum melting point, M, at an unknown pressure. Such data as are available for the location of the G, Cu, Cu_2O equilibrium give pressures that appear impossibly low and have been disregarded.

Cu-Pb Copper-Lead

By Paul A. Beck*

The position of the eutectic point, according to thermal analysis by Heycock and Neville,[1] and confirmed by industrial experience, is approximately at 0.06% Cu (326 C).

The solid solubility of copper in lead is less than 0.007% Cu as determined microscopically by Greenwood and Orr.[2] The solid solubility of lead in copper is probably of the order of 0.002 to 0.005% Pb.

The monotectic point is at about 41% Pb (953 C) in accordance with Heycock and Neville's liquidus curve for the copper-rich alloys[3] and with Briesemeister's data for the liquid miscibility gap.[4] The lead-rich end of the two-liquid field is probably about 92.6% Pb, where the liquidus curve of the lead-rich alloys, given by Bornemann and Wagenmann,[5] intersects the monotectic horizontal. The data of Friedrich and Waehlert[6] and of Briesemeister[4] indicate that the critical temperature (where the two-liquid field closes) is below 1025 C and probably close to 1000 C. This is confirmed by industrial experience with the casting at 1040 C of alloys that contain up to 45% Pb.†

Cu-Pd Copper-Palladium

By E. M. Wise*

At temperatures above 600 C, only a face-centered cubic solid solution exists, but several transformations occur at lower temperatures.[2,3,4,5]

The β phase, in the region near PdCu, is of the ordered body-centered cubic type. The range of β (41 to 51% Cu) was determined by electrical resistivity measurements.[5] No evidence of any substantial hysteresis was found during the $\beta \rightarrow \alpha$ transformation in an alloy containing 60 atomic % Cu.[5]

An ordering transformation occurs, extending from about $PdCu_3$ some distance toward the copper side of the diagram. This has been considered analogous to the $AuCu_3$ transformation, which is of the ordered face-centered cubic type, but the work of Jones and Sykes[5] shows that in the area close to $PdCu_3$, designated α' in the diagram, very slowly cooled alloys (cooled to room temperature over a period of four months) develop a slight tetragonality; the axial ratio decreases to 0.986. This is confined to the α' region; the alloys containing from about 72 to 87% Cu (designated α'') become ordered but remain face-centered cubic.

The 40% Cu alloy is used for electrical contacts (*see* page 1128).

Cu-Pt Copper-Platinum

By E. M. Wise*

The liquidus was determined by Doerinckel.[1] CuPt, according to Linde,[4] has trigonal symmetry, and when the ratio of platinum to copper atoms exceeds unity, the excess platinum atoms assume an ordered arrangement. Another ordering reaction stems from $PtCu_3$, but these alloys remain face-centered cubic. For temperatures lower than 900 C, the diagram is drawn according to the results of Schneider and Esch.[6]

Cu-Si Copper-Silicon

By Cyril Stanley Smith*

The κ phase is very similar to α and alloys that contain both have the microstructural appearance of heavily twinned α, even after long annealing. The κ phase decomposes very slowly below 550 C unless cold worked.

There are no data concerning the solubility of copper in solid silicon, but it is presumed to be extremely small.

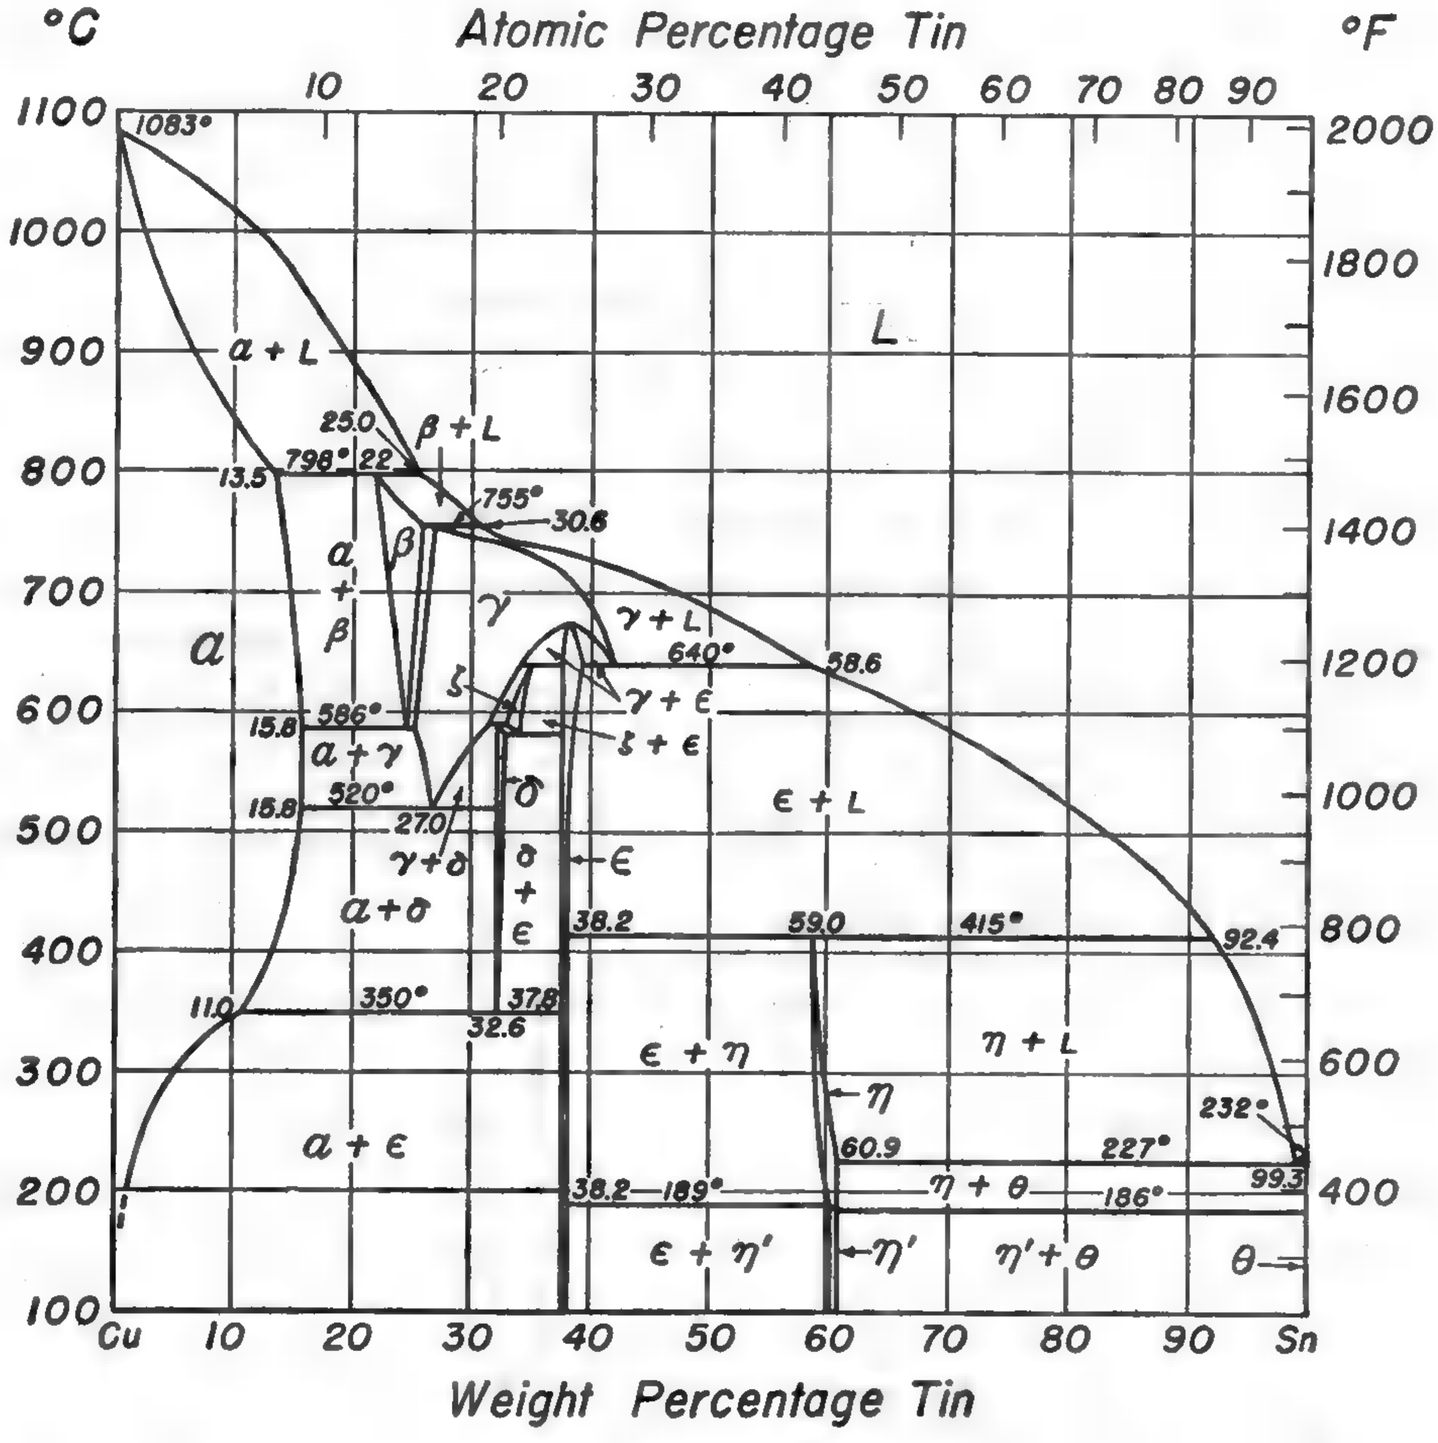
Crystal Structures and Lattice Parameters of Copper-Silicon Alloys

Phase	Crystal Structure	Lattice Parameter a, kX units
α (0% Si)	Face-centered cubic	3.608
α (5.5% Si)	Face-centered cubic	3.615
κ (5.2% Si)	Close-packed hexagonal ($c/a = 1.635$)	2.554
κ (6.9% Si)	Close-packed hexagonal ($c/a = 1.633$)	2.556
β	Body-centered cubic (?)	....
γ	Cubic (β-Mn type) (?)	6.21
δ	Cubic (γ-brass type) (?)	....
ϵ	Cubic (76 atoms per unit cell)	9.694
η	Hexagonal (?)	....

Cu-Sn Copper-Tin

By Cyril Stanley Smith*



The diagram is taken without change from Raynor,[1] who made a detailed critical study of the literature.

Though equilibrium is as shown in the diagram, in commercial operations the diminution of solubility of tin in the α phase below 520 C rarely occurs and, in all but alloys annealed for extremely long times after severe cold working, the solubility below 520 C can be considered as constant at 15.8%. Similarly, the decomposition of δ below 350 C occurs extremely slowly, and the $\alpha + \delta$ region, for most purposes, can be considered as extending vertically below the 520 C horizontal; that is, α 15.8% and δ 32.4%.

The β and γ fields have been the subject of much disagreement among investigators, for the phases do not differ much in crystal structure or in microstructure and are difficult to distinguish. Neither can be retained at room temperature by quenching the pure alloys, but a series of complex metastable transition structures form.

* Institute for the Study of Metals, University of Chicago, Chicago

The solubility of copper in tin is not greater than about 0.006% at the eutectic temperature.[6]

The crystal structures of the phases are, as follows: α, face-centered cubic; β and γ, both body-centered cubic (probably one is partially or completely ordered); ζ ($Cu_{20}Sn_6$), hexagonal with 26 atoms per unit cell; δ ($Cu_{31}Sn_8$), gamma-brass structure; ϵ (Cu_3Sn), orthorhombic; η' (Cu_6Sn_5), nickel arsenide structure, ordered.

Cu-Te Copper-Tellurium

By F. N. Rhines*

It is not certain whether the β phase (Cu_2Te) melts congruently at 870 C, as indicated in the diagram, or undergoes peritectic reaction at 857 C. If the latter is correct, the β field should end at 857 C and the liquidus should be continued from the point at 870 C uninterrupted to the end of the monotectic reaction horizontal at 1055 C. There is uncertainty about the transformations in β and γ, since these transitions are based on thermal evidence alone.

Cu-Ti Copper-Titanium

By H. L. Burghoff*

The diagram shown is based on the work of Kroll.[1] There appears to be a eutectic at about 24% Ti. The solubility of titanium in copper decreases from approximately 4% at the eutectic temperature (900 C) to less than 0.5% at 350 C. Alloys that contain 0.5% or more of titanium are age hardenable.

According to Hensel and Larsen,[2] the second solid phase may be either titanium or a titanium-copper compound.

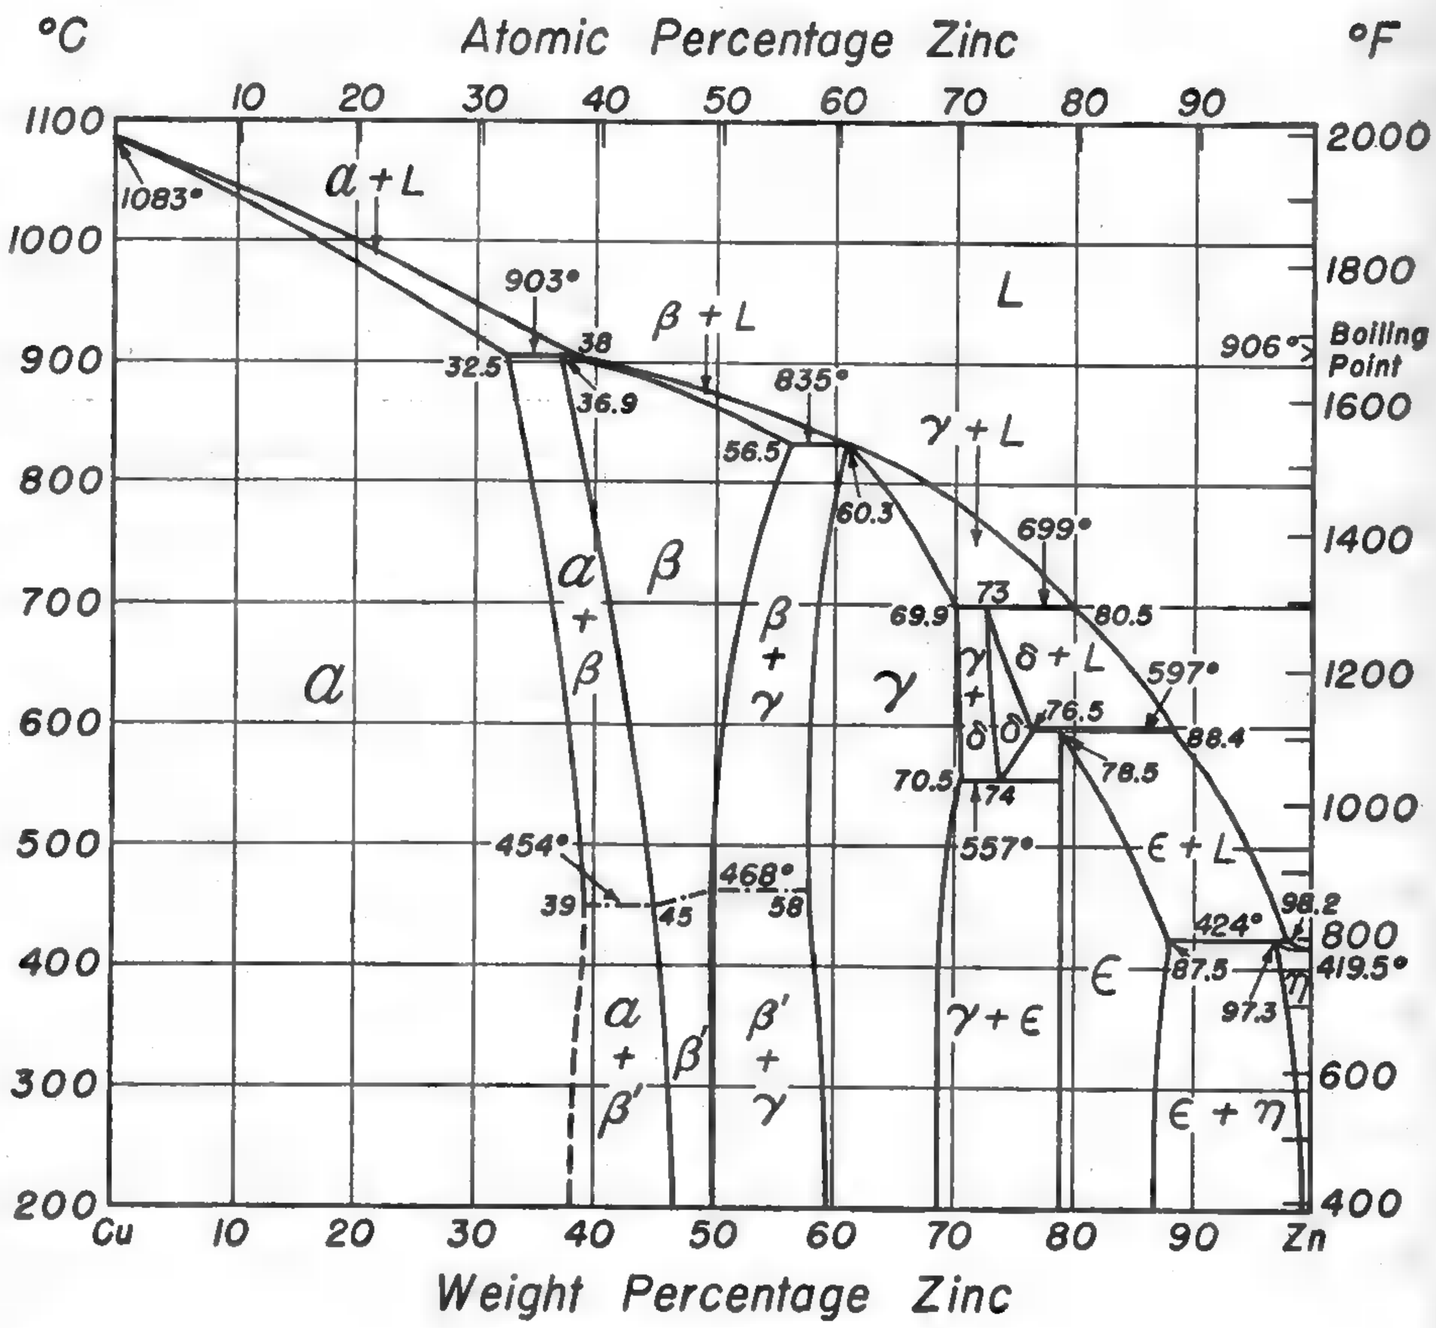
Cu-Zn Copper-Zinc

By Arthur Phillips* and R. M. Brick*



In 1944, Raynor[1] published a completely annotated copper-zinc diagram. Raynor's diagram is in essential agreement with the diagram given here, with the exception of the lower end of the line showing the solubility of zinc in the α phase. In Raynor's diagram the solubility of zinc is shown to decrease from 39% at 454 C to 35% at 250 C. In the present diagram, the solubility line is drawn to show only a very slight decrease below 454 C.

The line traversing the $\alpha + \beta$, β, and $\beta + \gamma$ fields (454 and 468 C) indicates a progressive change of the β phase from a disordered to an ordered structure (or vice versa). On cooling to the temperature shown by the dot-dashed line, the body-centered cubic β with copper and zinc atoms randomly dispersed at lattice points becomes unstable and changes continuously to β'. β' has a body-centered cubic crystal structure identical with that of β, but with an ordered structure in which the copper atoms are segregated at the corners of the unit cubes and zinc atoms at their centers.[2,3] The ordering reaction is so rapid that it cannot be prevented or even retarded by quenching.

Various factors, including minute specific heat anomalies and the large effect of cold working on the electrical resistance, suggest that there may be some tendency to precipitation or ordering in the alpha solid solution.

An alloy containing about 62.5% Cu is of particular interest because, under equilibrium conditions, it has a completely β structure at 900 C and a uniform α structure below about 500 C. By a drastic quench from 900 C in an iced brine solution this alloy undergoes a diffusionless transformation resulting in a structure similar to the martensitic structure of steels. By the rapid quench, permitting no opportunity for time-consuming diffusion in the range 900 to 500 C, the retained beta transforms at about minus 14 C to a face-centered structure similar to alpha, but differing in that one edge is longer than the other two, thus forming a face-centered tetragonal structure. The high-temperature beta and the room-temperature alpha are of the same composition, and the change from body-centered cubic beta to face-centered cubic alpha requires only a slight change in crystal structure. If the dimensional readjustment is incomplete (because of lattice rigidity at low temperatures), the intermediate, unstable tetragonal lattice is found.[4] The diffusionless transformation of this brass is of no industrial importance, since the requirement of heating to within a few degrees of the melting point results in very coarse grains and the rapid quench required can be attained only in relatively thin specimens.

Some of the potential Widmanstätten structures in this system have been investigated. It has been found that α forming in β tends to grow as needles parallel to the [111] directions in the β structure. γ precipitating from β forms small polyhedra whose faces are parallel to the {110} planes of the matrix. ϵ precipitates from η with its {10.4} planes parallel to {10.4} planes of the η phase.

Fe-C Iron-Carbon

See "C-Fe Carbon-Iron", pages 1181 and 1182.

Fe-Ge Iron-Germanium

By R. M. Parke*

The composition limits of the $\alpha + \gamma$ field were not determined, but observations on alloys containing 0.5 and 1.5% Ge indicated a closed "gamma loop".[1]

The ϵ and ζ phases correspond approximately to the compositions Fe_2Ge and $FeGe_2$ respectively.[1] The ϵ phase (Fe_2Ge) is hexagonal (NiAs type), isomorphous with Fe_2Sn and Co_2Sn.[1] For an alloy corresponding to $Fe_{1.76}Ge$, the lattice parameters are $a = 4.031$ kX, $c = 5.022$ kX, $c/a = 1.275$.[2]

When alloys containing more than about 65% Ge are solidified rapidly by quenching the liquid, the formation of ζ is suppressed, and the alloys freeze metastably as a eutectic of ϵ and η. The eutectic point in the metastable system is at 830 C and 75% Ge.[1]

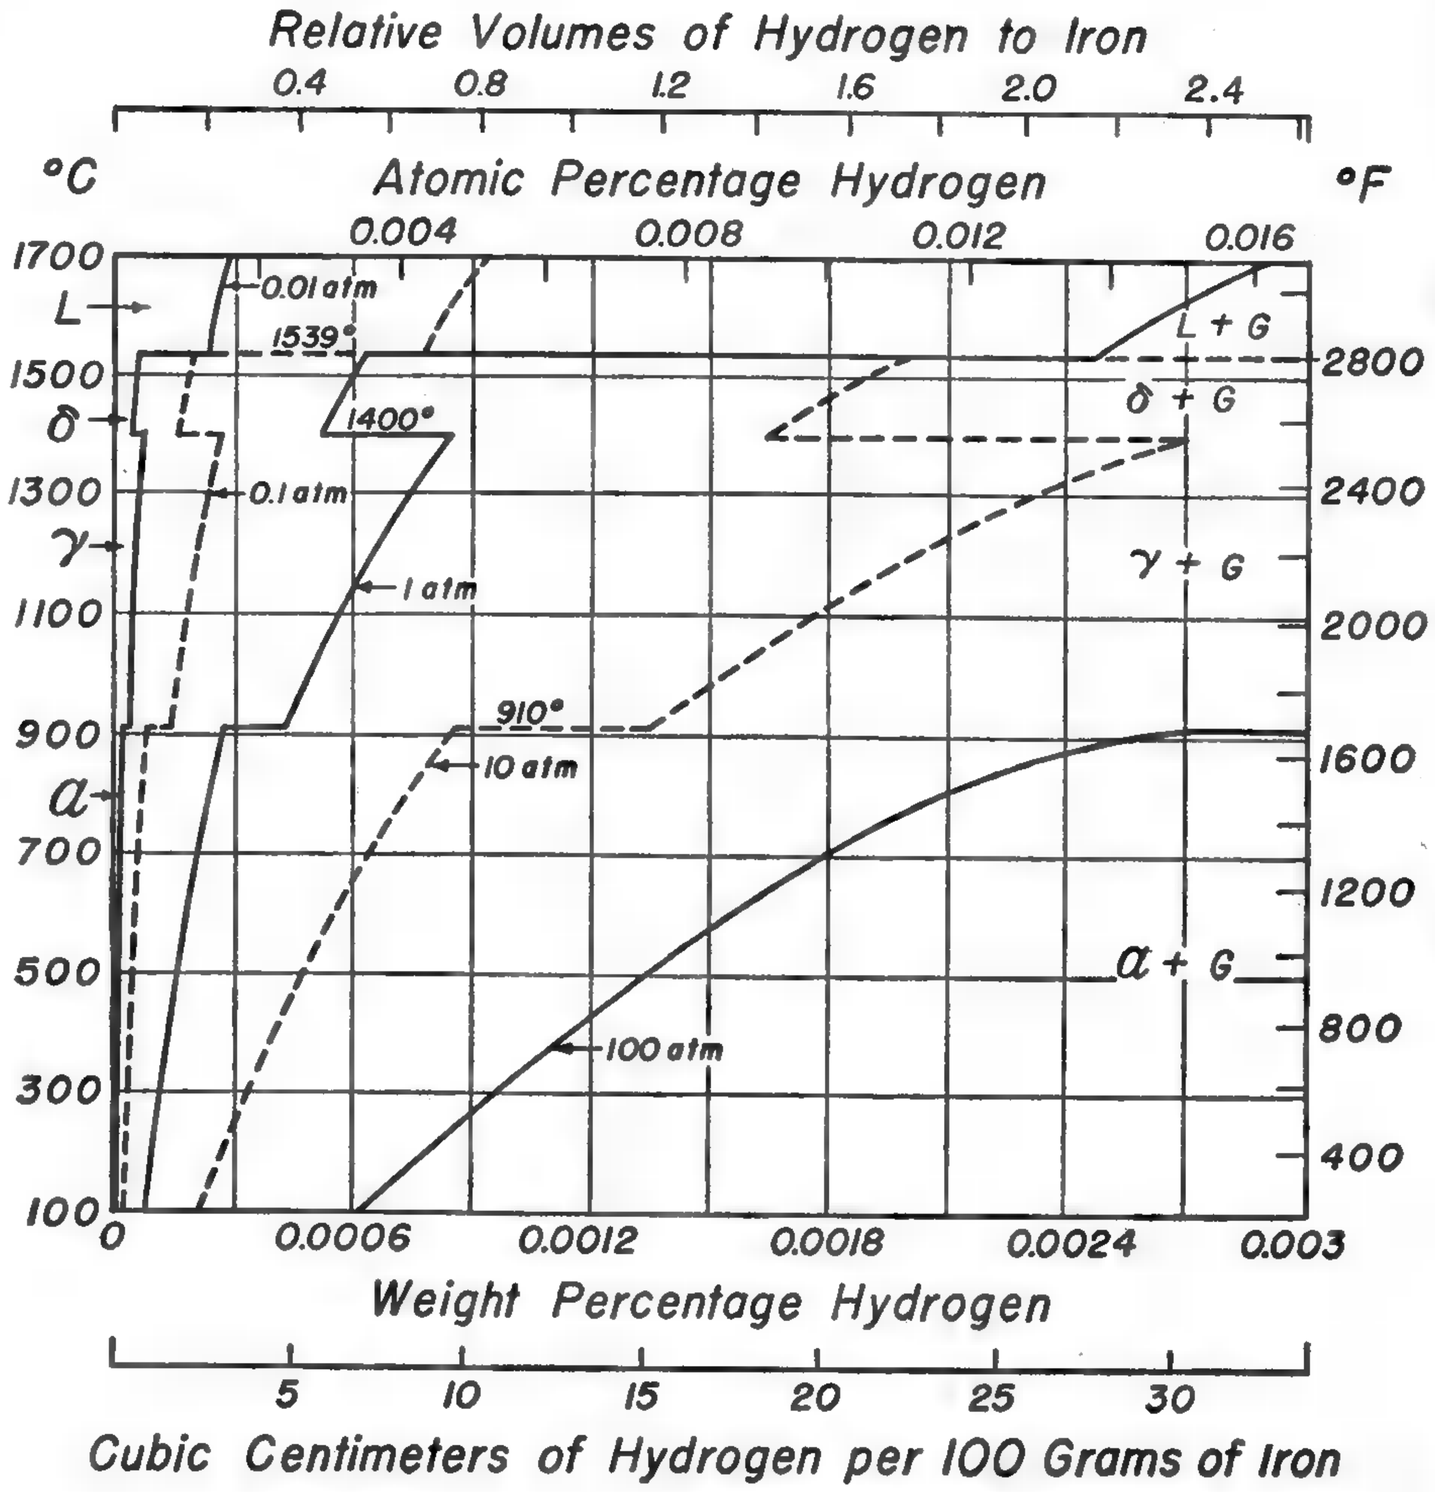
Fe-H Iron-Hydrogen

By Carl A. Zapffe*



Constitutional study of the iron-hydrogen system began at least as early as 1862 when Meisinger[1] collected large quantities of H_2 from electrolytic iron; and 1863 when Deville and Troost[2] proved that a constitutional system existed by dissolving hydrogen in iron. Although numerous early investigators, such as Cailletet[3,4] and Graham[5] analyzed the hydrogen in iron, the work begun in 1907 by Sieverts and his colleagues[6-14] provided the first reliable data. Using a classic technique, Sieverts studied the absorption as the atmospheric pressure of H_2 varied up to 1.5 atm. His results established that the gas dissolves atomically and that the composition of the iron-hydrogen alloy varies with the square root of P_{H_2}:

$$[H] = K \cdot (P_{H_2})^{1/2}$$

Later quantitative work by Iwasé,[15,16] Martin,[17,18] and Luckemeyer-Hasse and Schenck,[19] (also related work by others[20,21]) essentially completed the iron-rich end of the system as shown in the diagram presented here.

Since iron-hydrogen alloys are pressure-sensitive, the system is only properly depicted in three dimensions. However, a solid model has not yet been proposed; and the isobaric sections in the accompanying diagram serve to show the measured absorption boundary at $P_{H_2} = 1$ atm and to indicate the probable boundaries at higher and at lower pressures as calculated from the quadratic relationship, assuming an unchanged activity coefficient. All values below about 400 C are similarly estimated, since their measurement has not yet been accomplished.

The solubility is known to increase sharply on passing from alpha to gamma, and seems reliably proved to decrease again abruptly on reverting to delta,[19] such that the boundary in delta ferrite becomes an extrapolation of the curve in alpha ferrite. On liquation, the solubility again increases sharply. No changes in transformation temperatures are indicated, because the single proved instance, discussed below, is too minor to register on the scale of the diagram.

No compounds are yet known for certain to exist. Atomized iron may combine with extremely large quantities of hydrogen, attaining stoichiometric Fe:H ratios of 1:1[21-25] and even 12:1;[26] but the highest recorded hydrogen content in bulk iron is only 0.45 atomic %.[27] Because of the common phenomenon of hydrogen embrittlement, an endothermic hydride has often been assumed to exist. Simons and Ham[28] describe diffusion in terms of hydride formation; and Andrew and his associates[29] observed a thin white constituent bounding hydrogen-caused cracks which they believe to be a hydrogen-rich phase. However, embrittlement occurs at such unlikely Fe:H ratios as 5000:1. In addition, it is known that at ordinary temperatures the gas resides largely within intragranular rifts[30] as an occluded phase under high pressure.[30] If a compound does exist, certainly its dissociation pressure is extremely high.

In 1899 Roberts-Austen[31] described several anomalous "hydrogen points" occurring in the ferrite range during the cooling of iron containing hydrogen. Ewing and Rosenhain[32] attempted to relate the point at 487 C to a surface phenomenon observed on iron heated in hydrogen; and Rawdon and others[33,34] and Jaquerod and Gagnebin[35] similarly discussed these points. An extensive series of investigations by Ham and his students[36-43] refined the definition of the phenomenon until Ham and Samans[44] in 1946, in a related research, demonstrated that at least six thermal points do exist in the ferrite range, probably representing subtle electronic changes not yet understood.

As for the effect of hydrogen on the allotropy of iron, Andrew[45] in 1911 reported finding no changes. Later, Esser and Cornelius[46,47] claimed that the doubling of A_3 and A_1 points noted by Harrington and Wood[48,49] was caused by hydrogen. Post, Lake, and Ham[50] then carefully measured the effect of hydrogen on A_3 in pure iron and found that the absorption from $P_{H_2} = 1$ atm caused a lowering of 4 °C which was proportional to the hydrogen content.

Wever and Pfarr[51,52] hydrogenized ferrite cathodically and, from X-ray diffraction patterns, computed an increase in the lattice parameter from 2.8609 to 2.8614 kX, a supposed expansion of 0.12% per 1 atomic % [H]. In view of the diffuseness of the patterns, the extremely low proportion of hydrogen atoms to iron atoms (one H atom in a cube 27 Fe atoms on an edge) and the planar-pressure theory of hydrogen embrittlement,[20,30] these results probably should not be regarded as decisive.

Fe-Hg Iron-Mercury

By R. M. Parke*

Most of the data on iron-mercury alloys pertain to solubilities, and agreement on this point is lacking. Tammann and Kollmann[1] give 1.15×10^{-17}% Fe at 170 C, and Palmäer[2] reported 0.00007% Fe between 20 and 211 C. Brill and Haag[3] found by X-ray examination that iron amalgams containing up to 25% Fe consist of a suspension of alpha iron in mercury. This fact may account for the conflicting reports of other investigators.

Fe-Li Iron-Lithium

By R. M. Parke*

Iron is not dissolved by liquid lithium. Lithium is insoluble in solid iron, and although its solubility in liquid iron is not known, the formation of alloys is considered improbable.[1]

Reference

1 M. Hansen, "Der Aufbau der Zweistofflegierungen", J. Springer, Berlin, 1936

Fe-Mg Iron-Magnesium

By G. F. Sager* and B. J Nelson*

Magnesium is not soluble in solid iron.[1] The solubility of iron in magnesium at the melting point of magnesium is 0.026%.[2]

Iron has a very adverse effect on the resistance of magnesium to corrosion, causing deep pitting in saline environments (*see* Fig. 7 on page 997). Iron can be removed from liquid magnesium alloys by precipitation with an excess of manganese or zirconium. This process is discussed under Refining, Settling and Sludging, in the article on page 973. Wrought magnesium alloys that contain 0.005% Fe, or less, are available commercially and have better resistance to corrosion than do magnesium alloys of normal iron content.

Fe-Mn Iron-Manganese

By F. T. McGuire* and A. R. Troiano*

The manganese-rich portion of the diagram[1,2] has been drawn to indicate four allotropic forms of manganese.[3,4,5] There are no experimental data for iron-manganese alloys containing more than 95% Mn, and the diagram has been left blank between 1100 and 1245 C, from 95 to 100% Mn.

The γ phase containing up to 15% Mn transforms to supersaturated α by a martensite reaction during cooling; γ containing approximately 13 to 25% Mn transforms to close-packed hexagonal ϵ, also by a martensite reaction.[6] Neither ϵ nor supersaturated α is an equilibrium phase; therefore, they are not shown on the phase diagram. Transformation temperatures for the martensite reactions in iron-manganese alloys are shown in Fig. 1 of the article "Manganese in Steel", on page 465 of this Handbook. For a discussion of the characteristics of martensite transformations in general, see the article on page 263.

Fe-Mo Iron-Molybdenum

By W. P. Sykes†

When the molybdenum content exceeds about 3%, γ is completely replaced by α.[1,2] The ϵ phase, of very narrow homogeneity range, has a limiting composition represented by the formula Fe_3Mo_2[1,2,3] or by Fe_7Mo_6[4] while that of ζ appears to be represented by FeMo.[2] The η phase[5] is a substitutional solid solution of iron in molybdenum. The ϵ phase is hexagonal with $c/a = 5.404$.

Fe-N Iron-Nitrogen

By J. T. Norton*

The diagram shown does not represent the iron-nitrogen system in equilibrium at atmospheric pressure but rather shows the phases that are in equilibrium with nitrogen at the very high pressures corresponding to the dissociation of ammonia.

The γ' phase (Fe_4N) is cubic with $a = 3.789$ kX. The ϵ phase containing 8% N is hexagonal with $a = 2.695$ kX, $c = 4.362$ kX.

Fe-Ni Iron-Nickel

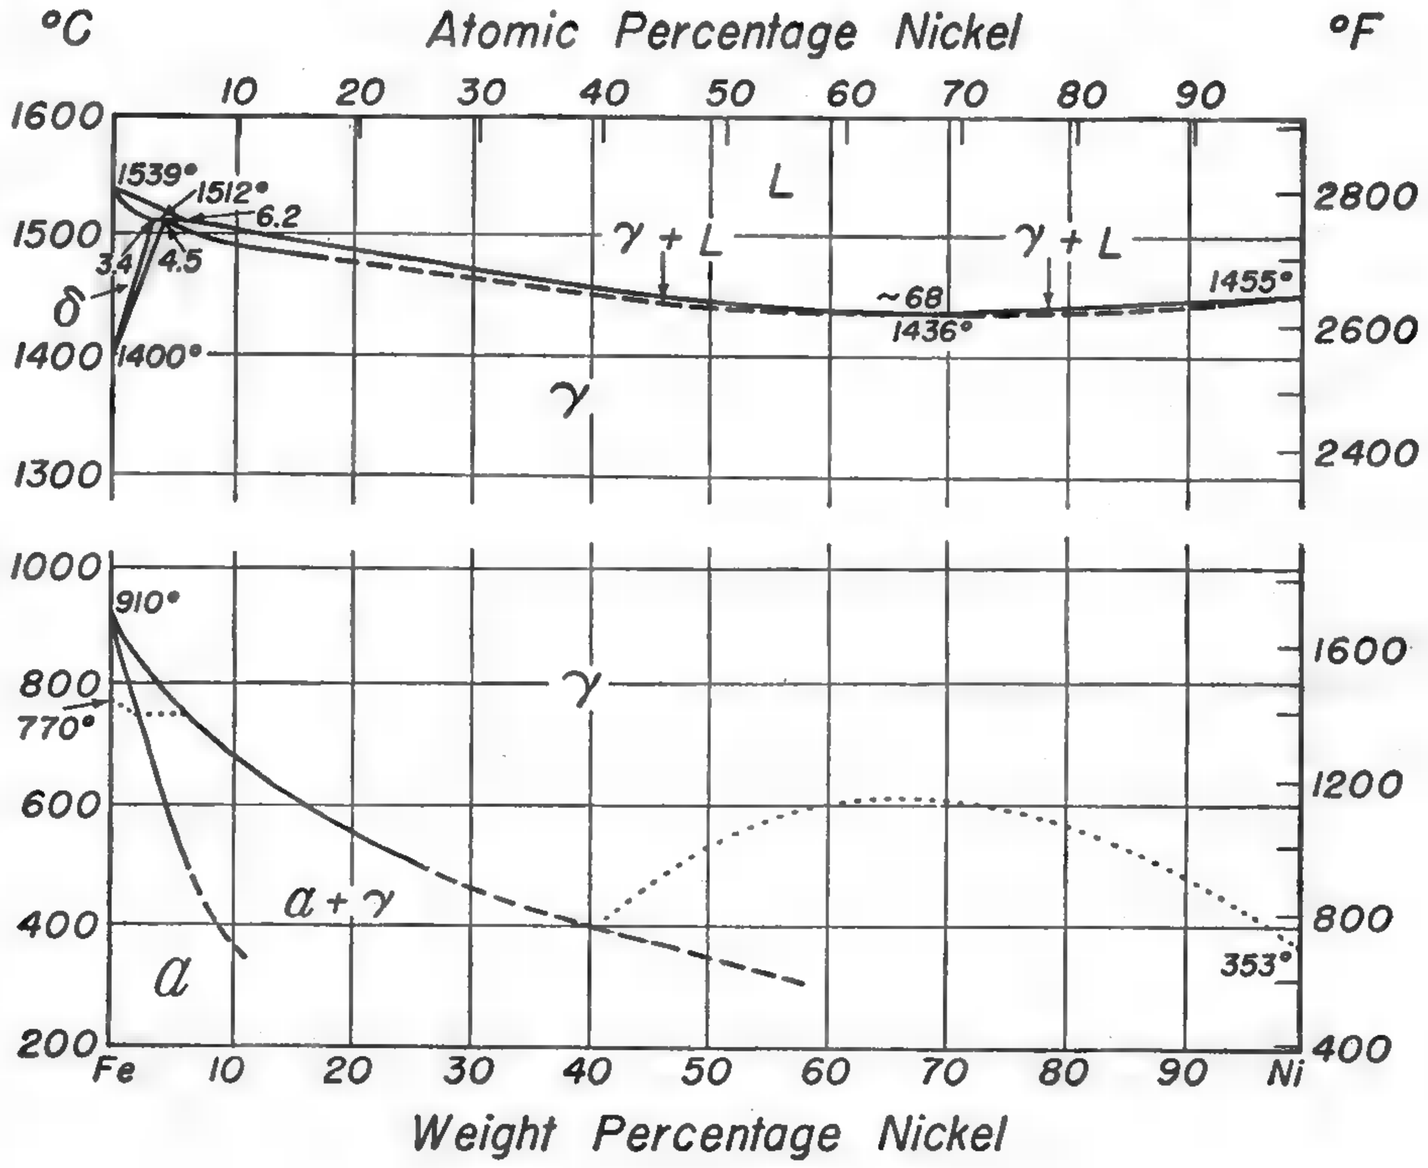
By George Sachs†

Because of the sluggishness of structural changes at low temperatures, the accurate phase boundaries below approximately 600 C have not yet been established. However, recent X-ray[1,5,7,9,14] and magnetic[11,15,16] investigations agree regarding the general extension of the $\alpha + \gamma$ field, down to a temperature of 350 C.

Considering the structure and properties at room temperature, under conditions of commercial treatments, the alloys can be grouped in six ranges of composition:

1 Alloys that contain up to 6% Ni are ferritic. With increasing nickel content, the alloys become increasingly subject to air hardening on slow cooling.[14]
2 Between 6 and 25% Ni, the alloys are martensitic after fast cooling; after slow cooling or reheating, they decompose into

† Case Institute of Technology, Cleveland



$\alpha + \gamma$. The structure varies from the martensitic to the Widmanstätten type observed in meteorites.[2,10,12]

3 Between 25 and 30% Ni, the alloys may consist either of a mixture of α and γ, or of pure γ, after fast cooling.[9] They decompose into $\alpha + \gamma$ on reheating to 350 to 450 C. Cold working at room temperature may transform them completely into α.[14]

4 Between 30 and 45% Ni, the structure of the alloys appears to be γ, after either rapid or slow cooling.[9] However, the lattice parameters are slightly affected by the rate of cooling and reheating, indicating some decomposition of an unknown nature.[13] Long-time heating at a temperature of 350 C causes a definite decomposition into $\alpha + \gamma$. These observations may also explain the maximum value of lattice parameter at 38 to 39% Ni,[3,4,13] and the low expansion of the alloys in this range (invar).

5 Alloys with more than 50% Ni are, for all practical purposes, γ or austenitic, and possess the characteristics of nickel-base solid solutions. The existence of $\alpha + \gamma$ in the lower-nickel part of this range, at temperatures below 400 C, has no practical significance.

6 Alloys near 76% Ni assume a superstructure, $FeNi_3$, on slow cooling.[4,8] This transition is probably related to the unique magnetic properties of the 78% Ni alloy (permalloy).

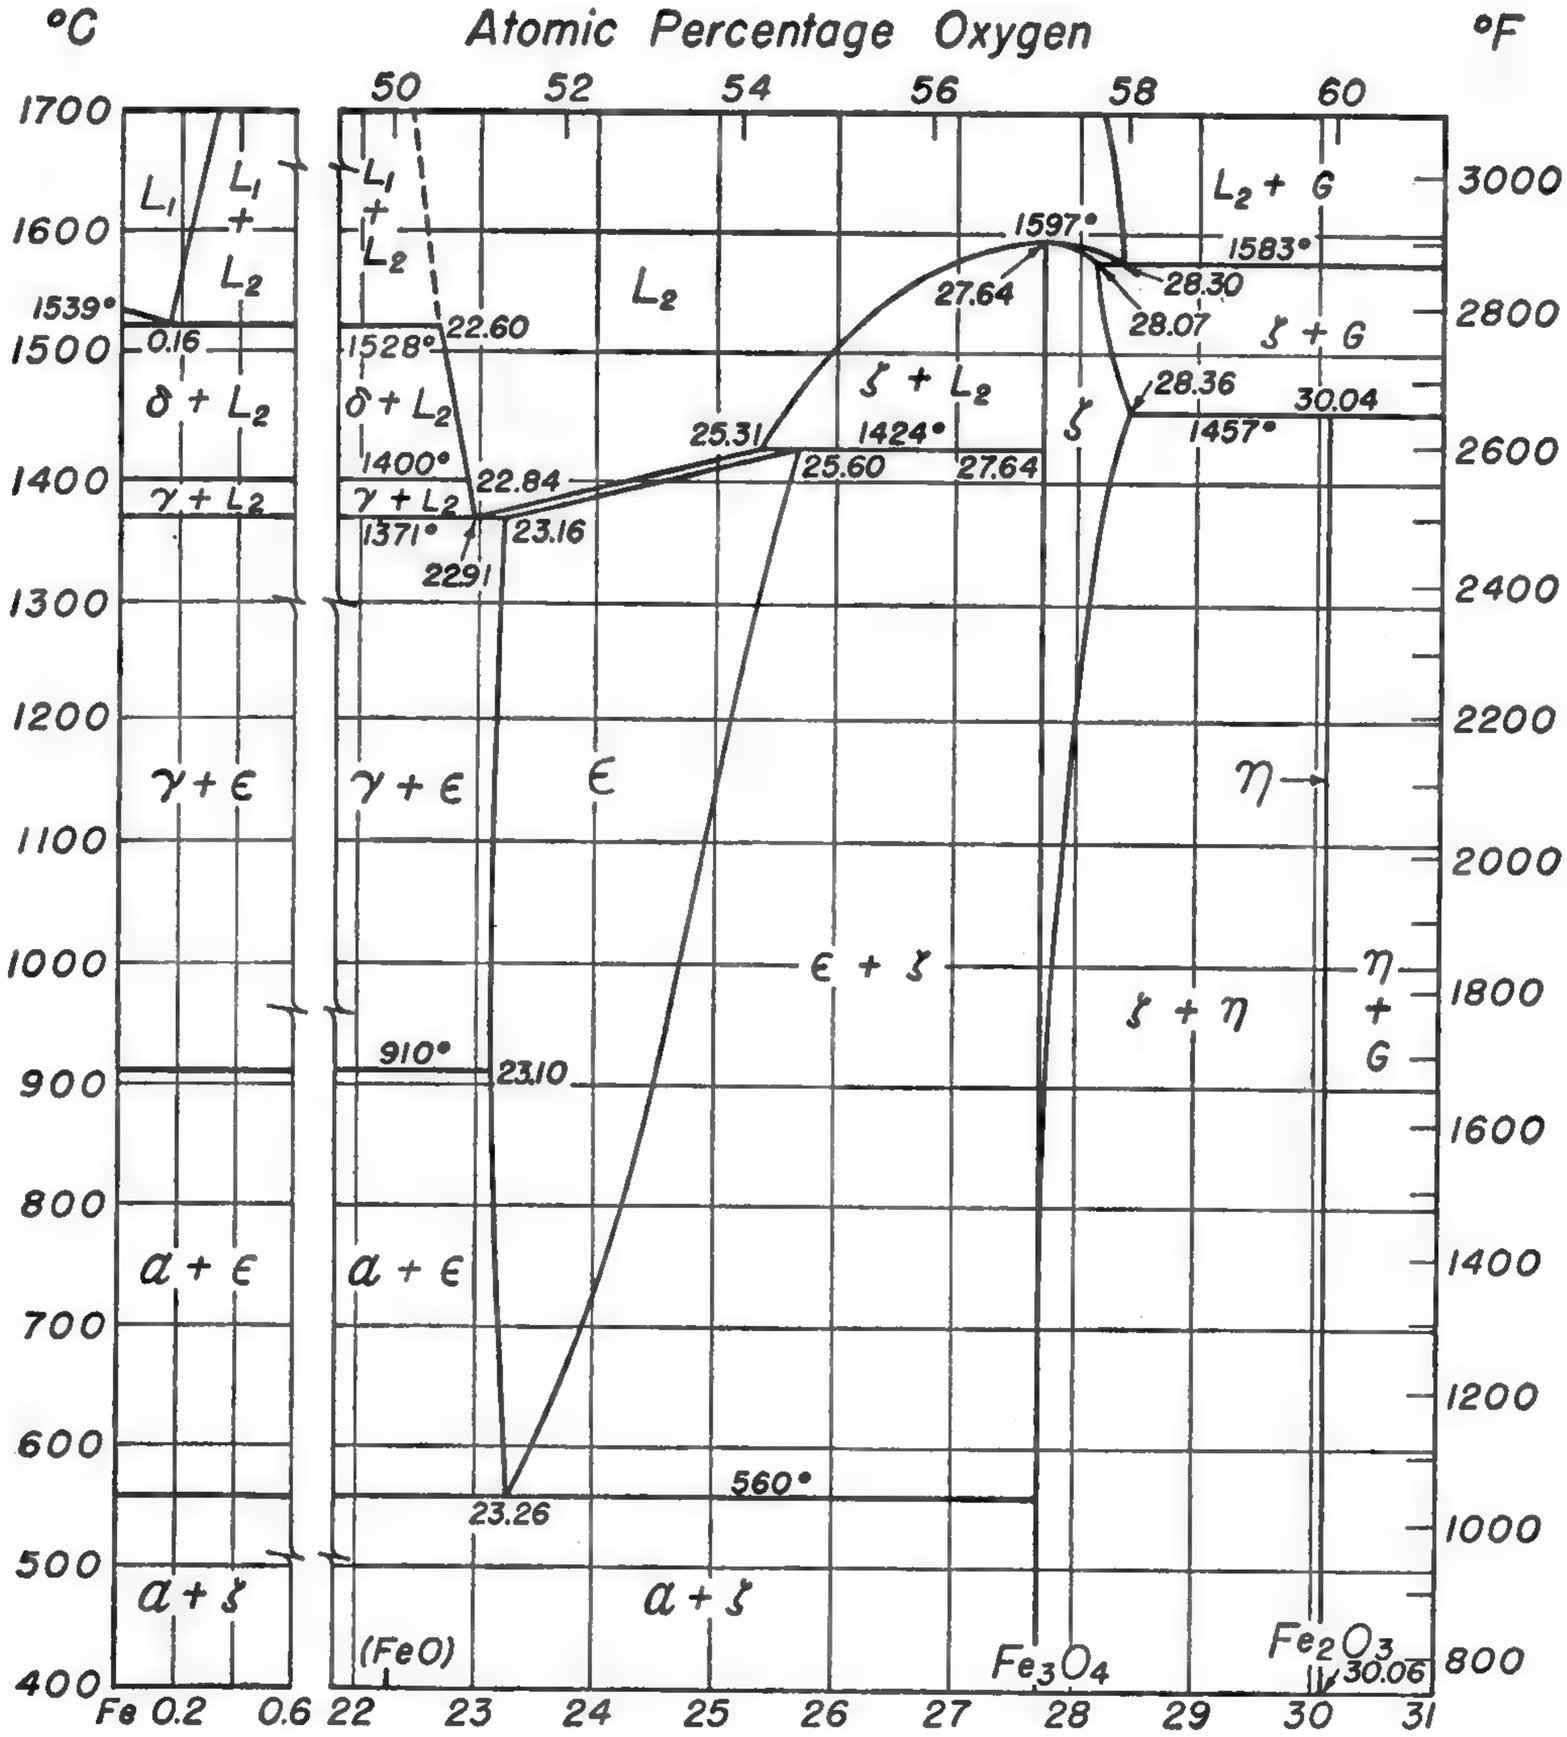
Fe-O Iron-Oxygen

By L. S. Darken* and R. W. Gurry*



The common names of the ϵ, ζ, and η phases are, respectively, wüstite, magnetite, and hematite.

The solubility of oxygen in molten iron is now fairly well established.[8,9,10] However, there is still a great discrepancy in the results of various investigations as to the solubility of oxygen in solid iron. The careful work of Dünwald and Wagner[11] indicates that the solubility is less than 0.01% between 800 and 1000 C; this is among the lowest of recorded values. Since nearly all experimental

* United States Steel Corporation, Research Laboratory, Kearny, N.J.

errors are likely to lead to an overestimate of this quantity it seems safe to conclude from the more reliable determinations[10,11] that the solubility is less than 0.10% at temperatures up to 1000 C and is probably less than 0.05%. The relative solubility of oxygen in α, γ, and δ iron is uncertain and hence it is not known whether oxygen raises or lowers the transformation temperatures. In view of these uncertainties, the diagram is drawn as though the solid solubility of oxygen in solid iron were very small.

On the decomposition of wüstite, magnetite usually separates out before iron,[7] thus leaving a wüstite considerably richer in iron; by this process it may be possible to form metastable wüstite containing considerably less oxygen than shown for the stable field in the diagram. It is difficult if not impossible to cool a high-oxygen wüstite to room temperature without the separation of magnetite.

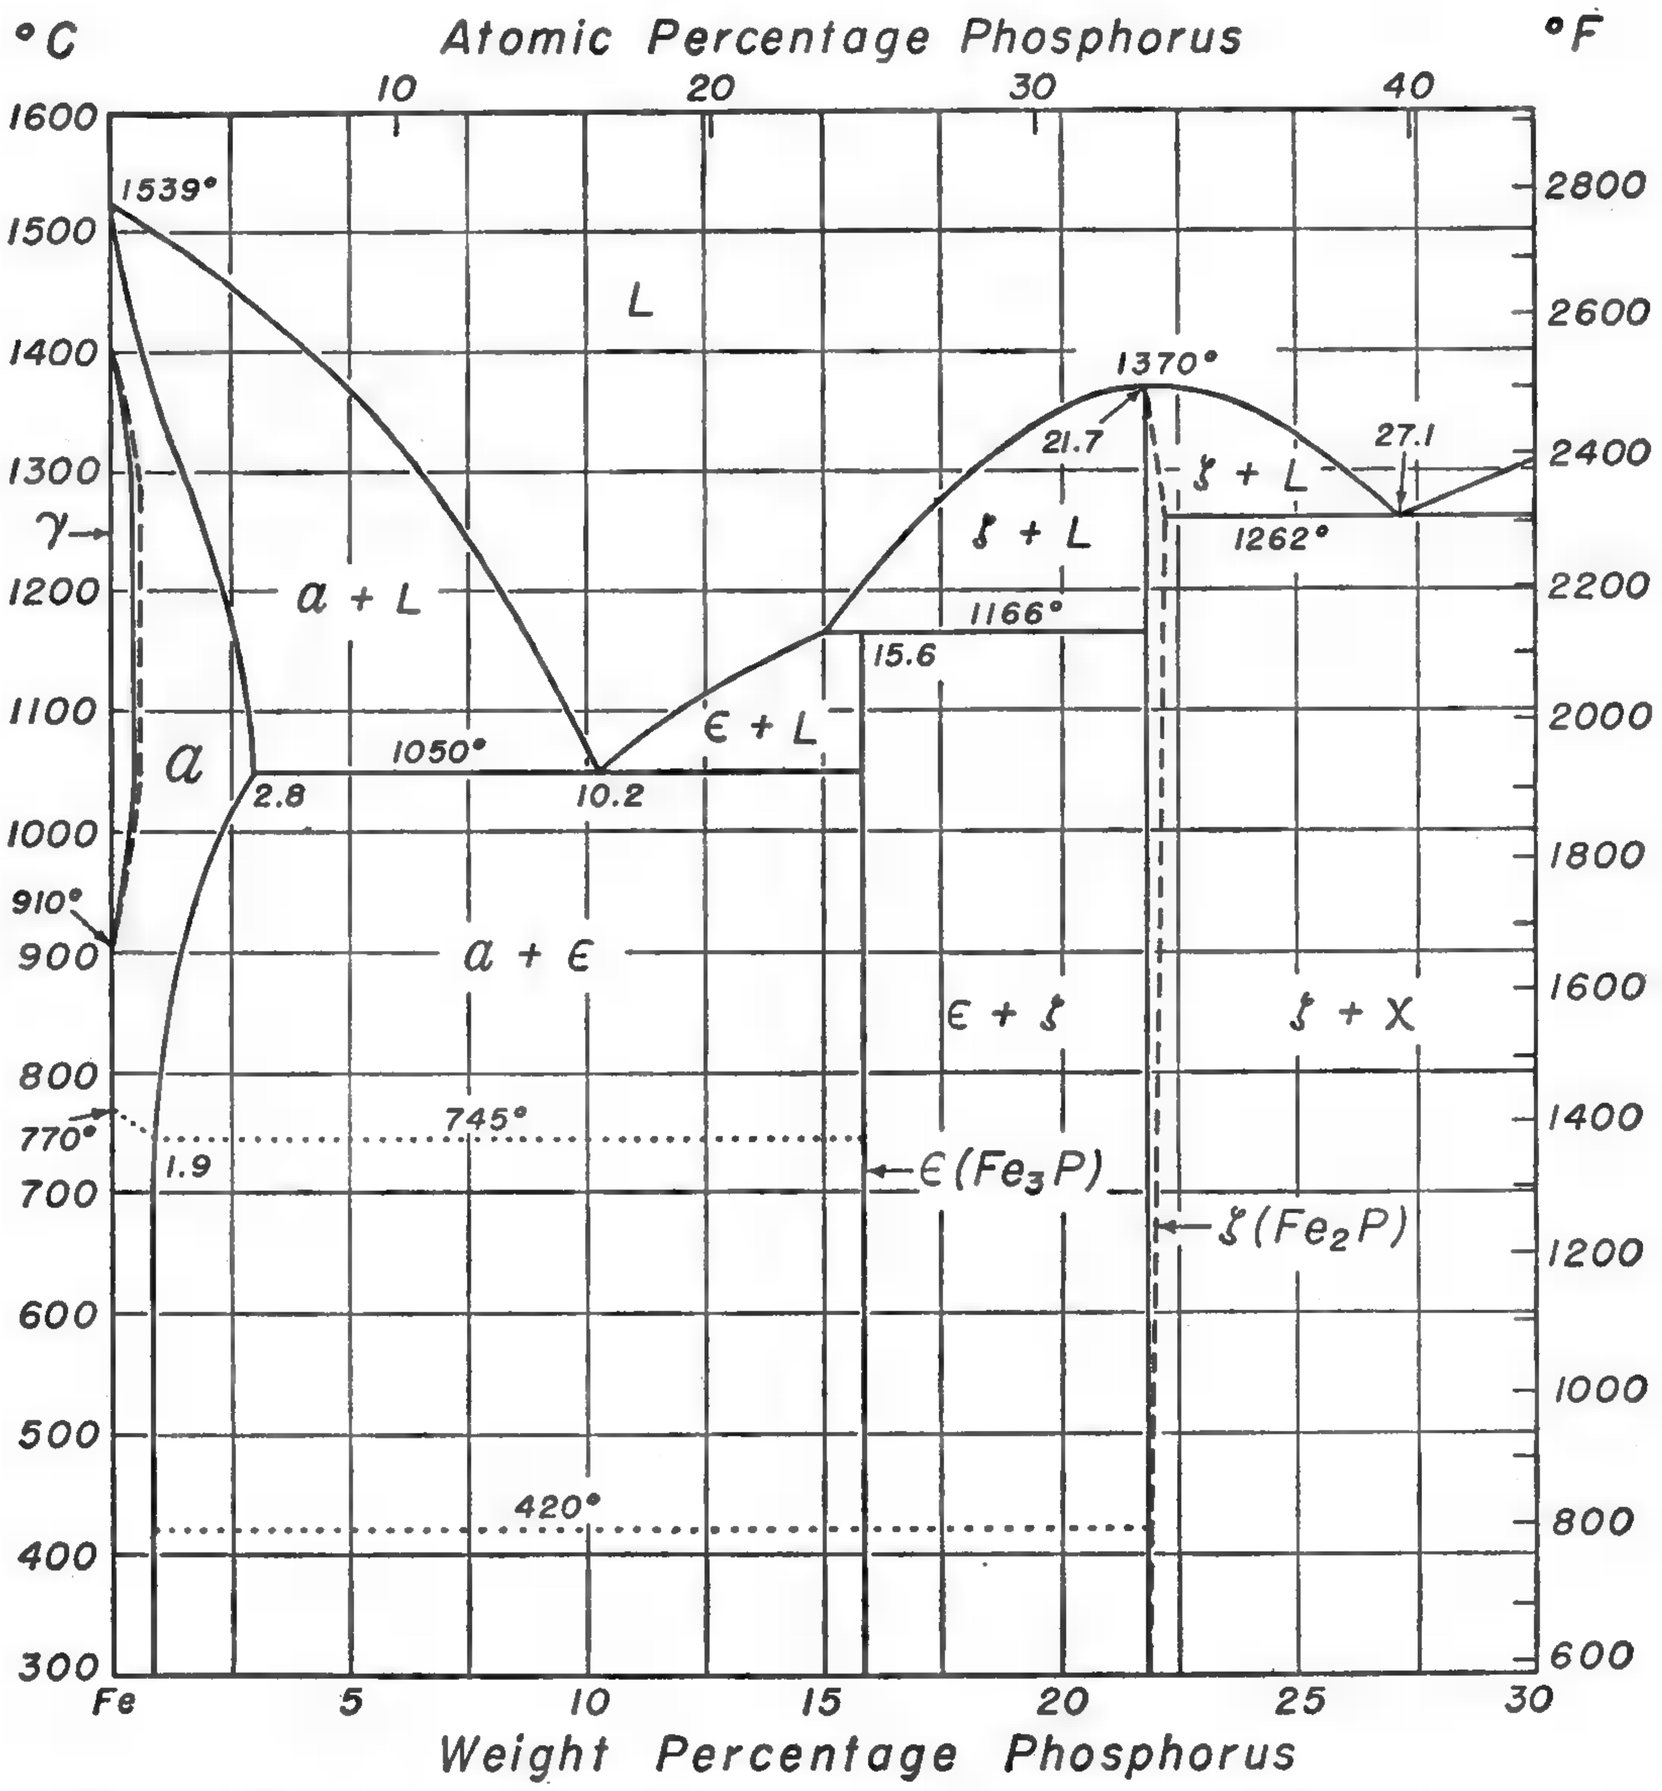
Fe-P Iron-Phosphorus

By C. H. Lorig*



Alloys containing more than 30% P have not been investigated. Constituent X is of unknown composition.

The line at 420 C represents the magnetic change in ϵ. This change is similar to the A_0 transformation in Fe_3C.

The boundaries of the $\alpha + \gamma$ region are doubtful.

The ϵ phase is tetragonal with $a = 9.09$ kX, $c = 4.45$ kX;[5] ζ (Fe_2P) is hexagonal with $a = 5.85$ kX, $c = 3.45$ kX.[3,6]

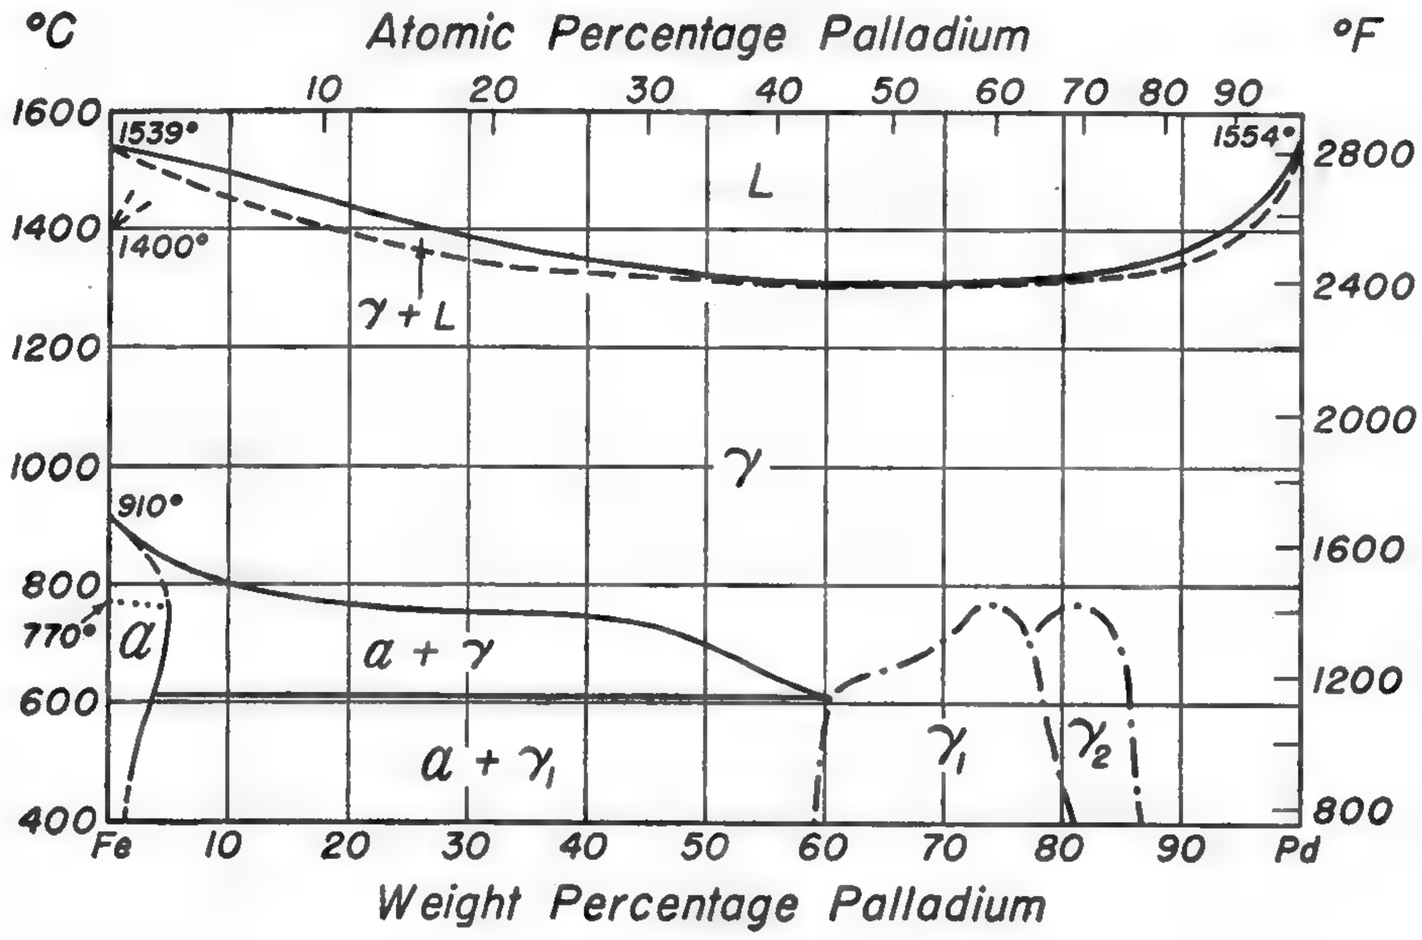
Fe-Pd Iron-Palladium

By R. M. Parke*



Palladium forms a complete series of solid solutions with gamma iron. There are two superlattices, corresponding to the formulas FePd and $FePd_3$. FePd is tetragonal, isomorphous with AuCu; and $FePd_3$ is cubic, isomorphous with $AuCu_3$.[1] An unstable intermediate phase, similar to martensite, formed by quenching gamma iron containing 5 to 20 atomic % Pd has been described by Hultgren and Zapffe.[1,2]

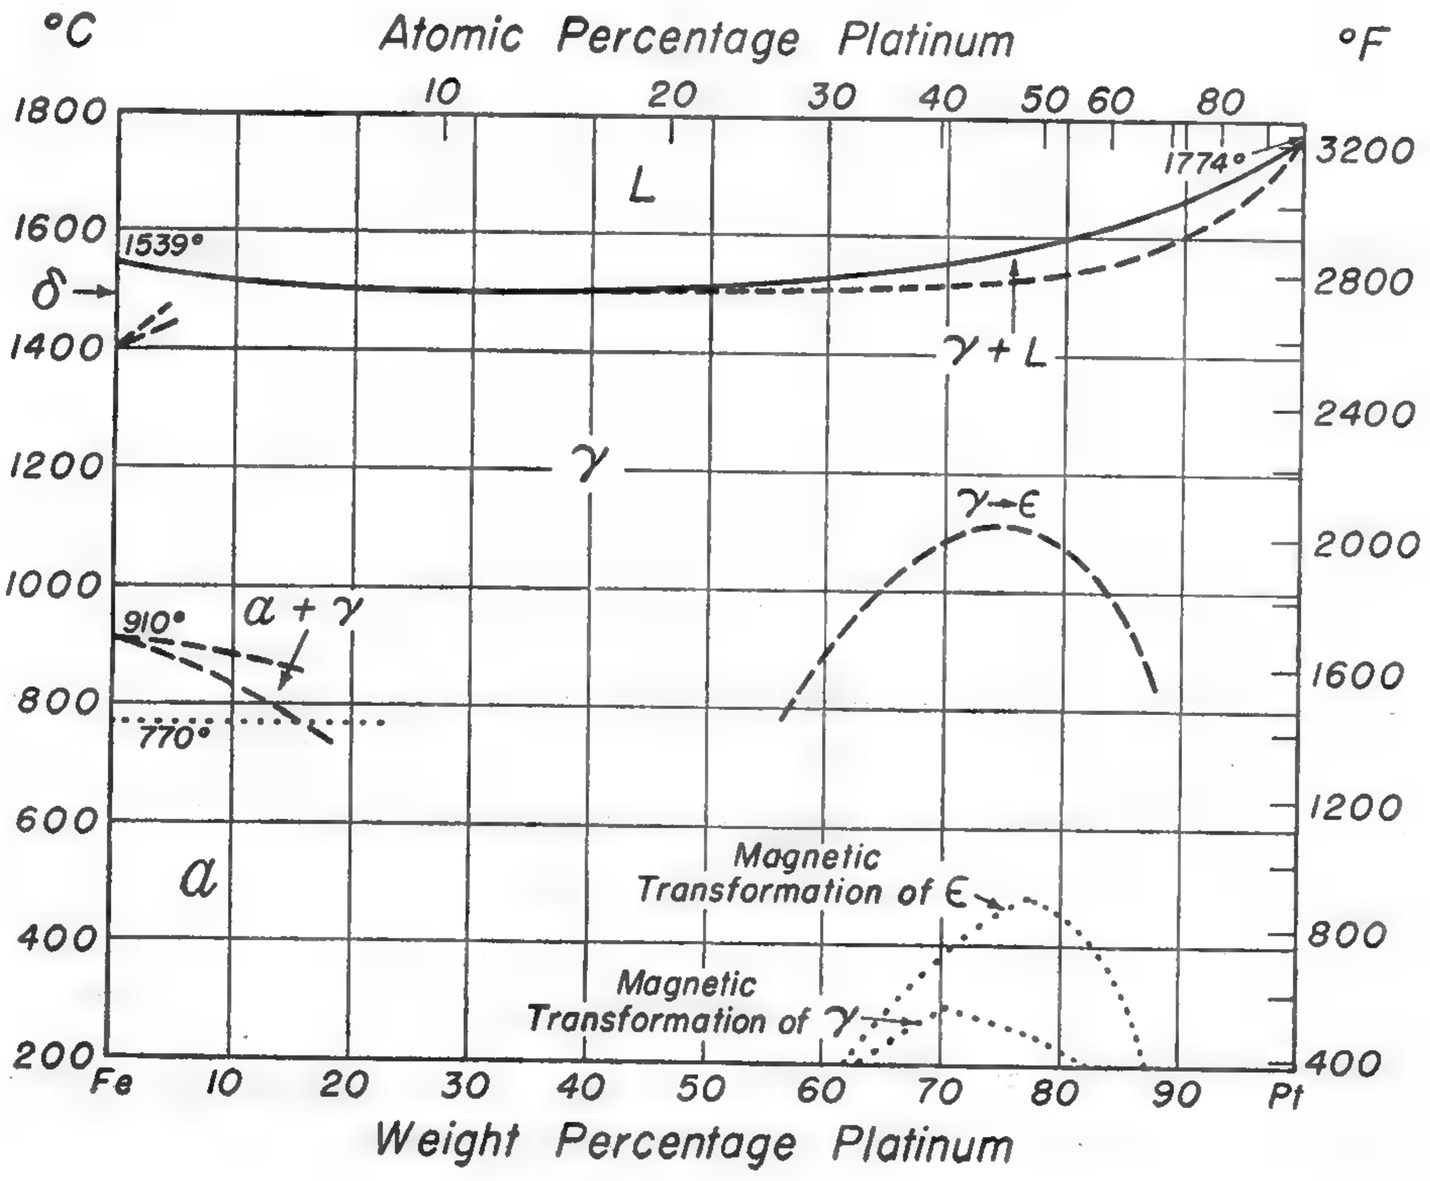
Fe-Pt Iron-Platinum

By R. M. Parke*



The alloys of approximately equiatomic composition (FePt, ε) undergo a transformation[4] near 1100 C, in which some γ is converted, on cooling, to a disordered body-centered cubic structure having a lattice parameter close to that of alpha iron. The change is not suppressed by quenching.

The gamma-alpha transformation occurs with considerable hysteresis. For example, the transformation temperatures during heating and cooling a 40% Pt alloy are about 700 and 400 C respectively.

According to Kussmann,[5] the alloys containing between 50 and 60% Pt have a negative coefficient of thermal expansion.

Fe-S Iron-Sulfur

By John Chipman*

The compounds of iron and sulfur are given the nominal formulas FeS and FeS_2. The latter is capable of existence in two allotropic forms: pyrite, which is cubic, and marcasite, which is rhombic. Pyrite (ζ in the diagram) is the more stable of these two forms.

The mineral pyrrhotite (ϵ in the diagram) varies in composition from FeS to approximately $FeS_{1.2}$ at elevated temperatures and to about $FeS_{1.1}$ at room temperature. The structure is that characteristic of NiAs and a superlattice occurs in the low-sulfur region. Alloys in the sulfur-rich region of the solid solution are ferromagnetic and the crystal structure is described as deficient in iron atoms. Several allotropic forms have been described, having the same structure but differing in lattice dimensions. Transformations occur at 138 and 325 C.

A continuous series of liquid solutions can be formed extending from pure iron to a composition higher in sulfur than FeS. The compound FeS melts over a temperature range of about 100 C. The highest melting composition in the pyrrhotite field is at 38.5% S, which corresponds to a formula $FeS_{1.09}$ or $Fe_{12}S_{13}$.

The transformation temperatures of iron are not appreciably affected by sulfur. The solubility of sulfur in solid iron has not been determined with accuracy but has been variously estimated from 0.01 to 1.5%. The most dependable value appears to be approximately 0.025% in gamma iron at 940 C, decreasing with increased temperature. In alpha iron, the solubility is probably smaller.

FeS_2 (pyrite) decomposes, on heating, into pyrrhotite and sulfur vapor; the pressure of the vapor reaches atmospheric at 693 C. The region above this temperature and beyond 41% S has not been investigated.

Fe-Si Iron-Silicon

By R. L. Rickett*

Ordering appears in α-phase alloys at about 7% Si; the superstructure has a parameter twice that of alpha iron. The solubility limit of silicon in iron between 1030 and 1200 C is given as 18.5% by Haughton and Becker[2] and 20.4% by Greiner and Jette,[3] whereas Farquhar, Lipson and Weill[4] report two phases of similar crystal structure in this range, one containing 18.5% and the other about 20.5% Si.

Greiner and Jette[3] have shown that although η is unstable above 1030 C or below about 825 C, the rate at which it transforms to $\alpha + \epsilon$ may be extremely slow.

Fe-Sn Iron-Tin

By O. E. Romig*

The complete constitution of the iron-tin alloys has not yet been definitely established. The diagram shown has been drawn to represent the present state of knowledge based mainly on the work of Edwards and Preece,[1] with modifications and additions by Ehret and Westgren,[2] Jones and Hoare,[3] Wever and Reinecken,[4] and recent work by Ehret and Gurinsky.[5] For the history of development, the reader may consult references 6 and 7. Below 496 C, from 10 to 100% Sn, the diagram seems well established.

It is likely that if more than 1.9% Sn is present the γ phase is not stable. With a given tin content, the positions of the transition points vary with carbon content, even when

Fe-Ti Iron-Titanium

By G. F. Comstock* and J. C. Southard*

The intermetallic compound nearest the iron end of this system has usually been considered to be Fe_3Ti, according to Tofaute and Büttinghaus,[1] although its identification as Fe_2Ti by Witte and Wallbaum[2] is now believed to be correct. There is also a slight disagreement regarding the extent of solid solubility at the eutectic temperature; this was reported as 6.9% by Vogel and Ergang,[3] and 6.3% by Tofaute and Büttinghaus.[1] The latter found the eutectic temperature to be 1350 C, while Vogel and Ergang[3] found it at 1298 C. The intermediate value of 1310 C, which is indicated, was proposed by Witte and Wallbaum.[2] The η phase (FeTi) was suggested by Wallbaum,[4] who found that this phase melted above 1600 C. Wallbaum also suggested the existence of $FeTi_2$, and indicated that the higher-titanium part of the system is solid at least up to 1550 C.

Hume-Rothery and Christian[5] indicate a maximum at 1600 C in the liquidus for a phase based on Fe_2Ti (30% Ti).

Fe-V Iron-Vanadium

By Jerome Strauss†

The gamma phase may extend to a vanadium content as great as 2.5%.[2,3,4,6] The crystal structure of the ϵ phase (FeV) is complex and has not been determined. Wever and Jellinghaus[3] have described this phase.

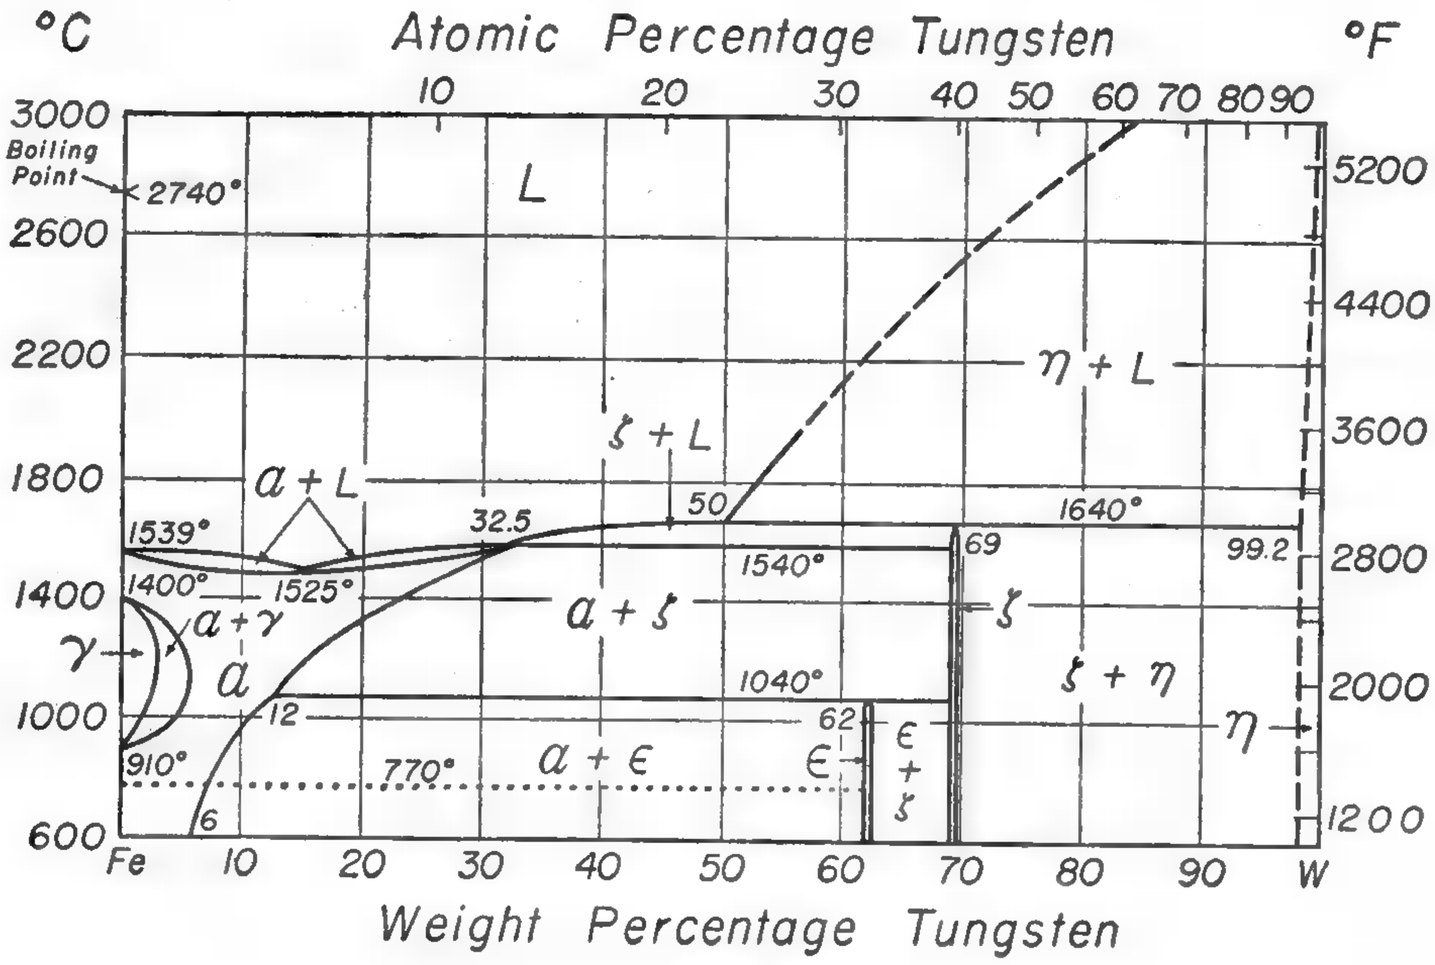
Fe-W Iron-Tungsten

By W. P. Sykes*



Solid tungsten dissolves about 0.8% Fe at 1600 C.[1,7]

Certain $a + \epsilon$ alloys can be precipitation hardened.

The ϵ phase is hexagonal with $a = 4.727$ kX, $c = 7.704$ kX, $c/a = 1.630$. ζ is also hexagonal with $a = 4.731$ kX, $c = 25.76$ kX, $c/a = 5.440$.

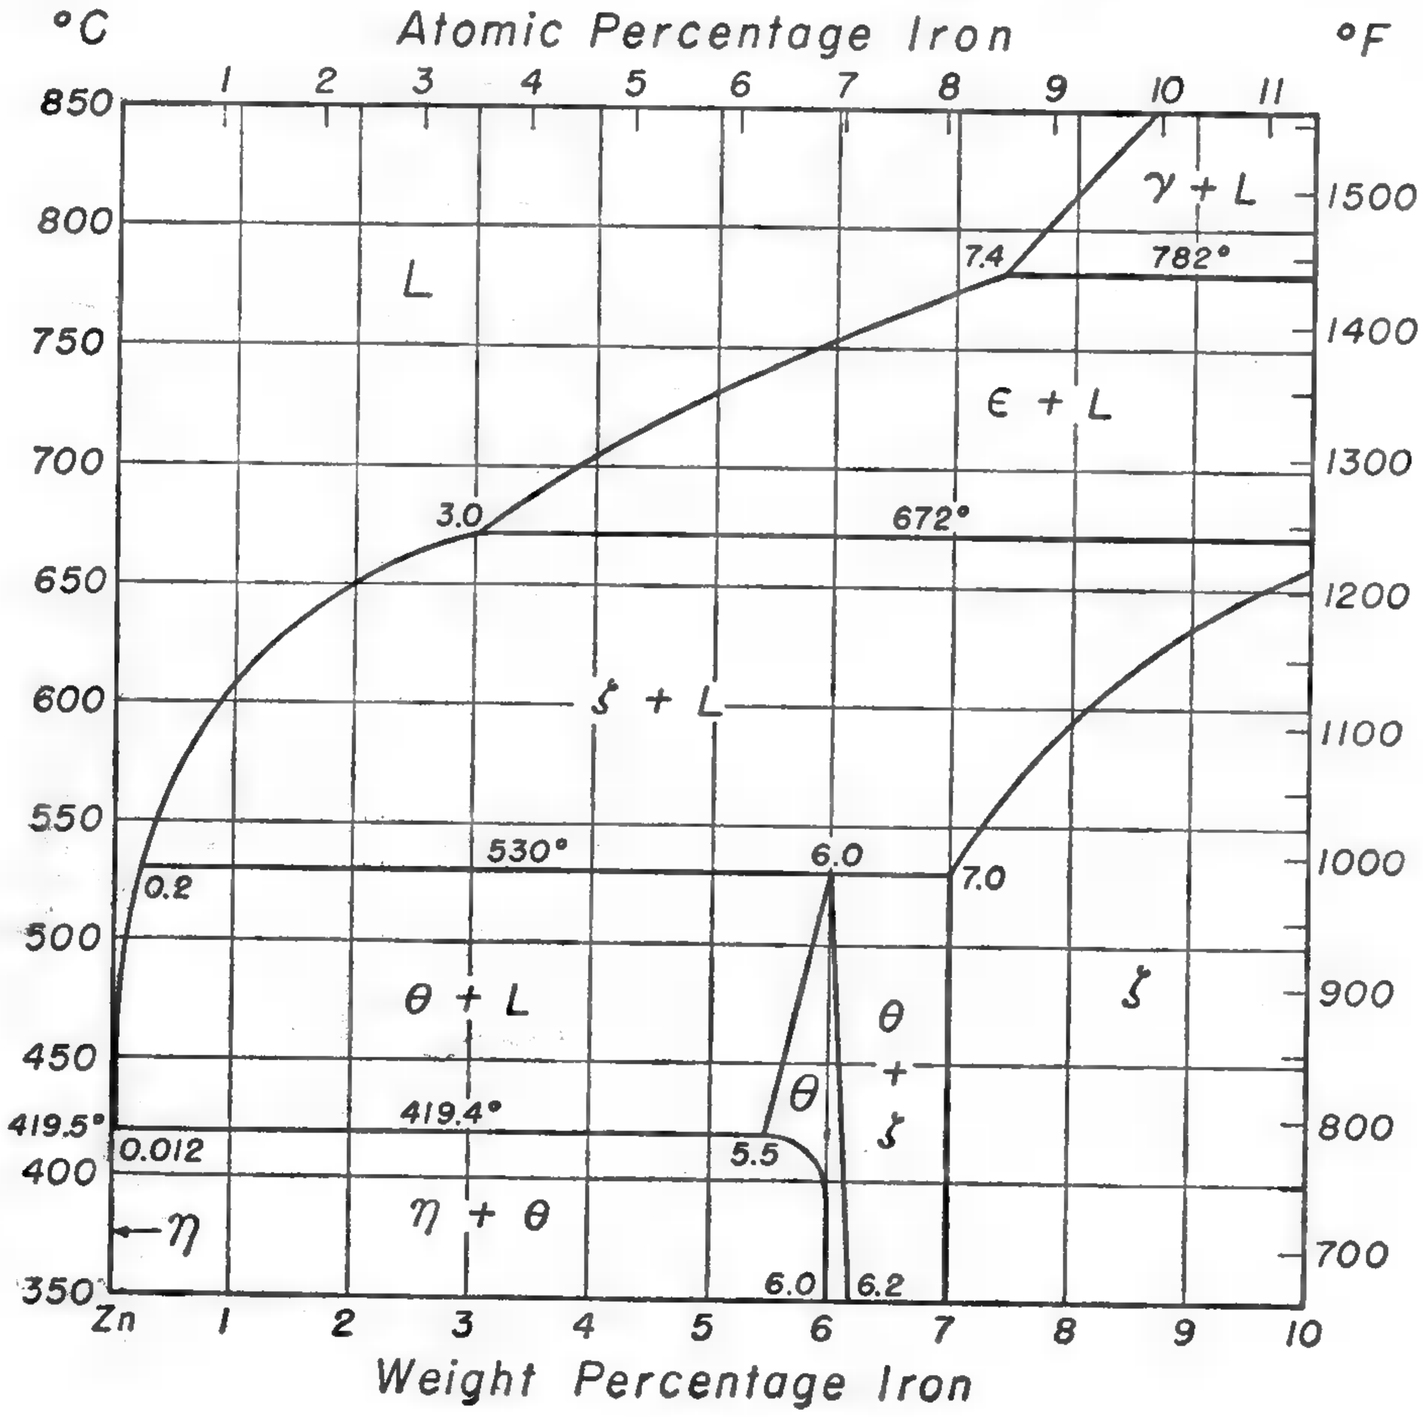
Fe-Zn Iron-Zinc

By E. A. Anderson*



The solid solubility of iron in zinc at 150 and 400 C lies between 0.0009 and 0.0028%. The work of Jones[3] and Svechnikov and Gridnev[4] indicates the existence of a gamma loop instead of the $a + \gamma$ region shown on the diagram by dotted lines. Further work in this region is needed.

Since zinc boils at 906 C, all portions of the diagram above this temperature must represent conditions at higher than atmospheric pressure.

The preparation of homogeneous and nonporous zinc-iron alloys is difficult when the iron content is more than a few per cent. By a unique method of preparing alloys containing from 4 to 20% Fe, Schramm[5,6] prevented the usual expansion and excessive porosity, and produced alloys suitable for microscopic examination. Alloys containing from 20 to 100% Fe were prepared by annealing highly compressed powder mixtures of iron with a zinc-iron alloy containing 15% Fe. The need for high temperature, and consequent high pressure in order to prevent volatilization of zinc, was avoided in this way.

The peritectic reaction at 530 C involves considerably

* Research Division, Technical Department, The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

more solid than liquid, is sluggish, and may often be suppressed almost completely during cooling from the liquid state.

Rapid attack of iron by molten zinc near 500 C may be associated with the formation of the θ phase.

The crystal structures of the phases are as follows:

Phase	Crystal Structure
α	Body-centered cubic
γ	Face-centered cubic
ϵ	Cubic, with 52 atoms per unit cell
ζ	Hexagonal
θ	Similar to ζ
η	Close-packed hexagonal

Fe-Zr Iron-Zirconium

BY R. M. PARKE*

The diagram is that of Vogel and Tonn,[2] modified to show the melting points of iron and zirconium as 1539 and 1750 C respectively. The ϵ phase is shown corresponding to Fe_3Zr_2. Wallbaum[2] reported different intermediate phases, including one forming by peritectic reaction.

Allibone and Sykes[1] made a preliminary study of alloys containing up to 30% Zr. The Brinell hardness number of the eutectic alloy in the as-cast condition was given as 290.

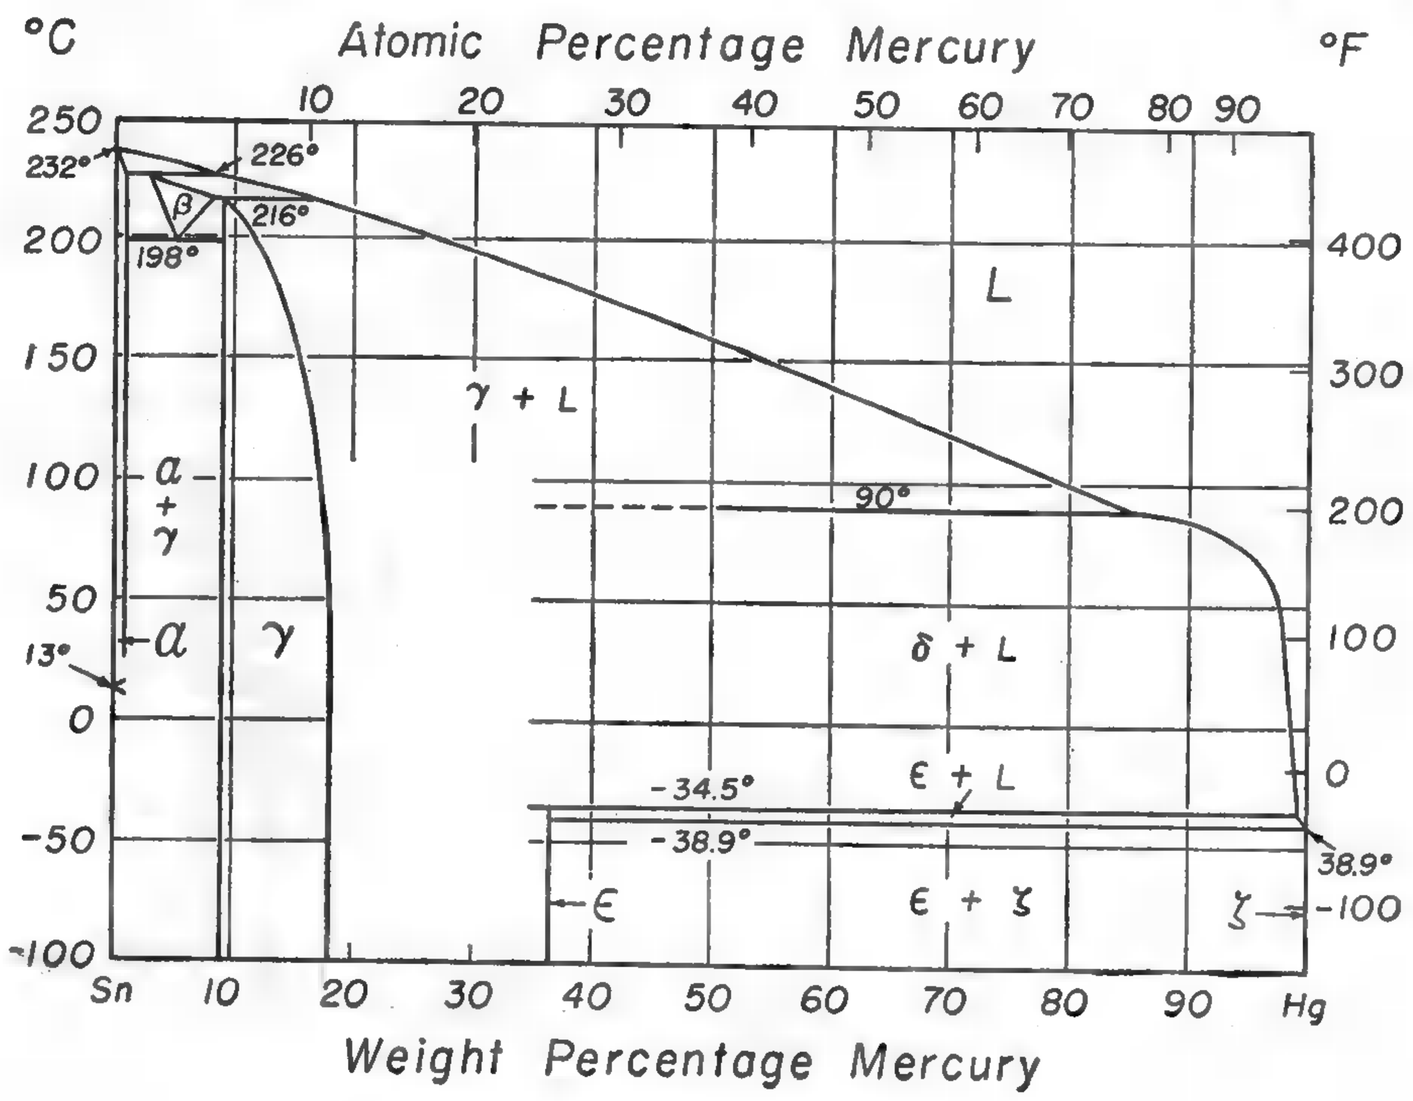
Hg-Sn Mercury-Tin

By Louis A. Carapella*

There is excellent agreement concerning the position of the liquidus curve.[1-6] However, the nature of the system below the liquidus temperatures has been reported with considerable variance, chiefly because of the difficulty of establishing equilibrium conditions at the relatively low temperatures where transformations involving solid phases occur. The latest contributions to the diagram, consistent with many early findings, are those of Prytherch and Gayler.

The β phase decomposes by a eutectoid reaction at 198 C. The eutectoid composition is about 5% Hg.

There is evidence for the formation of a δ phase — not shown in the diagram — which probably forms by peritectic reaction at 90 C. The structure of the silver-mercury-tin system indicates also that this phase exists.[6] Since the equilibrium relations between the δ phase and γ, ϵ and liquid are not known, the portion of the phase diagram between 20 and 35% Hg, and below 100 C, has been left blank in the adjoining cut.



The ϵ phase ($HgSn_3$) apparently has a very narrow range of homogeneity. No solubility of tin in solid mercury has been reported. The effect of mercury on the allotropic transformation of tin is unknown.

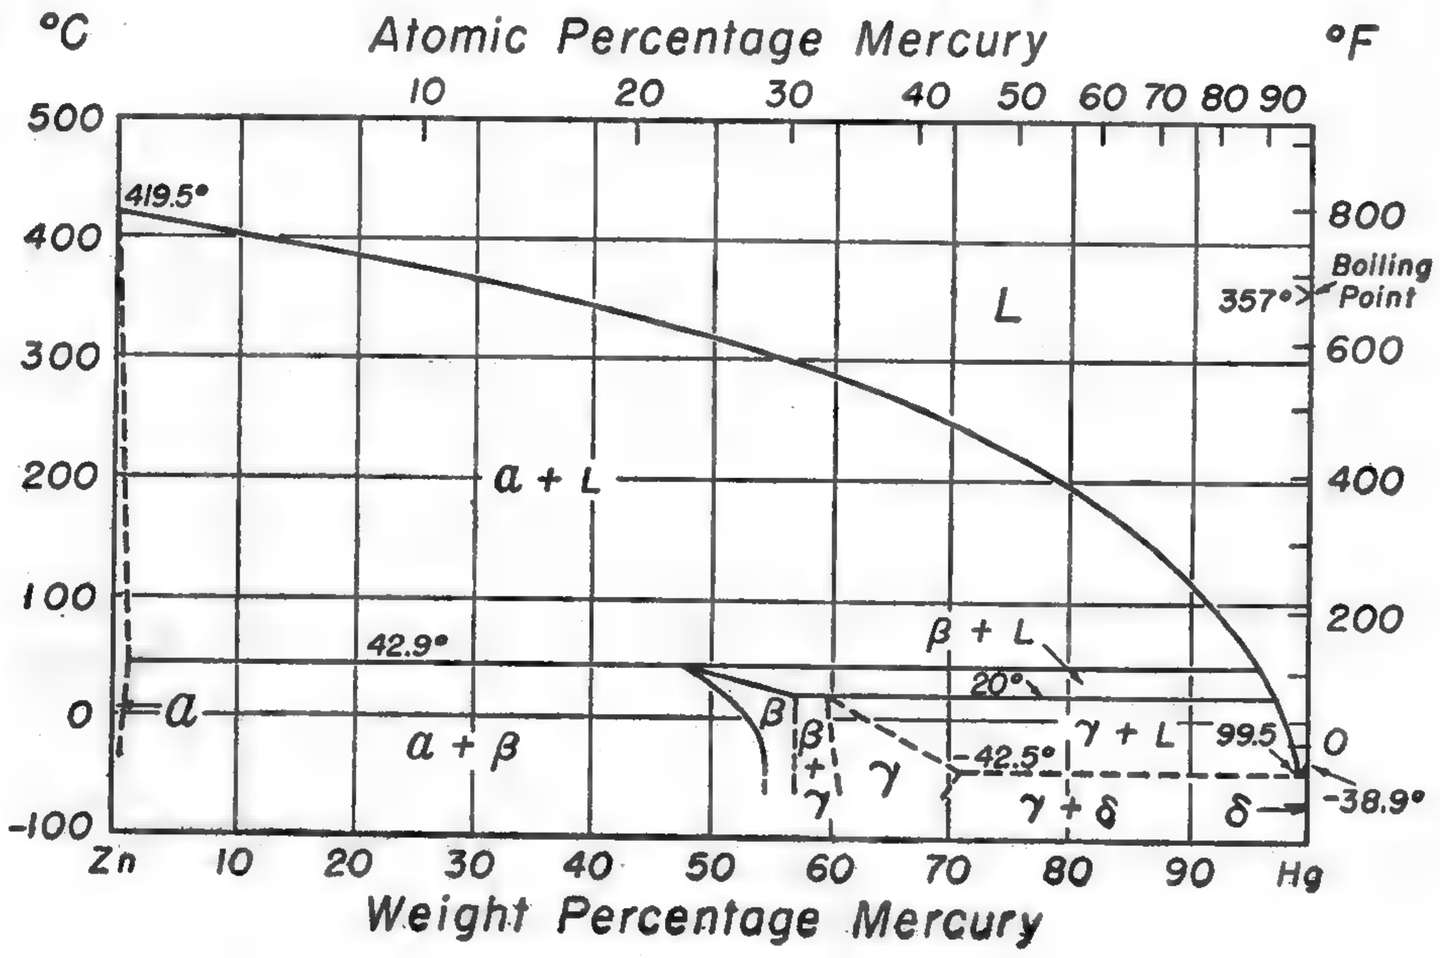
Hg-Zn Mercury-Zinc

By E. A. Anderson*



The solubility of mercury in solid zinc has not been established accurately but is probably less than 1% at room temperature. No data are available concerning the solubility of zinc in solid mercury.

According to von Simson,[4] the β phase is hexagonal with an axial ratio of 2.01. Apparently the crystal structure of the γ phase, stable only below room temperature, has not been determined.

* Editor's Note. In the original work, the melting point of indium was determined as 157.3 C, but it is shown on the diagram here as 156.4 C, which is the value employed elsewhere in this Handbook.

Ir-Pt Iridium-Platinum

By E. M. Wise†

The liquidus is based on the results of Feussner and Müller,[1] adjusted to conform with more recent determinations of the melting point of iridium. The solidus probably is close to the liquidus throughout. There is some evidence of a sluggish transformation at intermediate temperatures in platinum-rich alloys. (*See also* page 1124.)

Li-Mg Lithium-Magnesium

By G. F. Sager* and B. J Nelson*

The work of Henry and Cordiano[4] indicates a peritectic reaction between the magnesium-rich solid solution and the melt to form a lithium-rich solid solution, rather than the eutectic type of diagram shown. The slightly increasing solubility of lithium in solid magnesium with decreasing temperature[5] seems most probable although some investigators[2,4] found that the solubility decreased with decreasing temperature. There is some evidence[1,5] of a superstructure near the boundary between β and $\alpha + \beta$.

The β-phase alloys are ductile, and Hume-Rothery[5] has suggested the possibility of obtaining strong, body-centered cubic alloys, lighter than magnesium, in this range of composition.

Li-Pb Lithium-Lead

By H. Osborg*

According to a recent investigation[3] only one compound ($Li_{10}Pb_3$) exists in the region occupied by δ, ϵ and ζ in the diagram shown here. However, insufficient data are available to warrant changing the diagram from the form in which it was presented by Hansen.[7] The γ, δ, ϵ and ζ phases are the compounds Li_5Pb_2, Li_3Pb, Li_7Pb_2, and Li_4Pb, respectively.

The β-β' transition is an order-disorder change.[4]

It has been reported[3] that the crystal structure of $Li_{10}Pb_3$ is of the same type as that of Cu_9Al_4; with a unit cell containing four $Li_{10}Pb_3$ groups (52 atoms) and having a lattice parameter of 10.082 kX.

Mg-Mn Magnesium-Manganese

By G. F. Sager* and B. J Nelson*

The β phase in equilibrium with magnesium-rich solid and liquid solutions is alpha manganese.[2]

The most reliable solubility values are, as follows:[2,3]

Temperature, deg Cent	651	670	700	765	850
% Mn in liquid Mg[3]	2.1	2.3	2.6	3.9	6.6
Temperature deg Cent	651	620	540	455	
% Mn in solid Mg[2]	2.45	2.06	1.00	0.25	

The Mg – 1.5% Mn alloy is used commercially in both cast and wrought forms. Manganese (0.1 to 1%) is a secondary component in all other commonly used magnesium alloys.

Mg-Ni Magnesium-Nickel

By A. M. Hall*

The presence of a two-liquid field has been suggested between 16 and 28% Mg with a lower boundary at 1145 C; however, there is considerable question about the existence of such an area. The phenomenon is probably related to the formation of the β phase (Ni_2Mg) at 1145 C.

The solubility of magnesium in solid nickel is considered to be less than 0.10% at 1100 C.[5] The solubility of nickel in solid magnesium is less than 0.10% at 500 C.[3]

The β phase is hexagonal with $a = 4.81$ kX and $c/a = 1.65$.[6]

Greatest commercial interest is in age-hardenable high-nickel alloys containing small additions of magnesium.

Nickel, like iron, has an extremely adverse effect on the resistance of magnesium alloys to corrosion in saline environments (*see* the article on page 994 in this Handbook). For specialized applications, the control of the nickel and iron contents of magnesium alloys offers a means for obtaining an alloy with a controlled rate of corrosion.

Mg-Pb Magnesium-Lead

By A. A. Smith, Jr.*

The diagram is based largely on references 1 to 4.

The solubility of magnesium in solid lead decreases from 0.7% at 245 C to 0.2% at 20 C.[7] Vosskühler[3] reported the solubility of lead in solid magnesium to be about 27% greater than shown here.[4]

The β phase (Mg_2Pb) is face-centered cubic (CaF_2 type) with $a = 6.75$ kX.[5,6]

Even as little as 1% Mg in lead produces an alloy that is unstable in moist air.[8]

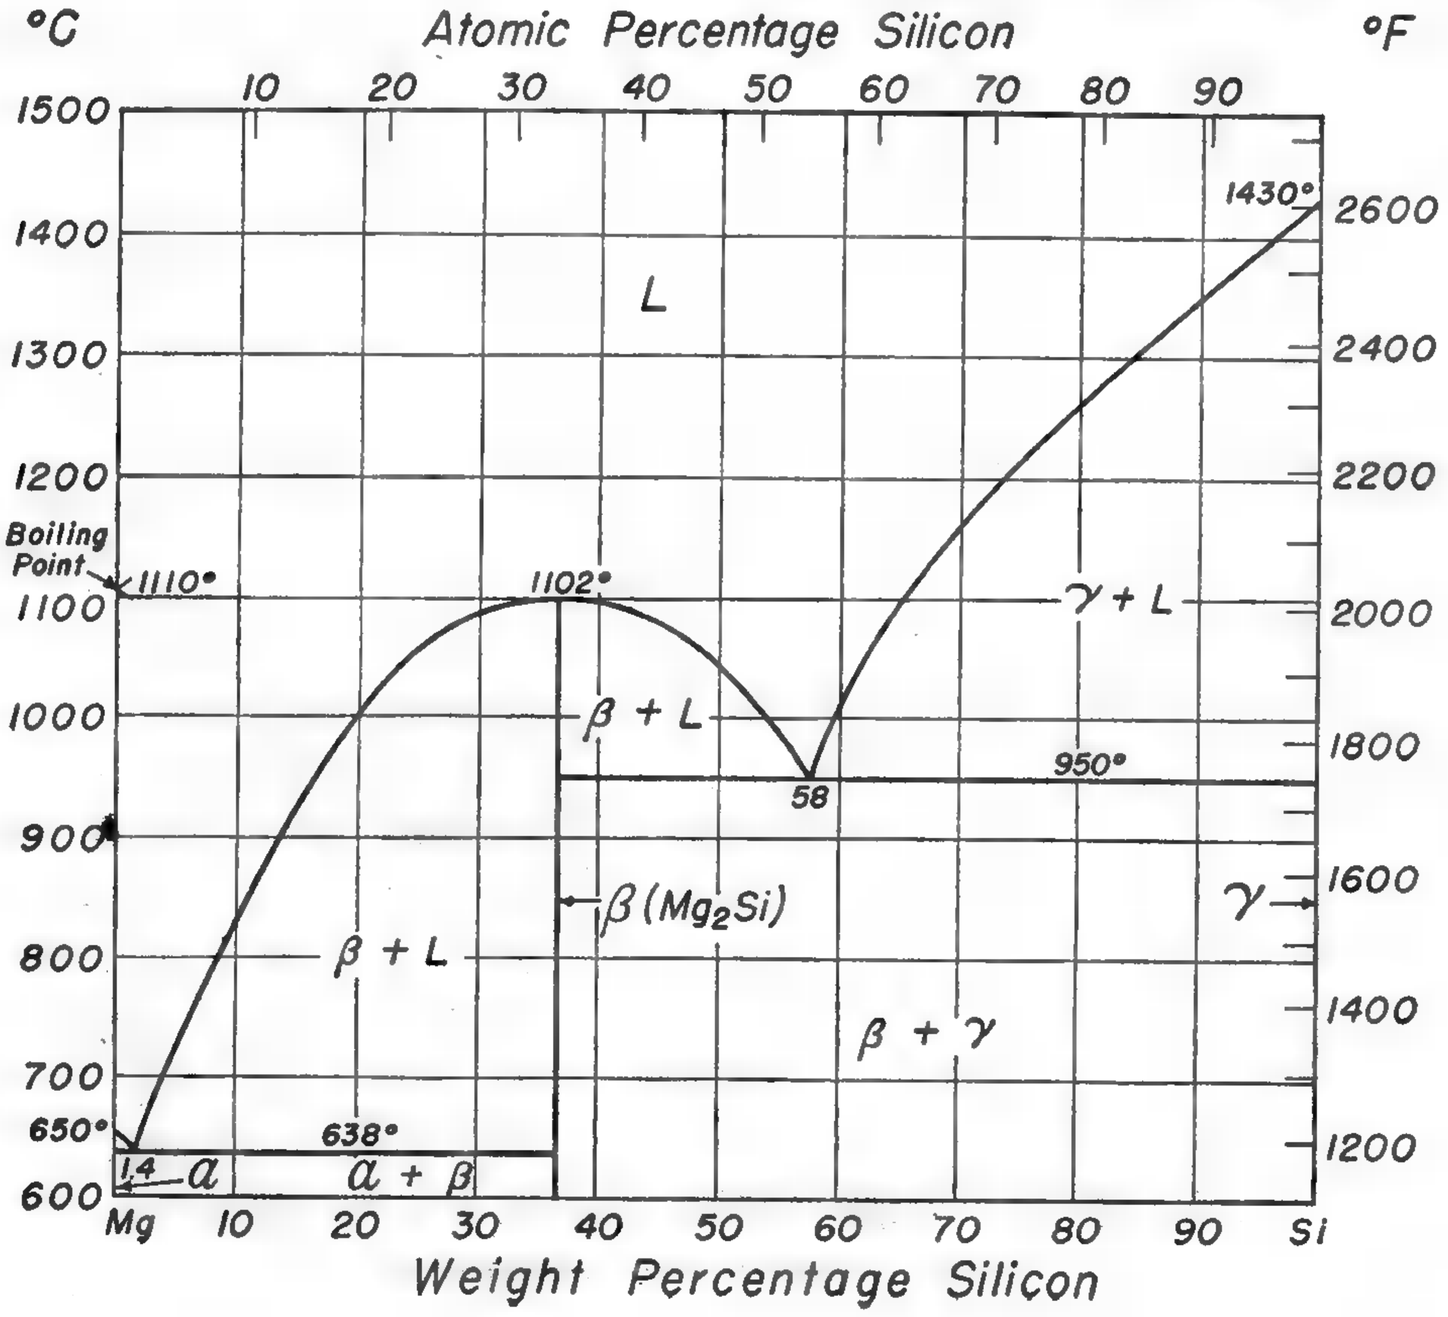
Mg-Si Magnesium-Silicon

By G. F. Sager* and B. J Nelson*



The solubility of silicon in solid magnesium is of the order of 0.003 atomic % at 600 C.

No range of solubility has been detected for the β phase (Mg_2Si).

The β phase (Mg_2Si) is face-centered cubic (CaF_2 type) with a lattice parameter of 6.391 kX.[5]

The boiling point of magnesium and the melting point of Mg_2Si are at nearly the same temperature. During the distillation of magnesium that contains silicon, the residue consists mainly of Mg_2Si crystals.

Silicon increases the hardness of magnesium alloys; the tensile strength reaches a maximum at about 1% Si.

Mg-Sn Magnesium-Tin

By G. F. Sager* and B. J Nelson*

The β phase is the compound Mg_2Sn; no range of solid solubility of magnesium or tin in this compound has been detected. The solubility of tin in solid magnesium, from unpublished results of L. A. Willey,* is as follows:

deg Cent	560	525	500	475	422	325	300	250
% Sn	14.7	11.75	9.95	8.10	5.25	1.90	1.40	0.98

The β phase (Mg_2Sn) is face-centered cubic (calcium fluoride type) with a lattice parameter of 6.76 kX.

A quaternary magnesium-base alloy containing 5% Sn is used commercially in making hammer forgings.

Mg-Zn Magnesium-Zinc

By J. B. Hess*

The solubility of zinc in solid magnesium is as follows:[3]

deg Cent	340	300	250	200	150
% Zn	8.4	6.0	3.3	2.0	1.7

The solubility of magnesium in zinc has been reported to be approximately 0.11% at 364 C[1,2] and less than 0.002% at room temperature.[4]

At least three intermetallic phases have been identified. The β phase (MgZn) is hexagonal, with $a = 5.33$ kX, $c = 8.58$ kX.[13,14] The γ phase ($MgZn_2$) is also hexagonal, with $a = 5.15$ kX, $c = 8.48$ kX.[11] The δ phase (Mg_2Zn_{11}?) is probably cubic.[4,13,14,15] Solid solubility in these compounds has been both reported and denied.

Early work on the magnesium-rich alloys indicated the phase diagram to be of the simple eutectic type, and consequently this part of the diagram has received limited study subsequently. However, there is now ample metallographic,[4,7,10,†] thermal,[7,10] X-ray,[9,†] and other[5,6,8] evidence to establish the existence of an additional phase, in the neighborhood of 50 to 54% Zn, which undergoes eutectoid decomposition at lower temperature. The data are still not sufficient to permit a revision of the diagram in this region. The reported evidences of polymorphic transformations in β and γ are probably misinterpreted effects of this eutectoid.

Mg-Zr Magnesium-Zirconium

By G. F. Sager* and B. J Nelson*

The evidence for this system is too fragmentary to allow the construction of a diagram. Siebel[1] reports a peritectic system analogous to the magnesium-manganese system, with the liquidus meeting the peritectic temperature at 0.26% Zr, near the melting point of magnesium, and rising steeply with increase of zirconium content until 1000 C is reached, at which point it curves away toward horizontal.

Vosskühler[2] states that the solubility of zirconium in magnesium is 0.8% at 500 C and less than 0.1% at 400 C. Nowotny, Wormnes, and Mohrnheim[3] report the solubility of zirconium as 0.8% at 700 C and 0.3% at 300 C.

* Aluminum Research Laboratories, New Kensington, Pa.

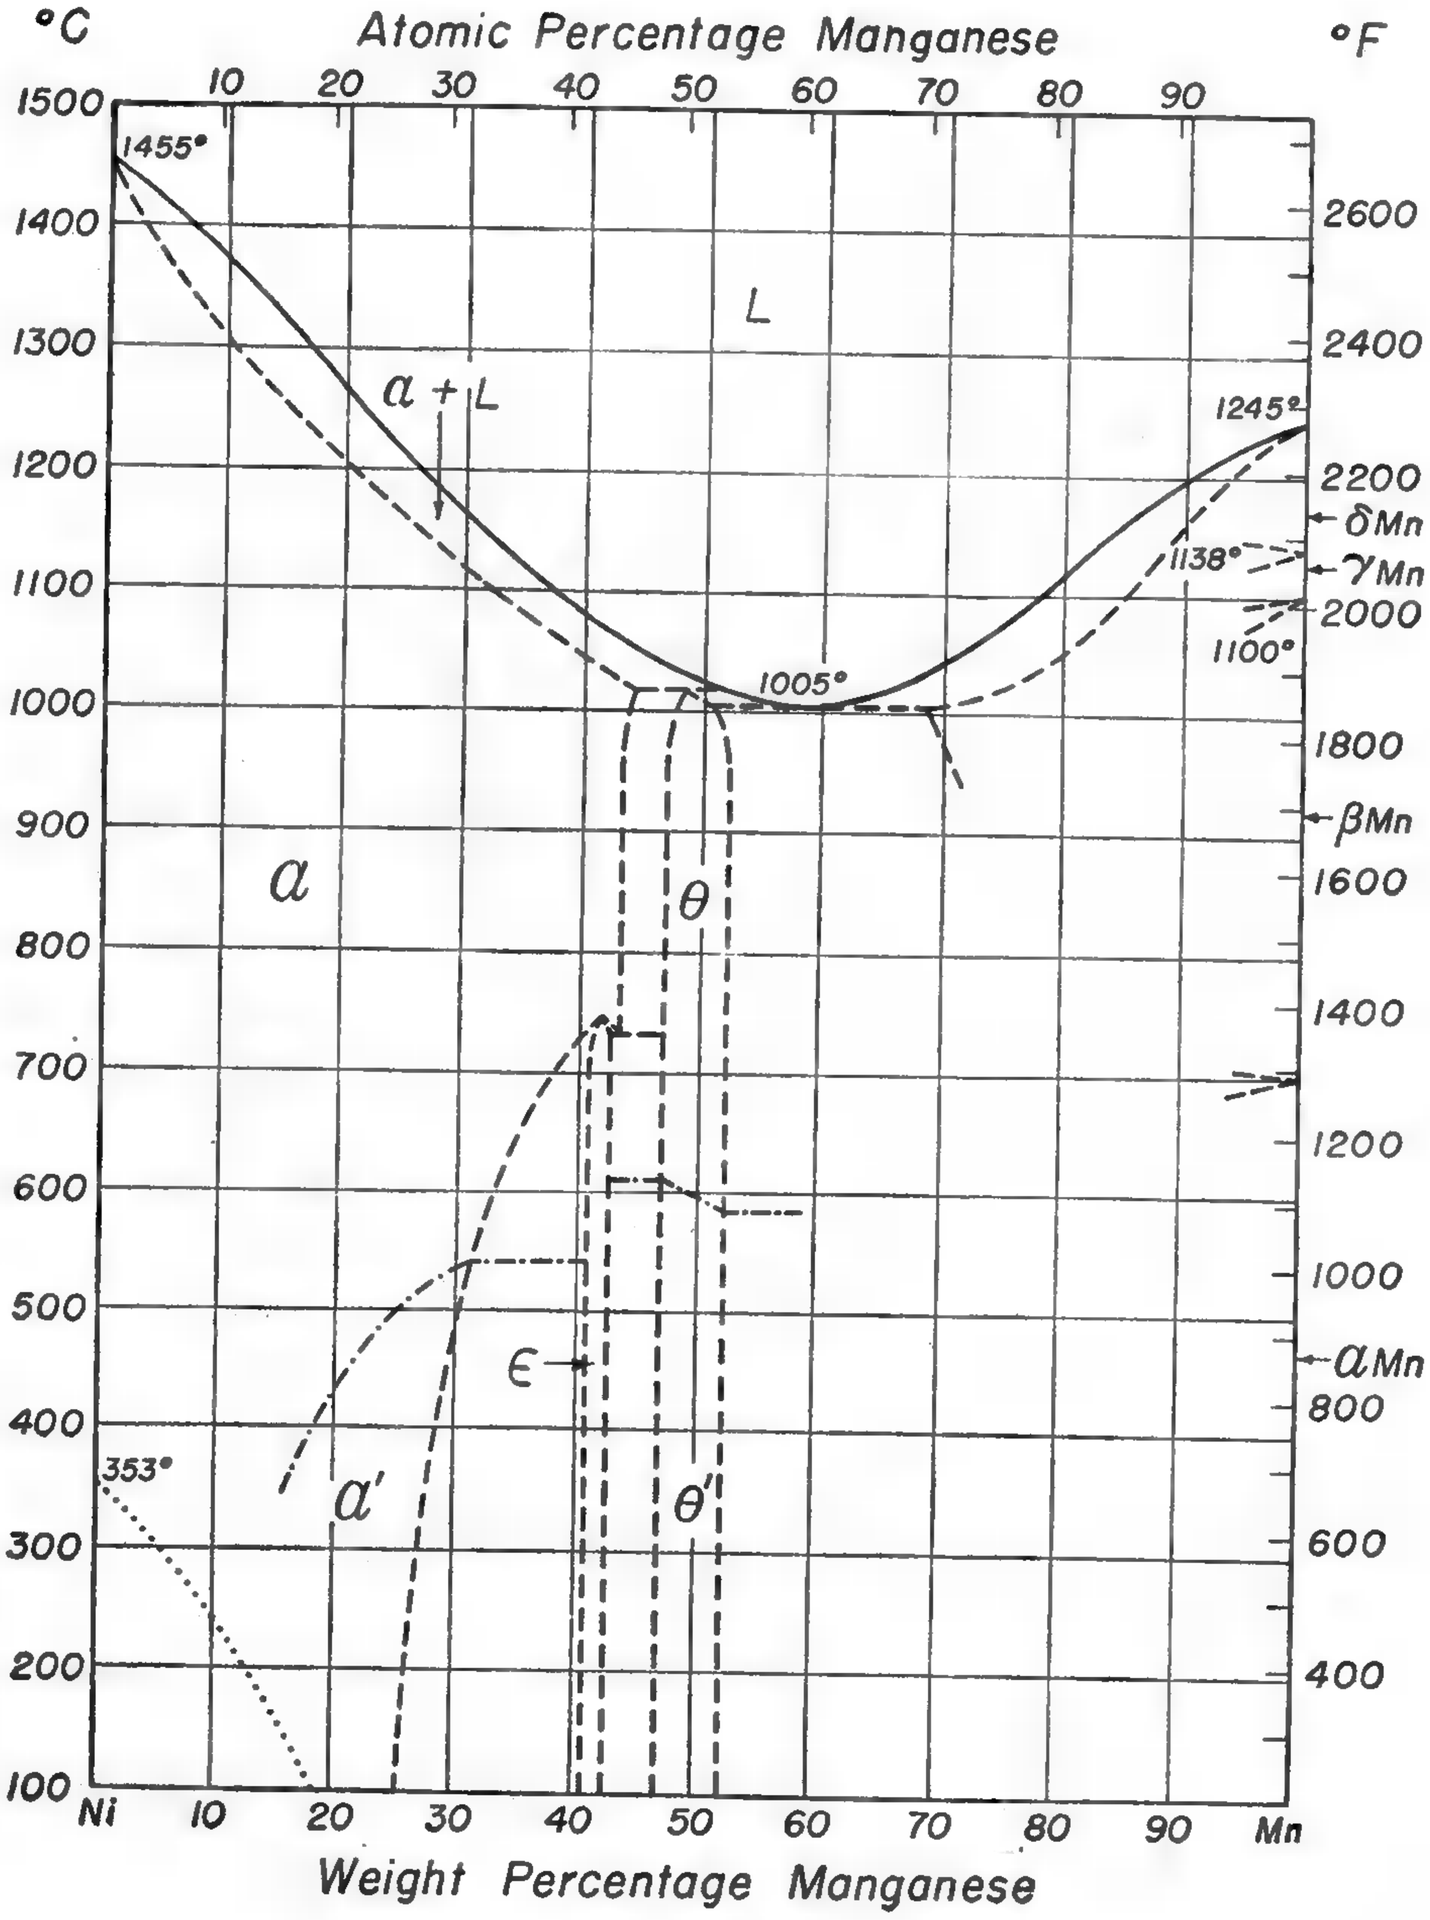
Mn-Ni Manganese-Nickel

By C. E. Lacy*



The equilibrium relationships shown for the region between 25 and 60% Mn are only approximate. They are based mainly on information given by Dourdine[2] and are supported in part by the data of other workers.[3,4] Valentiner and Becker[6] confirmed the θ phase, found an additional phase at 70% Mn, but failed to confirm the ϵ phase. Little is known about the diagram in the region from 50 to 100% Mn. Study of the manganese-nickel system is complicated by the fact that the alloys apparently freeze metastably.

It has been definitely established[3,6,7] that the magnetic transformation occurring in alloys containing from 15 to 40% Mn is associated with the formation of a $MnNi_3$ superstructure of the $AuCu_3$ type. The $MnNi_3$ superstructure is ferromagnetic. The θ phase may also form a superlattice.[6]

The transformation temperatures of pure manganese are based on the work of Potter and Lukens.[9]

The ϵ phase containing approximately 42% Mn is face-centered cubic; θ (48% Mn) is face-centered tetragonal.

Mn-Pd Manganese-Palladium

The rather complicated phase diagram, based on the works of several German investigators, is included in "The Platinum Metals and Their Alloys", by R. F. Vines, 1941. The liquidus and solidus temperatures of the palladium-rich alloys have an unusual sinuous form. The liquidus curve descends from the melting point of palladium (1554 C) to a minimum at 1350 C and 21.3% Mn, rises to a maximum at 1515 C and 34% Mn, and then descends to the eutectic point at 1147 C and 57.5% Mn.

Mn-Pt Manganese-Platinum

The platinum-rich alloys were studied by Nemilov, Vidusova and Pivovarova [Izvest Akad Nauk SSSR (Chim), 743 (1937)]. The liquidus curve reaches a minimum at about 45% Mn. Heat effects were obtained at 22% Mn (PtMn) and 956 C, and at 53% Mn ($PtMn_4$) and 980 C. Another intermediate phase is indicated at 8.5% Mn (Pt_2Mn) from measurements of hardness and temperature coefficient of electrical resistivity. Alloys containing up to 5% Mn are ductile enough to be drawn into wire.

Mn-Zn Manganese-Zinc

By E. A. Anderson*

The diagram is essentially that of Schramm.[1] Information is lacking regarding alloys that contain more than 50% Mn.

On the basis of unpublished data Rodda* places the solubility of manganese in solid zinc at 0.45% at the eutectic temperature, decreasing to less than 0.02% at 200 C.

* Research Division, Technical Department, The New Jersey Zinc Company (of Pa.), Palmerton, Pa.

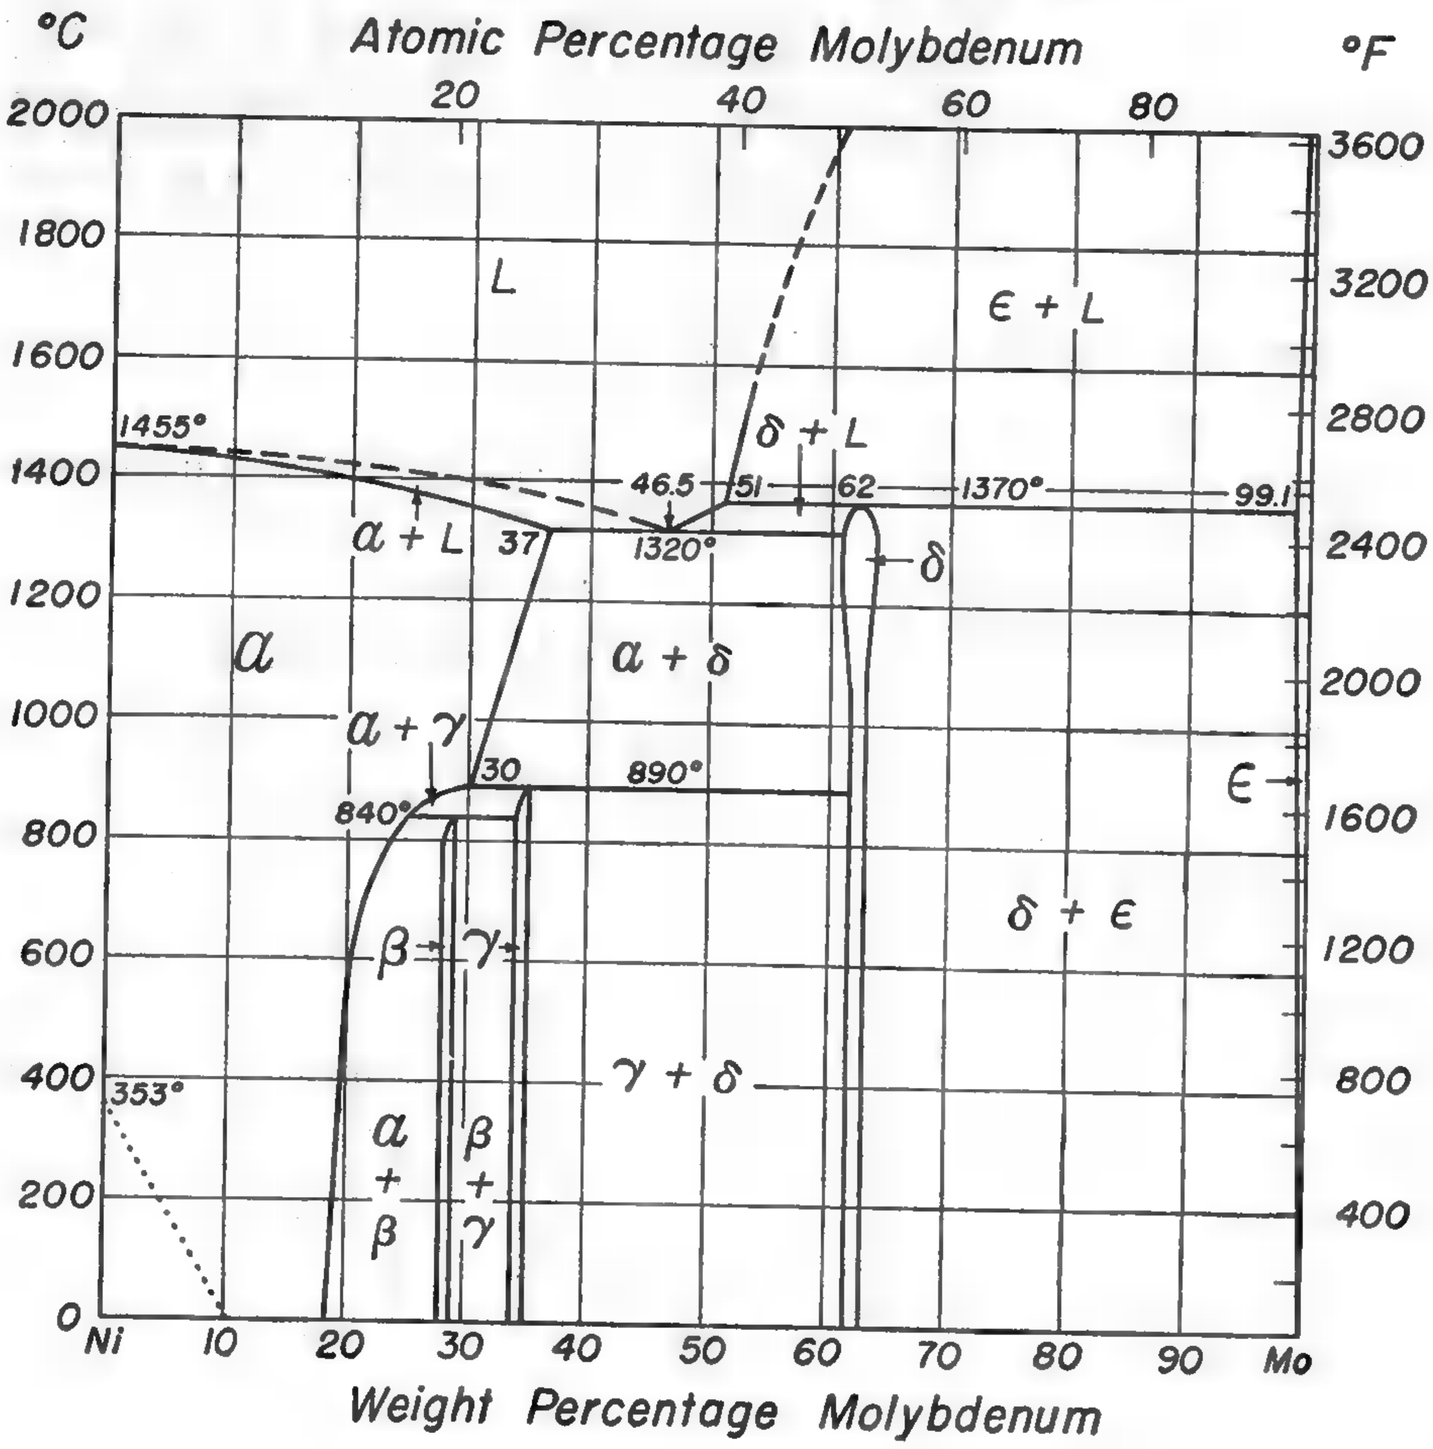
Mo-Ni Molybdenum-Nickel

By R. M. Parke*



The β, γ and δ phases are based on the compositions Ni_4Mo, Ni_3Mo and NiMo respectively.

The γ phase[1] is close-packed hexagonal with an axial ratio (c/a) of about 1.65. The β phase[2] is face-centered tetragonal with axial ratio 0.98.

Ellinger[1] investigated the age hardening of alloys in the range from 21 to 35% Mo. These alloys are in two groups: (1) those that harden by precipitation of β from supersaturated α, and (2) those that harden as a result of decomposition of α into β plus γ. Alloys that contain about 30% Mo do not over-age during 500 hr at 800 C.

Ellinger found that alloys containing about 30% Mo were not in equilibrium after prolonged annealing at 800 C; three phases (β, γ and δ) were present even after 1200 hr at 800 C. After these alloys had been cold worked, annealing at 800 C caused recrystallization and the structure consisted entirely of β plus γ.

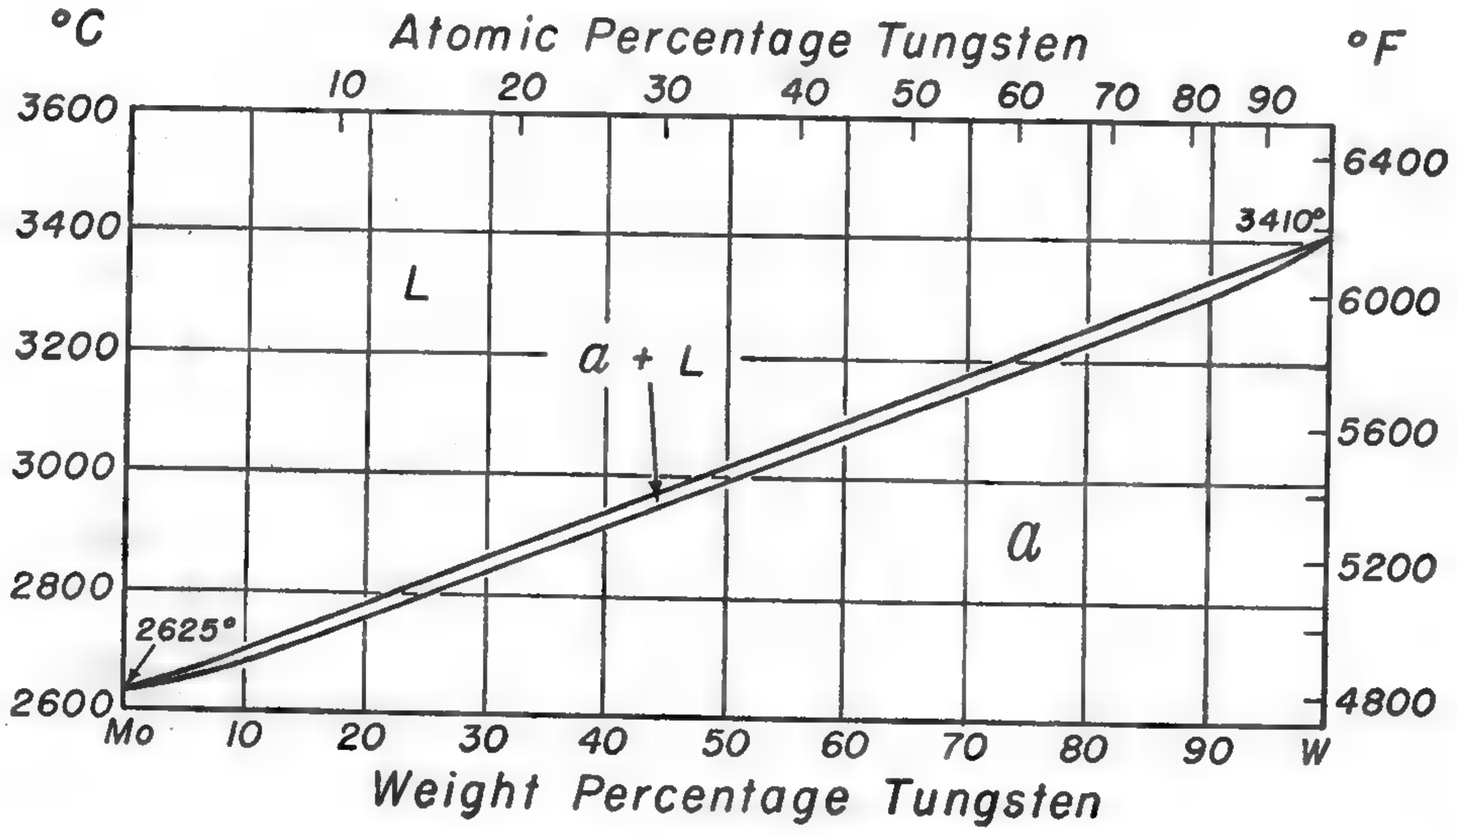
Mo-W Molybdenum-Tungsten

By W. P. Sykes*



The course of the solidus and liquidus curves has been established both by the composition-fusion wattage method[1] and by direct observation of temperatures with an optical pyrometer.[2] Measurements of electrical resistivity,[3] studies of microstructures[1] and X-ray diffraction patterns[4] indicate that this system is an unbroken series of solid solutions.

Ni-O Nickel-Oxygen

By E. N. Skinner*

Although the qualitative existence of a bi-liquidal region has been reported,[1] more recent evidence[2] has indicated complete liquid miscibility, at least up to 13.8% O (64.5% NiO). Therefore it seems likely that the liquidus extends in an unbroken flat curve to the melting point of NiO at 1990 C and 21.4% O.

The solubility of oxygen in solid nickel is exceptional; the amount dissolved increases with decreasing temperature:[3]

Temperature, °C	1200	1000	800	600
Solubility, % O	0.012	0.014	0.019	0.020

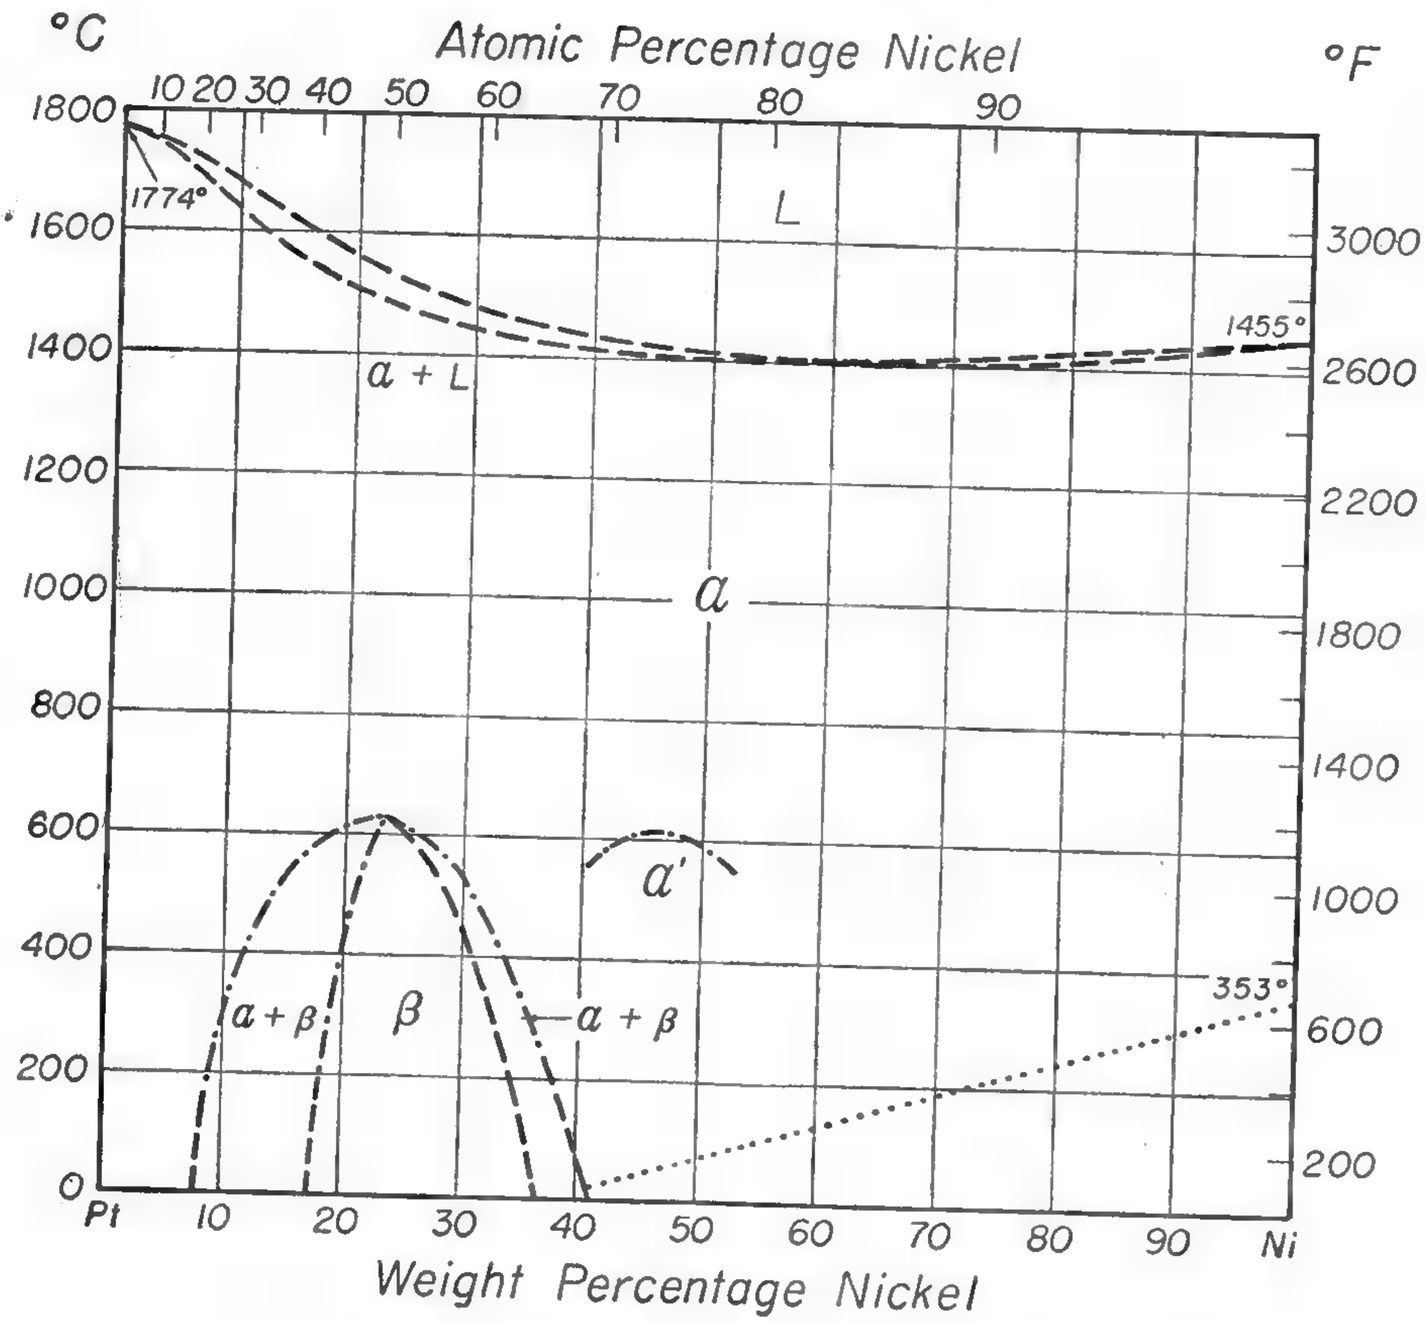
Ni-Pt Nickel-Platinum

By E. M. Wise*



Although the variation in lattice parameter with composition is virtually linear for alloys quenched from 900 C, long holding at about 450 C results in the formation of a superstructure in the vicinity of $PtNi_3$, or 47.5% Pt,[2] and also results in a slight decrease in electrical resistivity, Curie temperature and in the saturation magnetization of alloys in this region.

The NiPt phase[3] has an ordered tetragonal structure and is a relatively good electrical conductor; it resembles the AuCu phase.

The Curie curve shown is essentially that of references 3 and 4, modified to conform to a Curie temperature of 353 C for pure nickel.

The alloys of industrial importance contain 5% or less of nickel (*see* page 1125).

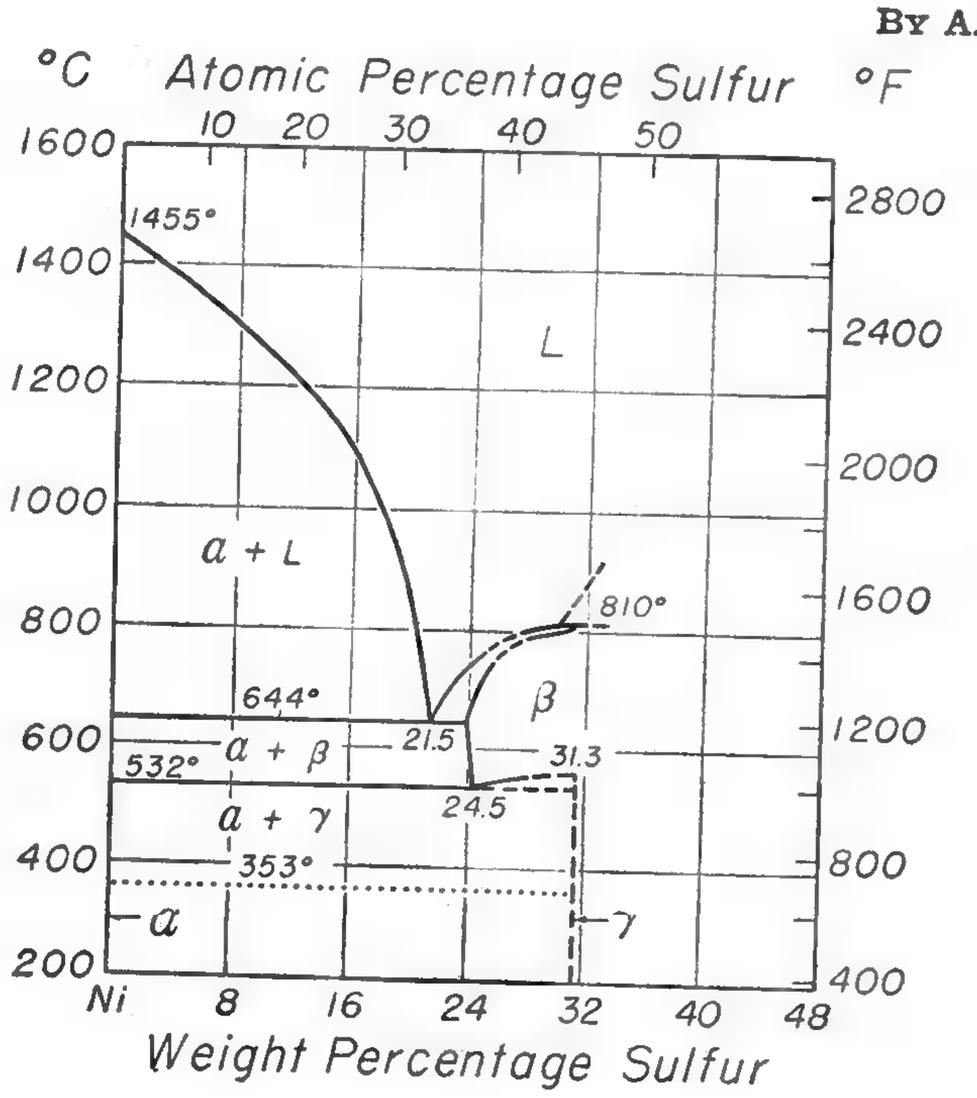
Ni-S Nickel-Sulfur

By A. M. Hall*



The solubility of sulfur in solid nickel is probably of the order of 0.005%.[4]

Apparently β decomposes eutectoidally at 532 C into α and a second phase, which may be either γ (Ni_6S_5) or NiS. Conflicting observations[1,2,3] indicate the complexity of the diagram in this region. The experimental data available are insufficient to determine the nature of the system beyond about 28% S. It has been reported that at high sulfur contents, NiS and NiS_2 form a series of solid solutions.[8]

The β phase is cubic with a lattice parameter of 4.08 kX.[6] NiS has the NiAs type of structure, hexagonal, $c = 3.4$ kX, $c/a = 1.55$.[7,8] NiS_2 has the pyrite type of structure, cubic with $a = 5.7$ kX.[7,8]

Methods for the identification of nickel sulfide and other sulfides in nickel have been described.[9] See also Table I and Fig. 3 in the article "Metallography of Nickel and Nickel Alloys", page 1045.

Ni-Si Nickel-Silicon

By E. N. Skinner*

Several investigators[1,2] have proposed the eutectoidal decomposition of the beta phase into alpha and gamma at 1125 C. There is, however, good evidence that Ni_2Si exists at room temperature[3,4] for, although the ordering transformation of β_2 to β_1 at 1040 C takes place slowly with a negligible heat effect, the changes in volume and crystal structure are clearly defined.

Silicon additions depress the Curie temperature of commercially pure nickel (containing iron and cobalt), as follows:[5]

% Silicon	0	1	2	3	4	5	6
deg Cent	362	320	263	195	130	45	−45

Ni-Sn Nickel-Tin

By H. P. Nielsen* and Bruce W. Gonser*

The transformation from β to β' is concluded to be a change from a disordered to an ordered structure.[4] The nature of the transformation at 600 C is not clear; a thermal effect and a change in crystal structure have been reported.[4]

There is some uncertainty concerning the existence of a eutectic near the melting point of tin. One report gives a eutectic at 0.18% Ni at substantially the melting point of tin;[8] another gives 0.13% Ni at 0.8 °C below the melting point of tin.[9] The solubility of nickel in solid tin is believed to be less than 0.005%.[8]

Between 2.0 and 19.8% Sn the lattice parameter of a changes from 3.5237 to 3.6084 kX.[7]

Ni-Ta Nickel-Tantalum

By R. W. Yancey* and W. H. Lenz*

A polymorphic transformation in the β phase (Ni_3Ta) has been reported at about 1350 C.[3]

According to unpublished results of W. H. Lenz and W. M. Shafer,* between 95 and 100% Ta and below 1600 C the alloys consist of the tantalum-rich solid solution containing less than 0.5% Ni, and an intermediate phase—probably a compound.

Ni-Ti Nickel-Titanium

By E. N. Skinner*

The peritectic formation of γ (NiTi) has been established,[1] but the temperature and composition limits have not.

A titanium-rich phase, δ ($NiTi_2$), exists at 62% Ti. This phase, not shown in the diagram, melts without decomposition and forms a eutectic with the titanium solid solution.

With 8% Ti dissolved in high-purity nickel, the Curie temperature is lowered to about 25 C.

The β phase (Ni_3Ti) is hexagonal with $a = 5.096$ kX and $c/a = 1.630$;[3] γ has the CsCl structure (body-centered cubic);[4] δ is face-centered cubic with 96 atoms per unit cell.

Ni-W Nickel-Tungsten

By W. P. Sykes†

The one intermediate phase, β, forms very slowly at temperatures just below 970 C and crystallizes with a face-centered cubic structure, the dimensions of which are nearly identical with those of the saturated alpha solid solution.[1]

Alloys that contain from 32 to 45% W can be precipitation hardened. A hardness of 490 Brinell is developed in an alloy containing 45% W, aged at 900 C for 100 hours, after solution treatment at 1200 C. Overaging occurs very slowly at 900 C.

P-Sn Phosphorus-Tin

By H. P. Nielsen* and R. I. Jaffee*

Vivian[1] found that alloys containing more than 8.5% P could not be made in an open crucible, but had to be made in sealed glass tubes. Consequently, not only were they in contact with phosphorus vapor, but they were subject to a varying and undetermined pressure. A true equilibrium diagram at atmospheric pressure would probably show a gas phase in equilibrium with either solid or liquid throughout the range where the diagram is drawn with dashed lines.

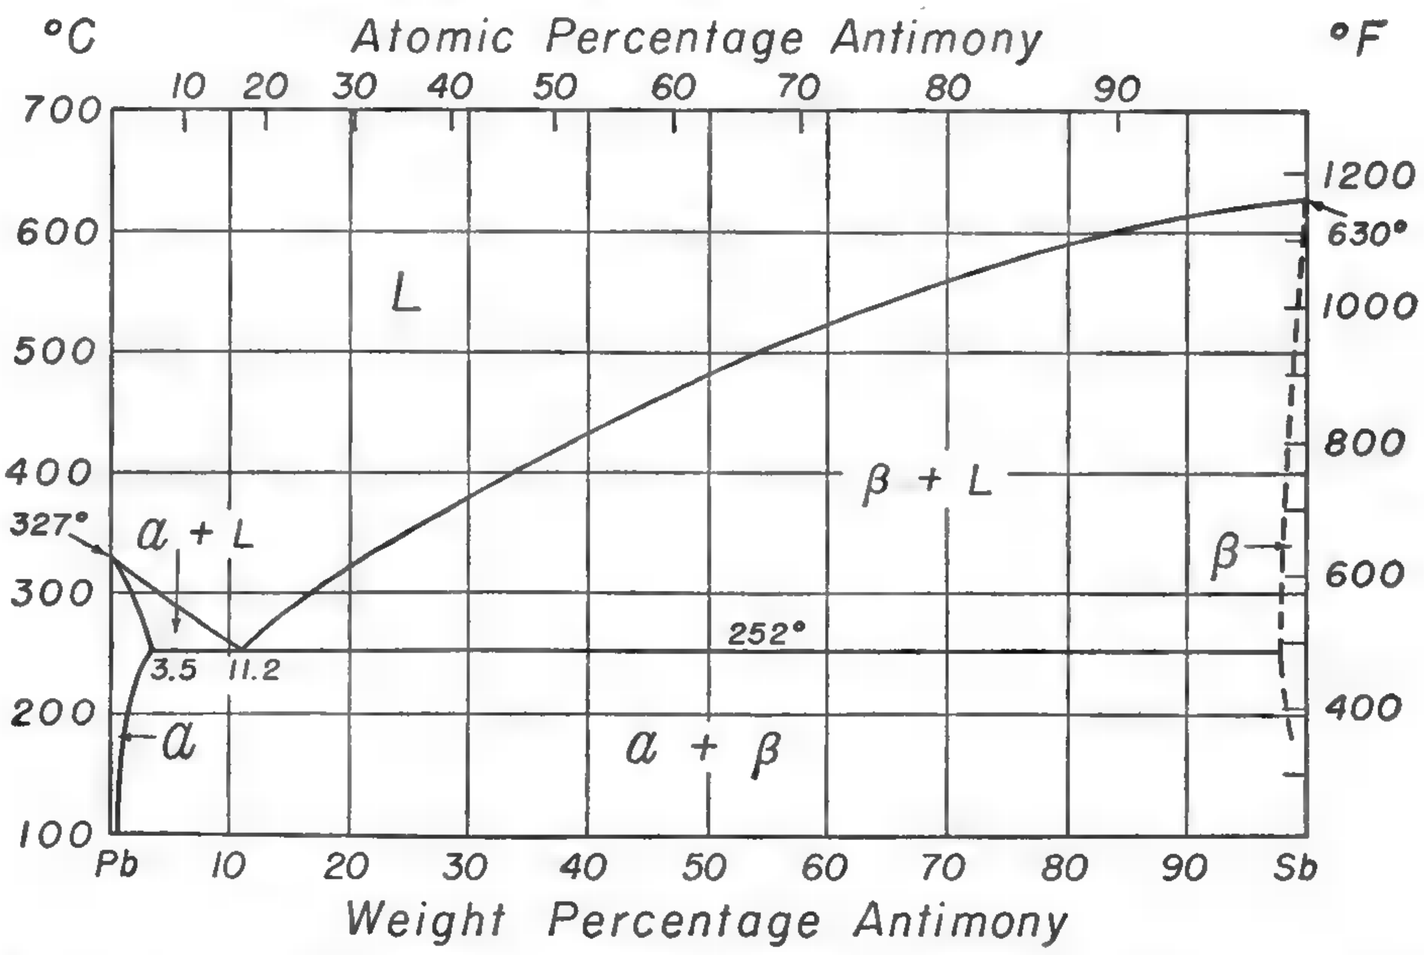
Pb-Sb Lead-Antimony

By E. E. Schumacher† and G. M. Bouton†



The lead-rich end of the system has been reviewed critically in recent years. Alloys containing about 1% Sb are very slow in reaching equilibrium conditions at ordinary, atmospheric temperatures. The properties and structure may change for many years. During solidification the alloys containing eutectic have strong supercooling tendencies. This has been responsible for reports of lower eutectic temperature than the one now accepted (252 C).

Pb-Sn Lead-Tin

By G. O. Hiers*

The diagram shown is taken without change from that given by Raynor.[14]

Alloys containing 18 to 62% Sn exhibit a slight exothermic point in the vicinity of 145 to 155 C in cooling curves determined with great sensitivity. This is attributed to accumulated supersaturation and a sudden precipitation consistent with the atomic mobility of the alloy.

Eutectiferous alloys in general exhibit instability in solid solution zones in finished products. From an engineering viewpoint detectable eutectic in actual soldered joints, where solders contain 10 to 19.2% Sn, justifies the consideration of 183 C as the solidus or zero mechanical strength point.

By X-ray methods, a solid solution of 0 to 3.6% Sn in Pb has been shown, corresponding to the face-centered cubic structure of lead and varying in size from 4.942 to 4.931 kX.

The solid solubility of tin in lead at 50 C is 2%.

Pb-Te Lead-Tellurium

By G. O. Hiers*

The general nature of the system has been well established. Further detailed data and X-ray crystallographic data are needed.

Because of the commercial importance of a lead alloy containing tellurium in an amount less than 0.1%, the following points were determined by means of both mechanical strength and microstructure of pertinent alloys: eutectic between the α and β phases, 0.025% Te; eutectic temperature, 0.7 C below the melting point of lead; solubility of tellurium in solid lead at 300 C, 0.004% Te.

The reference article by Greenwood and Worner includes micrographs of cast alloys containing 0.02, 0.03 and 0.05% Te.

For a summary of the properties of lead-tellurium alloys, the reader may refer to the book "Blei und Bleilegierungen", by Wilhelm Hofmann, J. Springer, Berlin, 1941, pages 52 to 55. (Republished by J. W. Edwards, Ann Arbor, Mich., 1944)

Pb-Zn Lead-Zinc

By E. A. Anderson*

Solid lead dissolves about 0.05% Zn at 318 C. Rodda[1] states that the solid solubility of lead in zinc definitely is less than 0.0019% and may be less than 0.0002%.

Waring and Springer* extrapolated the data of Waring, Anderson, Springer, and Wilcox[2] to the monotectic temperature by plotting $1/T$ against the logarithm of the mol fraction of lead in the liquid phase. The results alter slightly the interpolated values originally published by Waring and associates. The monotectic concentration, 0.9% Pb, shown in the diagram is that selected by Waring and Springer.*

Sb-Sn Antimony-Tin

By R. I. Jaffee† and B. W. Gonser†

Iwasé, Aoki, and Osawa[2] could find no evidence of the two-phase $\beta + \beta'$ region, nor could they find X-ray evidence for the existence of β in quenched specimens.

Williams,[3] using alloys annealed for 16 hours at 360 C, found a range of homogeneity for SbSn of only 47.5 to 50% Sb. For alloys cast under normal conditions, the transformation at 325 C may probably be ignored and the range of homogeneity of SbSn may be taken as quite small.

Sn-Te Tin-Tellurium

By John L. Everhart*

Hansen's diagram[1] has been modified by a change in the melting point of tellurium to 450 C.[2]

Hanson and Pell-Walpole[3] report the solubility of tellurium in solid tin as 0.12% at 230 C, decreasing to 0.07% at 20 C. Jenckel and Roth[4] state that the solubility is about 0.025% at 200 C.

The diagram for the high-tin alloys with 0 to 3% Te is from unpublished results of W. T. Pell-Walpole. No data on the solubility of tin in solid tellurium have been found.

The β phase (SnTe) is cubic (NaCl type) with a lattice parameter of 6.28 kX.[5]

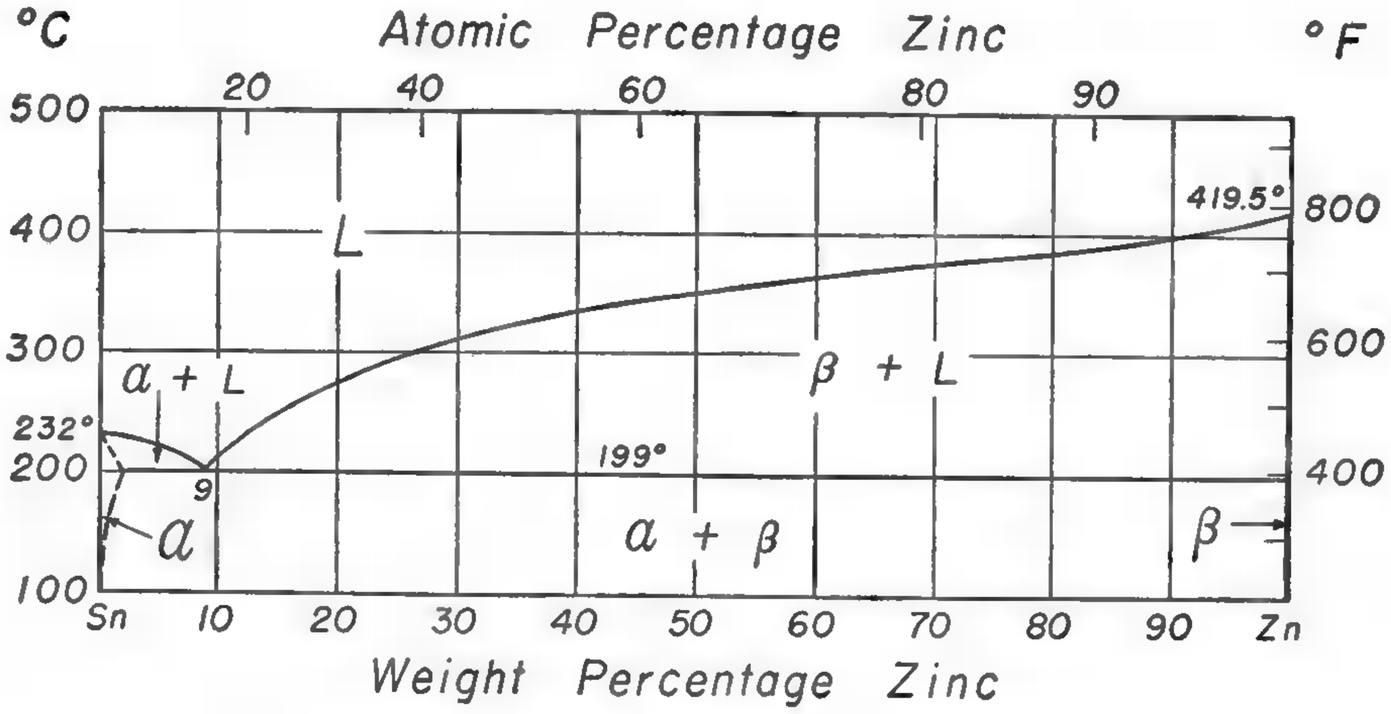
Sn-Zn Tin-Zinc

By E. A. Anderson*



Peirce[1] places the solubility of tin in solid zinc below 0.05%. It is probable from known effects of tin on the hot shortness of zinc that the actual solubility is much less than 0.05%.

The solid solubility of zinc in tin has not been established clearly. Saldau[2] places the limit between 0.5 and 1.5% at 185 C. There is reason to doubt this work because of Saldau's observation of polymorphic changes in his tin. Blondel and Laffitte[3] claim a solid solubility of 2.5%.

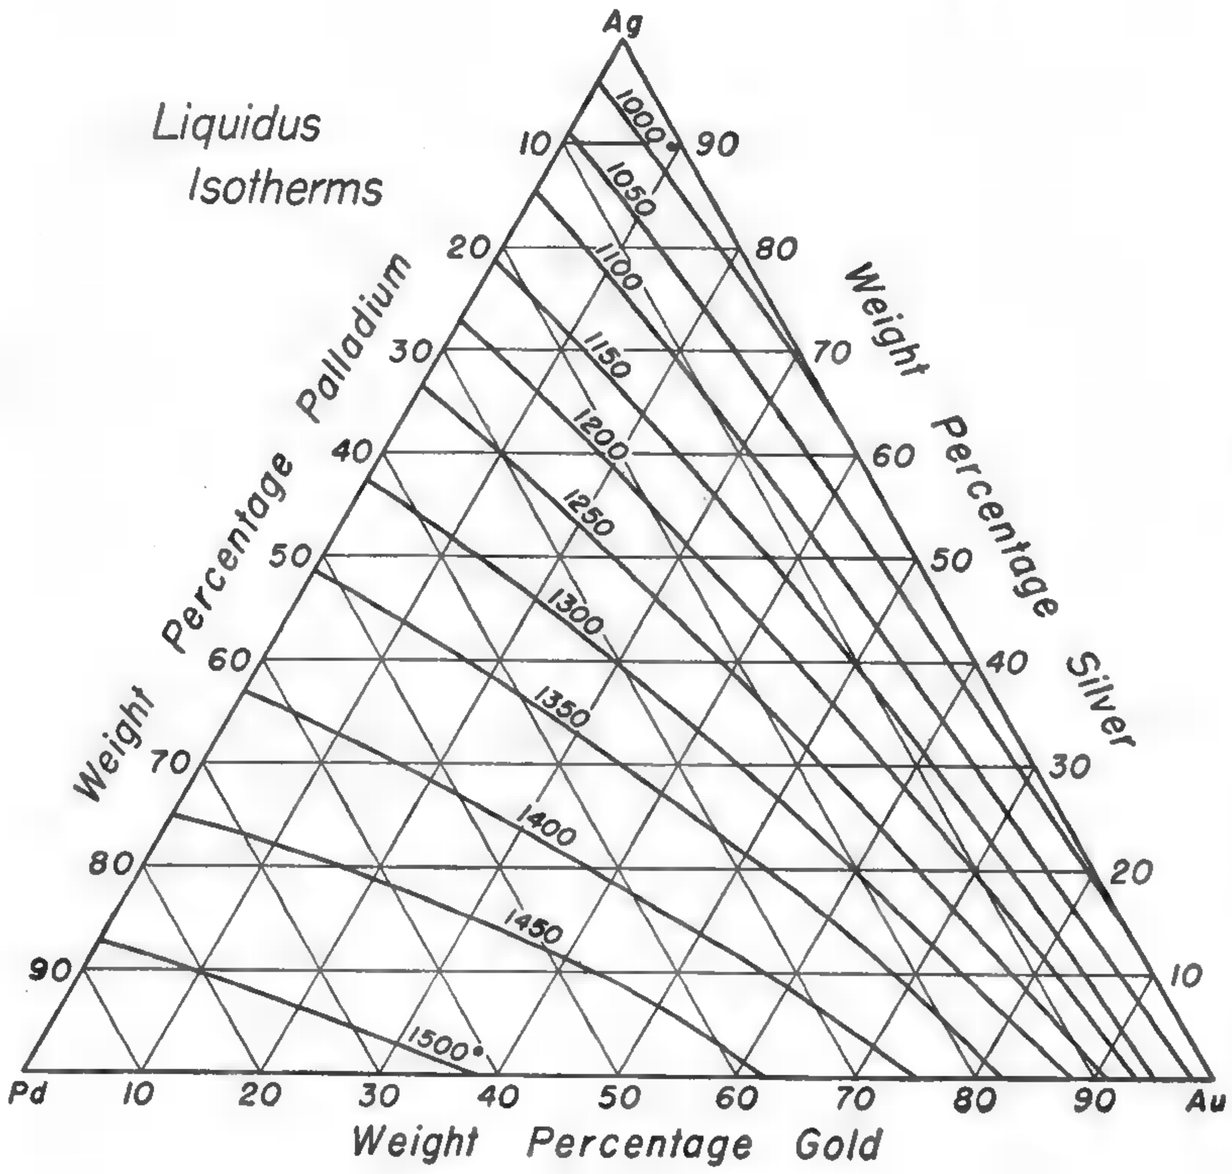
CONSTITUTION OF TERNARY ALLOYS

Ag-Au-Pd Silver-Gold-Palladium

By E. M. Wise*



Throughout the system, the melting range is narrow. The solid ternary alloys are probably free from transformations, as are all the binary alloys of these metals with one another.

Gold-palladium alloys that contain 15 to 20% Pd are essentially white, and are tarnish-proof. The gold-silver alloys that contain about 50% Ag also are white, but will tarnish. The ternary alloys extending from these points to the palladium corner are white. These alloys, however, should not be confused with the Au-Ni-Cu-Zn alloys ("white gold"), which are much harder and more difficult to fabricate than the Ag-Au-Pd alloys.

The resistance of the alloys to tarnishing increases with the sum of the percentages of gold plus palladium, but palladium is somewhat more effective than gold. The resistance to tarnishing becomes very good at 50 to 60% Pd or at about 70% Au.

The addition of copper to Ag-Au-Pd alloys provides metals that are responsive to age hardening and are the basis for many of the cast and wrought high-strength dental materials. Certain Ag-Au-Pd alloys have been used also as high-melting solders for joining palladium or platinum.

The Vickers hardness of annealed Ag-Au-Pd alloys is plotted on the ternary concentration plane on page 1129. The maximum hardness of the ternary alloys in the annealed condition is between 90 and 100 Vickers.

* The International Nickel Company, Inc., New York

Ag-Cu-Pd Silver-Copper-Palladium

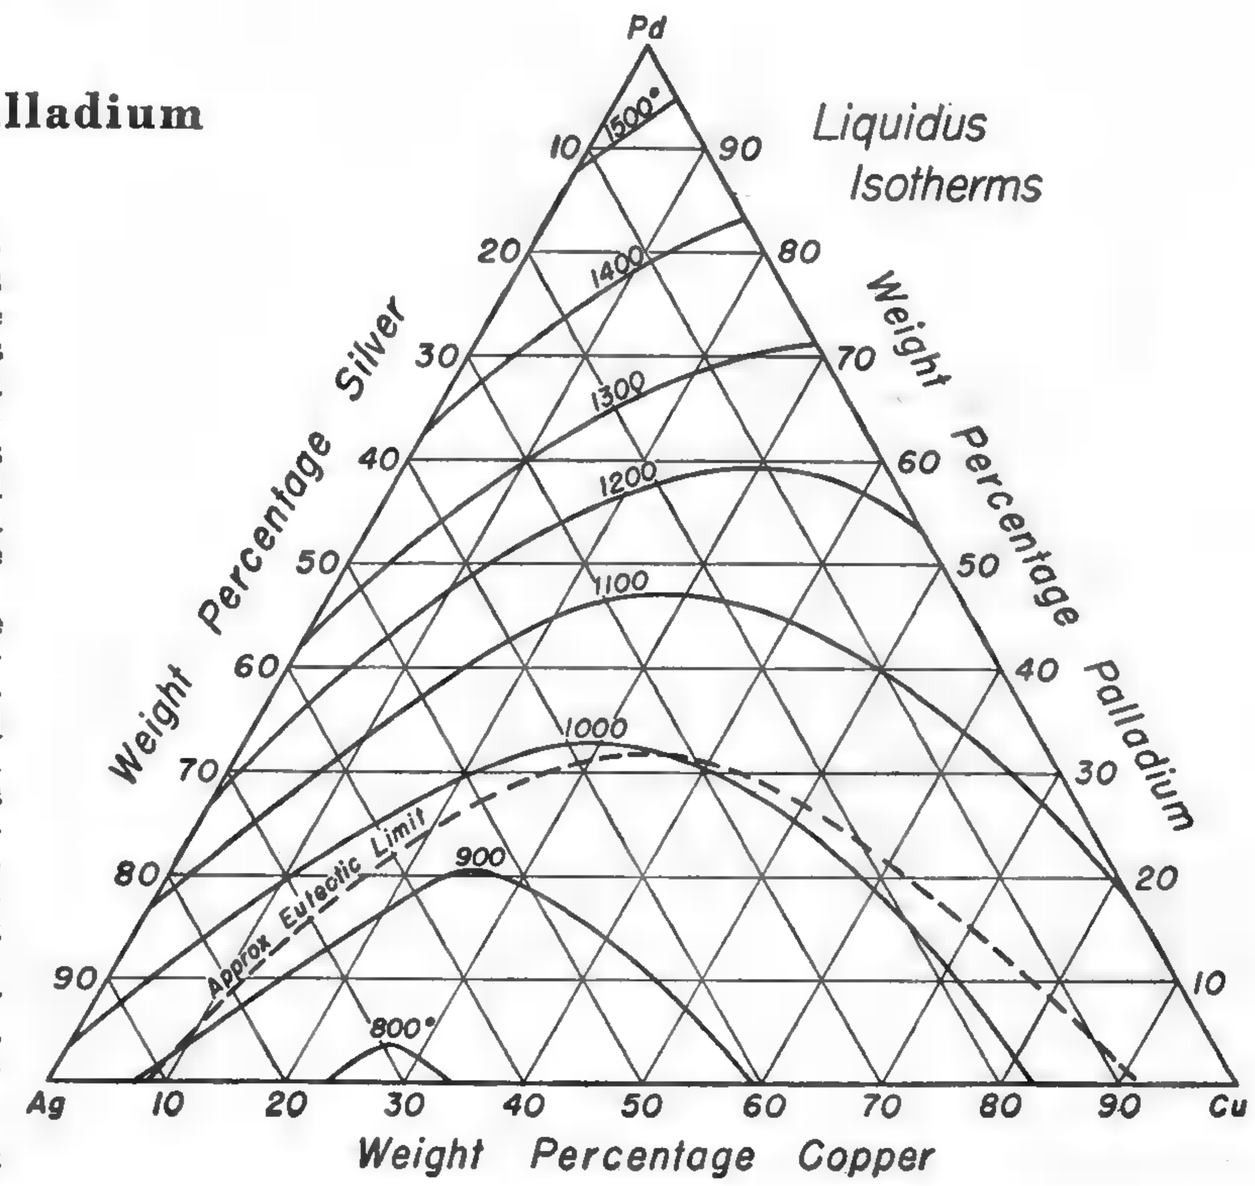
By E. M. Wise*

Palladium increases the mutual solid solubility of silver and copper. The first additions of palladium increase the temperature of the silver-copper eutectic; with further additions the eutectic reaction is eliminated. At high temperatures most of the alloys are single-phase solid solutions; at lower temperatures there are ordered phases based on PdCu and $PdCu_3$. In the low-palladium alloys, silver-rich and copper-rich terminal solid solutions are the stable phases below the solidus.

These low-temperature phases and the changes in solubility of the terminal solid solutions make age hardening possible. The maximum Vickers hardness of aged alloys is plotted on the ternary concentration plane in Fig. 1 on page 1128 in this Handbook. Hardness values higher than 450 Vickers or about Rockwell C 49 are attainable in alloys with approximately 30% Cu, 30% Ag, 40% Pd. This hardness is unusually high for an alloy that is readily workable in the quenched condition.

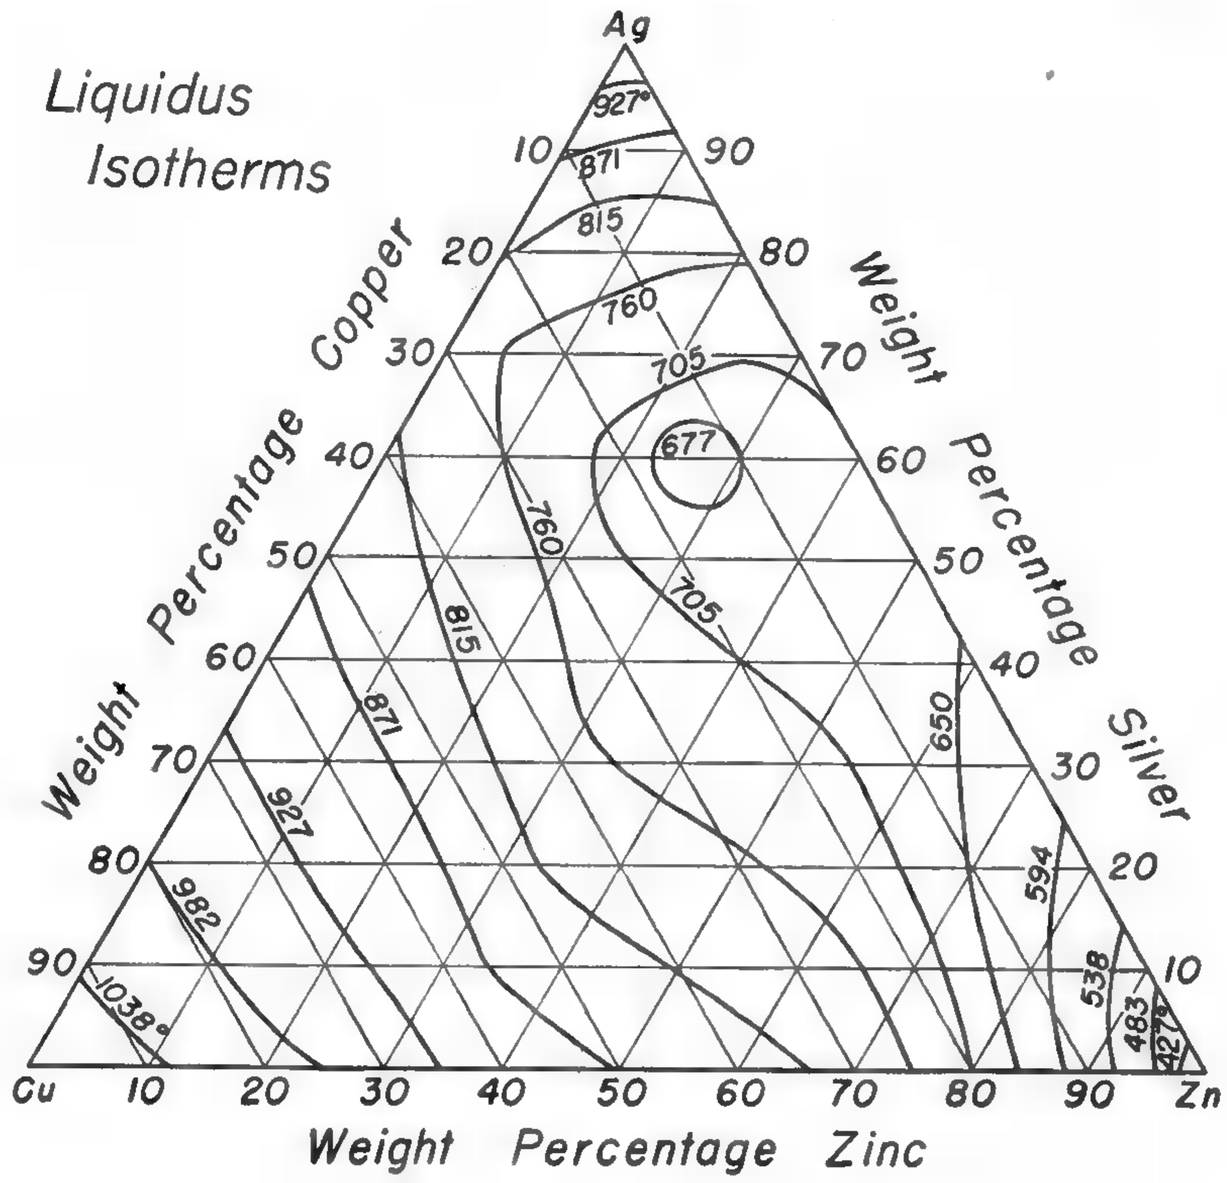
Alloys of this type containing 45% Pd, or slightly more, and modifications containing a little gold are used in dentistry and for electrical contacts subjected to sliding wear.

* The International Nickel Company, Inc., New York



Ag-Cu-Zn Silver-Copper-Zinc

By Robert H. Leach*



The liquidus diagram shown is based on cooling curves made in the research laboratory of Handy & Harman.

Alloys containing less than 15 to 30% Zn are eutectiferous, like the binary silver-copper alloys. Alloys with more than 15 to 30% Zn contain intermediate phases that derive from the corresponding phases in the copper-zinc and silver-zinc systems.

Addition of zinc to silver-copper alloys decreases the eutectic temperature and increases the silver-copper ratio of the eutectic. The silver-copper eutectic absorbs about 24% Zn. The approximate position of the terminus of the pseudobinary, ternary eutectic is indicated by the circular isotherm labeled 677° on the diagram. Copper-rich alloys absorb more zinc and silver-rich alloys less zinc than the eutectic.

Zinc broadens the melting ranges of the copper-rich and silver-rich alloys, since it lowers the eutectic solidus more than the primary liquidus surfaces.

The basic, intermediate copper-zinc and silver-zinc phases have similar structures and seem to alloy isomorphously.

Quaternary alloys with varying percentages of cadmium or tin, as well as silver, copper and zinc, have lower liquidus temperatures than the ternary alloys, and are used commercially as silver brazing alloys. For additional information, see the articles on pages 78 and 1113 in this Handbook.

Ag-Pd-Pt Silver-Palladium-Platinum

By R. F. Vines*

The addition of palladium to silver-platinum alloys decreases the difference in temperature between the liquidus and solidus. The approximate composition limits for coexisting solid solutions are shown as a dashed line on the diagram. This line refers to temperatures of about 500 to 800 C.

The wide separation between the liquidus and solidus temperatures of the silver-platinum alloys and the transformations that occur in the binary alloys generally have limited the interest to alloys containing a few per cent of platinum. The addition of palladium, which forms simple solid solutions with both platinum and silver, avoids both difficulties and gives rise to a wide field of readily fabricated single-phase alloys.

Some of the ternary alloys can be age hardened appreciably, but the solid solution alloys are of most interest. If higher hardness is desired, supplementary hardeners may be added — for example, a few per cent of nickel.

Alloys that contain about 25% Pt, 25% Ag, 50% Pd offer a good base for high-melting, corrosion-resistant dental alloys. These alloys, like those lower in platinum and palladium, can be hardened further by small additions of certain other metals.

The Vickers hardness of annealed Ag-Pd-Pt alloys is plotted on the ternary concentration plane on page 1129 of this Handbook.

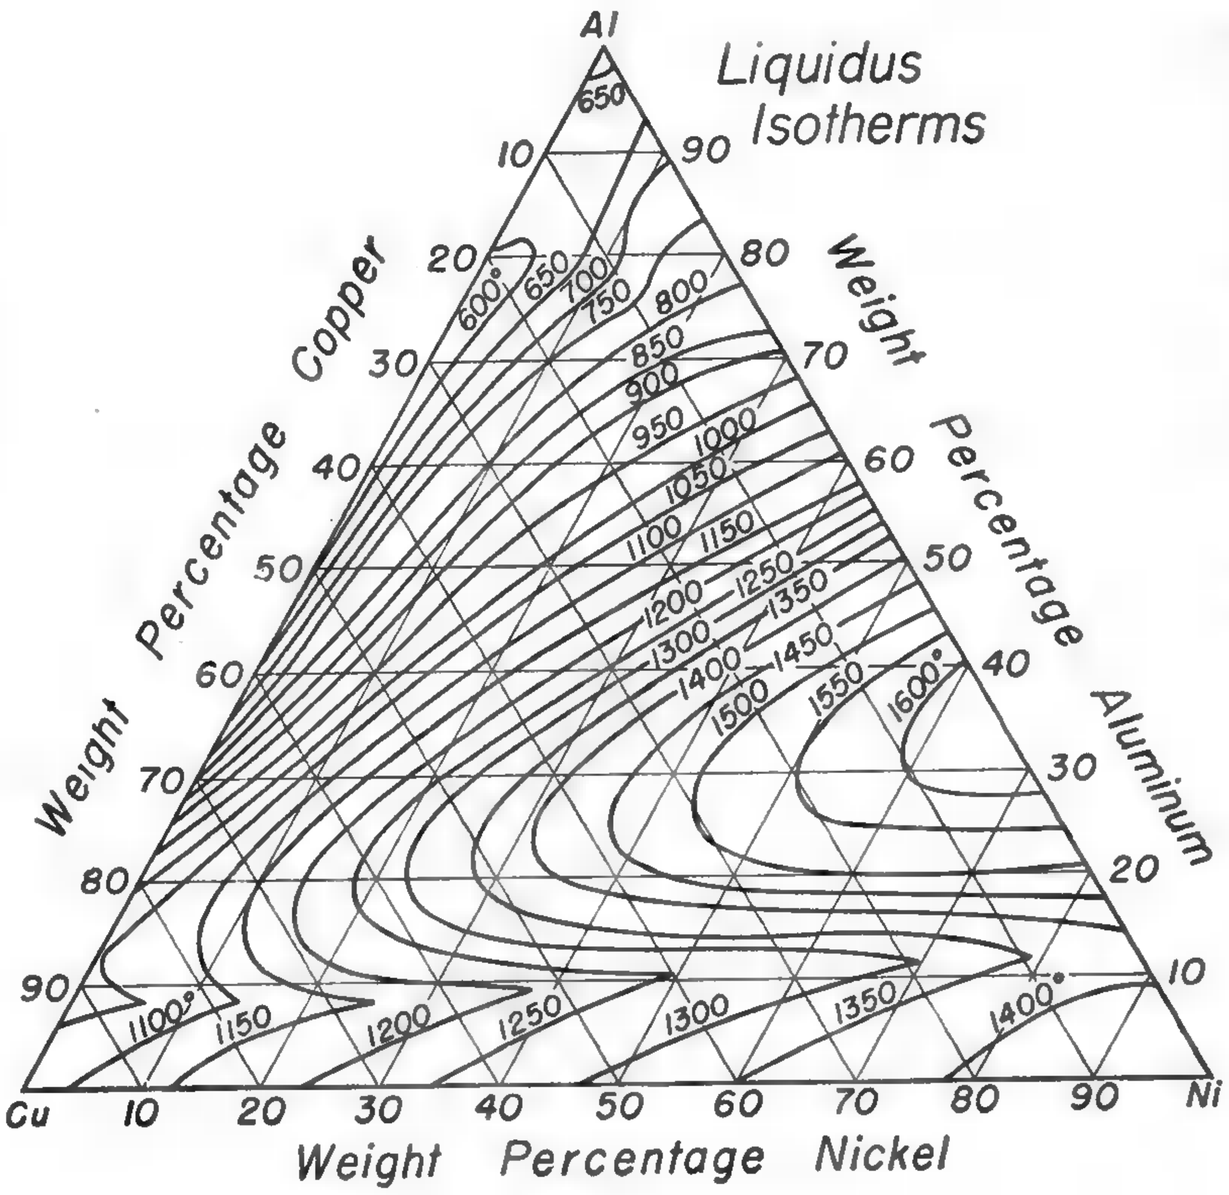
Al-Cu-Ni Aluminum-Copper-Nickel

By David I. Sinizer*



Evidence for the presence of a ternary eutectic at 32.5% Cu, 0.9% Ni, remainder aluminum, at 546.6 C, has been presented.[1,2]

At temperatures above 750 C the copper-rich β and the nickel-rich β_2 phases are isomorphous but immiscibility occurs below this temperature. The γ field is divided into three separate sections: γ, γ_1 and γ_2, each of which has a different superstructure.

The τ phase, which does not occur in any of the three binary systems, corresponds to an ideal formula Cu_3NiAl_6 and has a deformed body-centered cubic crystal structure.

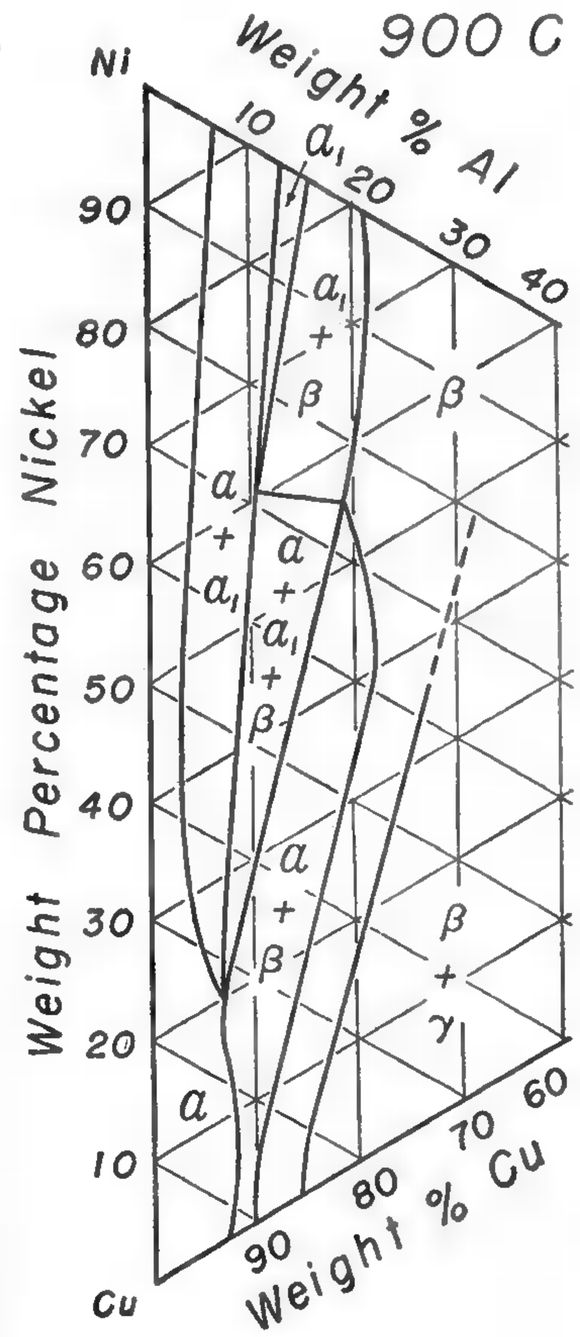
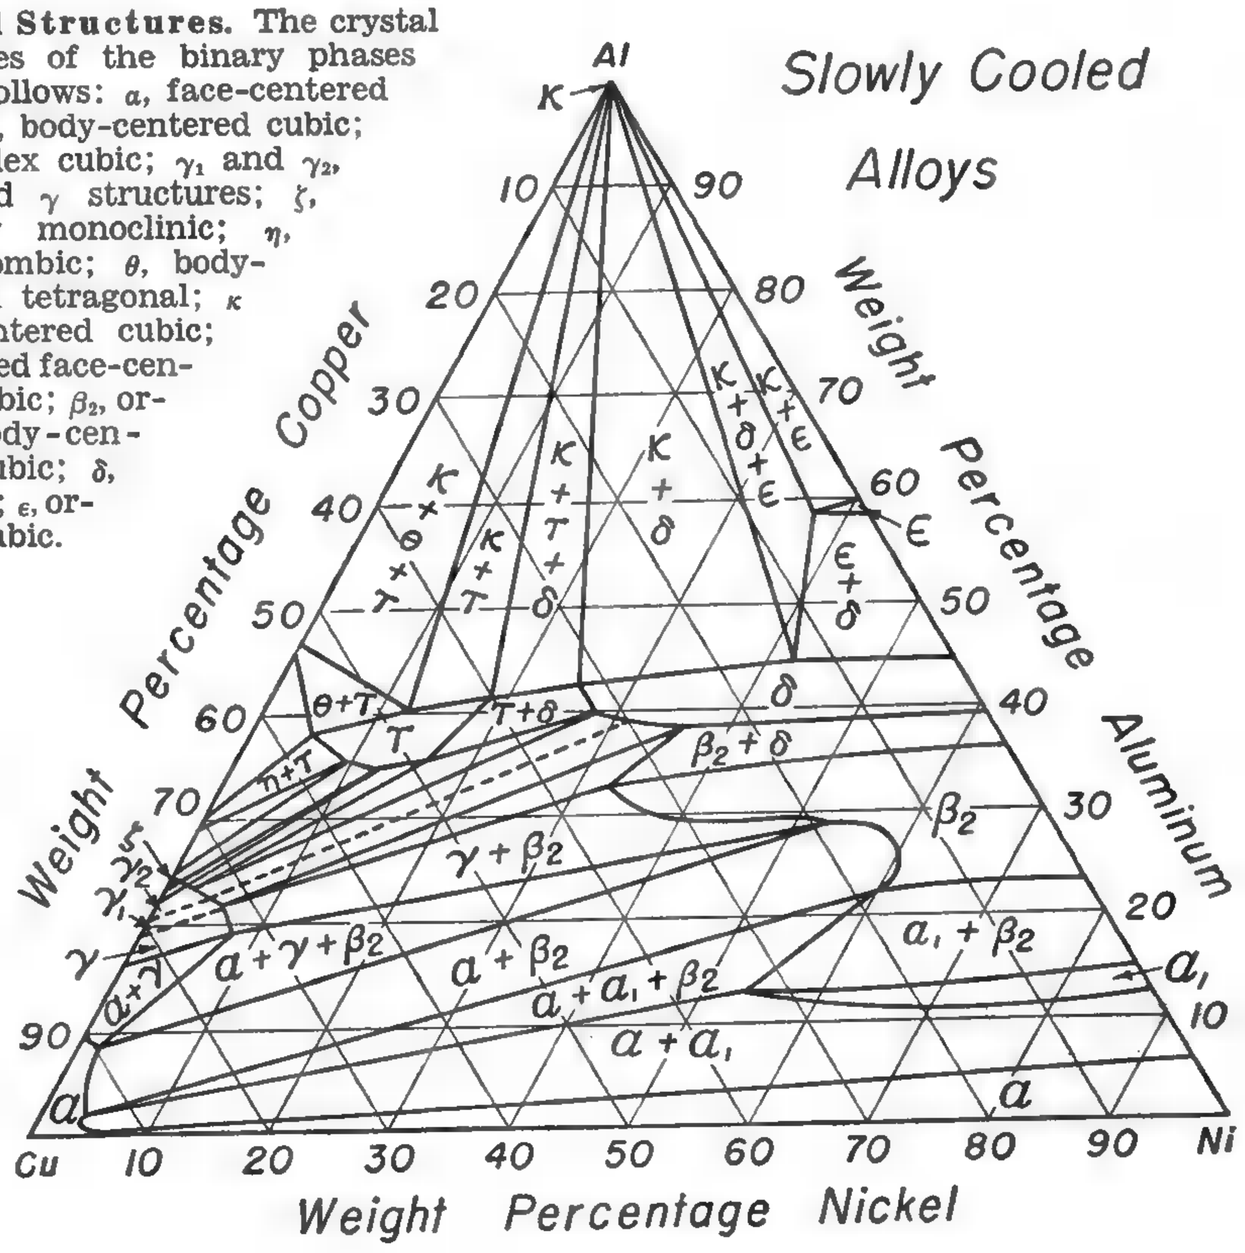
* Editor's Note. Alexander[4] investigated the constitution of about 80 copper-nickel-rich alloys by thermal, microscopic and X-ray methods. His results were reported as seven horizontal sections and ten vertical sections through the ternary space model. The horizontal sections include the liquidus, the solidus, and the phase fields at 900, 800, 700, 600 and 500 C. The vertical sections include 3, 6, 10, 20, 40 and 60% Ni; 4, 10 and 14% Al; and the section between β (Cu_3Al) and NiAl.



Crystal Structures. The crystal structures of the binary phases are as follows: α, face-centered cubic; β, body-centered cubic; γ, complex cubic; γ_1 and γ_2, deformed γ structures; ζ, probably monoclinic; η, orthorhombic; θ, body-centered tetragonal; κ face-centered cubic; α_1, ordered face-centered cubic; β_2, ordered body-centered cubic; δ, trigonal; ϵ, orthorhombic.



Al-Cu-Zn Aluminum-Copper-Zinc

By Cyril Stanley Smith*

Despite the importance of these alloys, large areas of the ternary diagram are still uncertain. The liquidus surface shown is based on that of Bauer and Hansen,[1] and Gebhardt[2] for the commercial brass and zinc portions respectively, smoothed into the data of Jares,[3] Hanson and Gayler,[4] and the well-established binary diagrams. The lines dividing the various liquidus surfaces are essentially those of Jares, except for the elimination of the line from the β (Al-Zn) phase, which is now known not to exist in the binary system and may not exist in the ternary system. At the ternary eutectic temperature (375 C) the following four phases are in equilibrium:

Liquid	7.0% Al	3.9% Cu
Zn-rich solid solution.	1.3% Al	2.9% Cu
Al-rich solid solution..	19.5% Al	1.8% Cu
Epsilon Cu-Zn	1.4% Al	15.2% Cu

At lower temperatures the aluminum-rich phase decomposes; the influence of copper on the extent of this decomposition is almost unknown except for the temperature at which the copper-saturated, high-zinc branch decomposes, which Gebhardt[2] gives as 274 C (2 deg higher than in the binary) at about 1% Cu.

The solubility of copper and aluminum in solid zinc was established by the work of Burkhardt,[6] Gebhardt,[2] and Löhberg.[7] The maximum solubility at the eutectic temperature (375 C) is 1.3% Al, 2.9% Cu. This decreases to about 0.9% Al and 1.9% Cu at 274 C, and is probably lower at lower temperatures.

The constitution is shown also at the lowest temperatures at which reaction rates are important—410 C for the high-copper end, following Bauer and Hansen;[1] 200 C for alloys with less copper than corresponds to the γ phase, following Hanson and Gayler.[4] It is to be noted that the more careful work at the extreme zinc corner does not fit in with Hanson and Gayler's work, for the (CuAl) phase is not found in equilibrium with (Zn), and the ϵ(Cu-Zn) phase is found to coexist with the (Zn) and the (Al) phases.

The a, β, and γ phases of the binary copper-aluminum and copper-zinc diagrams are isomorphous and extend across the diagram in bands of constant electron/atom ratio. The crystal structure of the γ phase is intermediate (Bradley and Gregory[8]). The eutectoid decomposition of β(Cu-Al) extends into the ternary diagram and decreases in temperature with added zinc, reaching the point shown at 410 C, below which temperature the transformation is very sluggish and commercially unimportant.

Al-Fe-Ni Aluminum-Iron-Nickel

By L. L. Wyman*

Recent work[1,2] on the low-aluminum alloys has somewhat modified the low-temperature phase limits in this system, and has attributed the increase in coercive force to the formation of $a_{2m} + \gamma$ from a_m rather than the a to γ reaction proposed earlier.[3,4] The γ phase apparently breaks up further into $a_m + a_{2m}$.

The aluminum-rich alloy region has been constructed entirely on the basis of X-ray powder analysis.[5] More recent work[6] has shown that prolonged annealing at 600 C shifts the phase boundaries to the left, in the aluminum corner.

The phases on the aluminum-iron side of the diagram have been labeled the same as in the binary aluminum-iron diagram on page 1161 of this Handbook. The correlation among the phase designations used in the Al-Fe-Ni diagram and in the several closely related systems in this Handbook, is given in the table in the left-hand column. The π and ρ phases occur only in the ternary system.

Correlation of Phase Designations

Al-Fe-Ni	Al-Fe	Al-Ni	Fe-Ni	Al-Cu-Ni
a_m	a_m	...	a	...
a_1	a_1	...	...	...
a_{2m}	a_{2m}	...	...	...

Al-Fe-Si Aluminum-Iron-Silicon

By W. L. Fink* and L. A. Willey*

Because all commercial aluminum alloys contain iron and silicon as impurities, the aluminum corner of the ternary system is of considerable importance. In addition to the aluminum solid solution, silicon solid solution and the binary intermediate phase $FeAl_3$, two ternary intermediate phases, commonly termed α(Fe-Si) and β(Fe-Si), may appear in the aluminum-rich alloys. The α(Fe-Si) phase forms primarily or by peritectic reaction between $FeAl_3$ and liquid; β(Fe-Si) forms primarily or by peritectic reaction between α(Fe-Si) and liquid. Whether or not these phases have fixed or variable compositions has not been definitely established.[1]

Al-Mg-Mn Aluminum-Magnesium-Manganese

By G. F. Sager* and B. J Nelson*

A peritectic reaction occurs between $MnAl_4$ and $MnAl_6$, and these, together with Al_3Mg_2, have been observed metallographically in a matrix of aluminum-rich solid solution.[1] A metastable ternary eutectic is found at 26.4% Mg, 2.35% Mn and 437 C.

The solubility of manganese in solid aluminum containing 2% Mg is 0.26% at 500 C, 0.45% at 550 C and 0.80% at 600 C. The solubility of manganese in liquid magnesium containing 8% Al is less than 0.15% at 650 C, 0.3% at 700 C, and 1.4% at 800 C.

In the range of 5% Mg and 0 to 2% Mn, all alloys with more than a trace of manganese are entirely $a + MnAl_6$.

Liquidus temperatures for a and $MnAl_6$ are:[3]

$$T_{(a)} = 660 - 5.28\,(\%\ Mg) - 0.76\,(\%\ Mn) + \tfrac{1}{2}\sqrt{(\%\ Mg)\ (\%\ Mn)}$$

$$T_{(MnAl_6)} = 601.0 + 0.5\,(\%\ Mg) + 29.2\,(\%\ Mn)$$

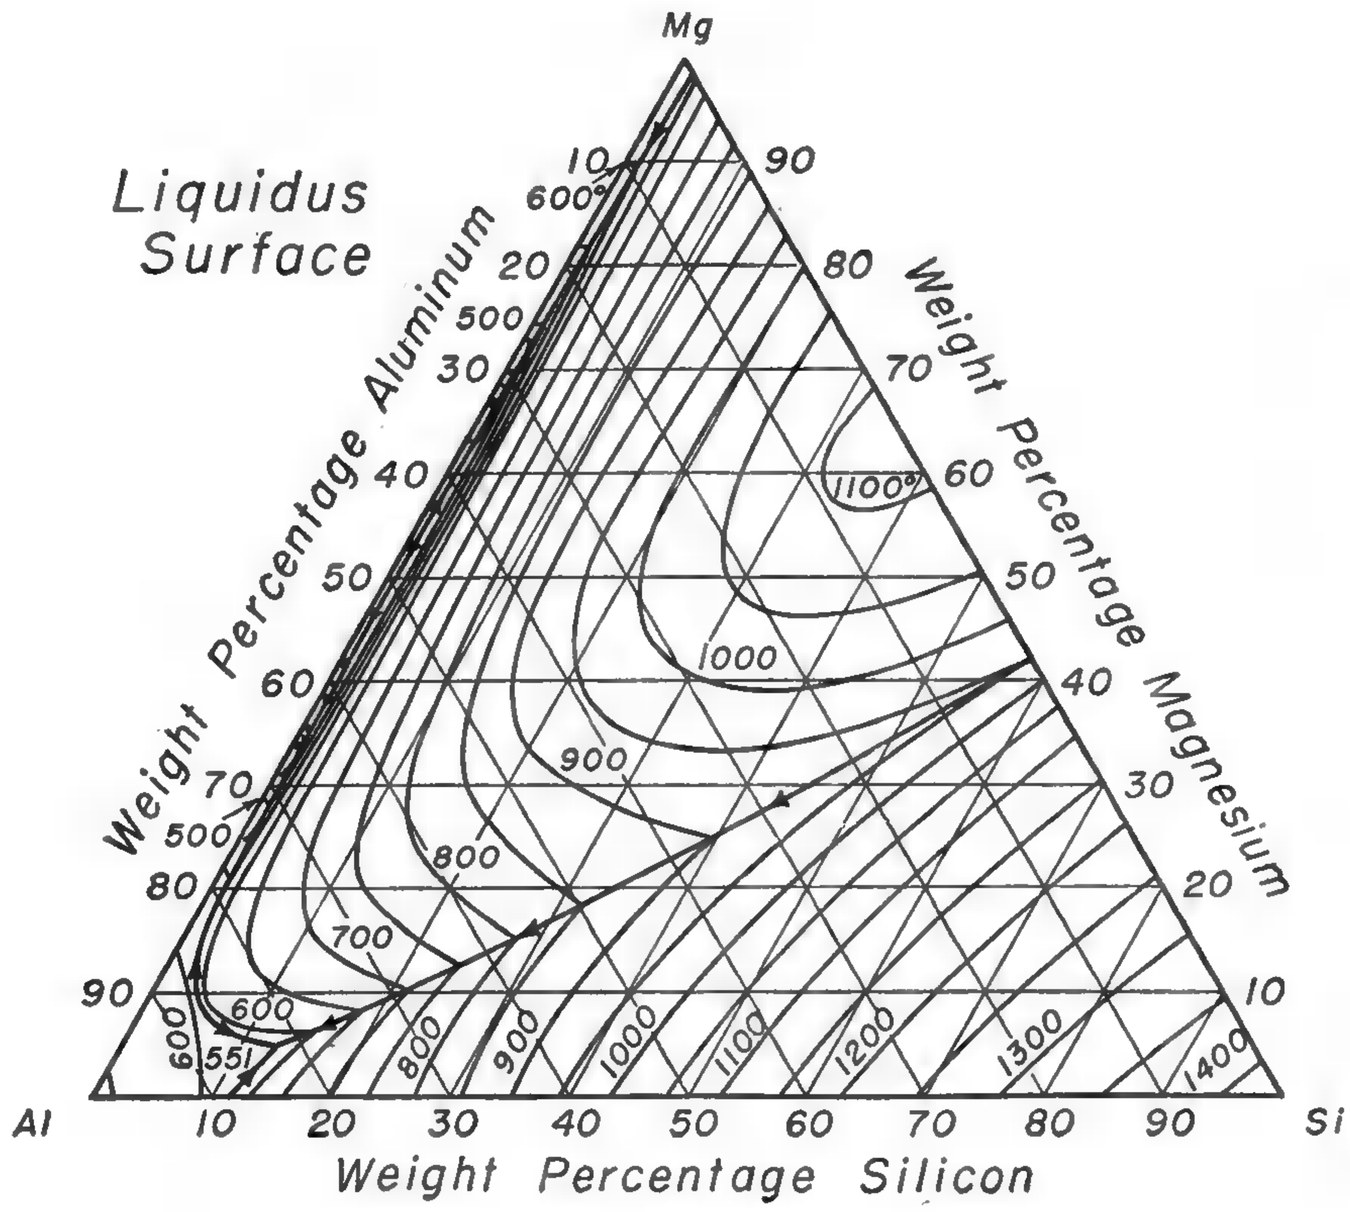
Al-Mg-Si Aluminum-Magnesium-Silicon

By W. L. Fink* and L. A. Willey*



The single binary intermetallic phase in the magnesium-silicon system forms quasi-binary systems with aluminum and with the binary intermetallic phases of the aluminum-magnesium system. No ternary intermetallic phases are formed.

The solubility of magnesium silicide in solid aluminum is as follows:

Temperature, °C	595	500	400	300
Percentage Mg_2Si	1.85	1.05	0.53	0.30

Several commercial wrought alloys of aluminum with magnesium and silicon as the major alloying additions are used extensively (*see* pages 819 to 822). The relatively high strength of these alloys is obtained by precipitation hardening. Alloys with the magnesium and silicon contents in the ratio for the formation of Mg_2Si are more common, although alloys with either excess silicon or magnesium are also used. Excess magnesium lowers the strength by decreasing the solid solubility of Mg_2Si in aluminum.

Al-Mg-Zn Aluminum-Magnesium-Zinc

By W. L. Fink* and L. A. Willey*

The liquidus surface, the solidus surface (except for isotherms that have been omitted for lack of data) and the phase fields at 100 C for the complete aluminum-magnesium-zinc system and the solvus surface for the aluminum corner of the system are shown.

It will be noted that the only ternary intermetallic phase, λ, extends halfway across the system (20 to 70% Zn) and is therefore not adequately described by the usual designation $Mg_3Zn_3Al_2$.[1,2,3,4] This phase is body-centered cubic with a lattice parameter of 14.29 kX.[4]

* Aluminum Research Laboratories, New Kensington, Pa.

Al-Mn-Si Aluminum-Manganese-Silicon

H. W. L. Phillips [J Inst Metals, 69, 291 (1943)] studied slowly cooled aluminum-rich alloys containing from 0 to 8% Mn and from 0 to 10% Si. Four invariant points were observed:

(i) 2% Mn, 1.3% Si, 649 C (Liquid, Al, $MnAl_4$, αMnSi)
(ii) 3.4% Mn, 0.5% Si, 660 C (Liquid, $MnAl_4$, $MnAl_6$, βMnSi)
(iii) 2.7% Mn, 1.3% Si, 658 C (Liquid, $MnAl_6$, αMnSi, βMnSi)
(iv) 0.75% Mn, 11.75% Si, 573 C (Liquid, Al, Si, αMnSi)

The following sections of the ternary diagram are given in Phillips' paper: the liquidus surface, the surfaces of secondary separation, the constituents in slowly cooled alloys, and vertical sections at 1.5% Mn, 6% Mn, 1.0% Si, and 4.0% Si.

Al-Mn-Zn Aluminum-Manganese-Zinc

Butchers, Raynor and Hume-Rothery [J Inst Metals, 69, 217 (1943)] have studied the aluminum-rich alloys containing from 0 to 3% Mn and from 0 to 10% Zn. These alloys — similar to the aluminum-rich Al-Mg-Mn alloys — are of two classes, in which the primary separations are aluminum solid solution and $MnAl_6$ respectively.

The temperatures of the liquidus surface at which aluminum-rich solid solution forms are given by the equation:

$$T_{(Al)} = 660 - 0.76\,(\%\ Mn) - 1.66\,(\%\ Zn)$$

The temperatures of the liquidus surface at which $MnAl_6$ forms are given by the equation:

$$T_{(MnAl_6)} = 601.0 + 29.1\,(\%\ Mn) + 0.25\,(\%\ Zn)$$

Be-Cu-Ni Beryllium-Copper-Nickel

By E. N. Skinner*

The fragmentary data available concern only the copper-rich and the nickel-rich portions of the ternary diagram.

Small amounts of nickel reduce[1,2] and, at about 2% Ni, completely obliterate the eutectoidal β-phase domain in the copper-beryllium binary diagram. The temperature of this eutectoid reaction, $\beta \rightleftarrows \alpha + \gamma$, is simultaneously raised from 573 C to the temperature of the one invariant reaction found that involves the liquid phase:

$$L + \gamma \rightleftarrows \alpha + \beta \text{ at } 868 \text{ C}$$

L = 4.4% Be, 0.8% Ni	α = 0.8% Be, 1.6% Ni
γ = ∽ 13.7% Be, 59% Ni	β = 5.7% Be, ∽ 2% Ni

With further additions of nickel, no new phasial equilibriums appear, other than the progressive shift of the eutectic temperature and composition up to that of the nickel-beryllium binary diagram. The γ phase, CuBe in the copper-beryllium binary system, is continuous with and structurally analogous to NiBe.

The two curves indicate the maximum solid solubility (immediately below the solidus) and the solid solubility at 500 C. The sharp decrease at low nickel contents reflects the extinction of the β phase.

The original investigation[1] contains no mention of the shift in eutectic temperature with variation in copper-nickel ratio. Unpublished results* indicate that this eutectic temperature is 1105 C at 68% Ni, 30% Cu, 2% Be.

C-Cr-Fe Carbon-Chromium-Iron

By W. D. Forgeng*

The general features of the carbon-chromium-iron system are well established. The section between Fe_3C and Cr_7C_3 is apparently a quasi-binary system, and the sections of the diagram have been constructed on this basis.

The carbide phases designated as C_1, C_2, and C_3 have the following formulas and composition limits:

C_1, $(Fe,Cr)_3C$ or cementite containing up to 15% Cr
C_2, $(Cr,Fe)_7C_3$ or trigonal chromium carbide containing up to 55% Fe
C_3, $(Cr,Fe)_4C$ or cubic chromium carbide containing up to 25% Fe

The other phases have been designated as follows: L, liquid; α, ferrite; γ, austenite; σ, sigma (FeCr).

Three of the four four-phase equilibriums that exist in this system are indicated at the points *A*, *B*, and *C* of the diagram that shows the liquidus surface. The equilibriums at *A* and *B* are of the transition-plane type; the equilibrium at *C* is of the eutectic type. The ternary eutectic point at *C* lies close to the plane of the iron-carbon system. The fourth nonvariant equilibrium, which is not shown in any of the horizontal sections included here, is of considerable practical importance and occurs at about 800 C. This equilibrium involves the phases α, γ, $(Fe,Cr)_3C$ and $(Cr,Fe)_7C_3$. The coordinates of the α and γ corners of this quadrangle are at 0.05% C, 2.6% Cr, and at 0.7% C, 2% Cr, respectively. Therefore, the carbide $(Cr,Fe)_7C_3$ is stable in medium-carbon steels containing more than 2% Cr, and the behavior of such steels during heat treatment is different from that of plain carbon steels.

Alloys with less than 2% Cr are similar in constitution to the iron-carbon alloys and differ only so far as three-phase regions can exist over a range of temperature and composition, rather than at a fixed point. With increasing chromium content, the single-phase γ region becomes smaller and disappears entirely at about 20% Cr. In addition, the temperature limits of this region become narrower at the higher chromium contents. From a practical standpoint, this means that steels containing from about 10 to 18% Cr must be heated to temperatures between 900 and 1000 C if full hardening is to be obtained during subsequent quenching, and that, for maximum hardening by transformation of the γ phase, the carbon content of a steel must lie within the limits of the γ region for a given chromium content. It should also be noted that the carbon content of the "eutectoid" is decreased by increasing the chromium content and at 12% Cr, the "eutectoid" contains only about 0.35% C. The α solid solution of the equilibrium $\alpha + C_2 + C_3$ becomes richer in iron at lower temperatures and consequently the carbide $(Cr,Fe)_4C$ may appear in alloys with as little as 10% Cr.

At chromium contents between 20 and 30%, hardening by transformation of the γ phase becomes less pronounced, and since alloys with 30% Cr contain only α, C_2 and C_3, such alloys cannot be hardened by heat treatment.

The solubility of carbon in the α phase of iron-rich alloys, at temperatures just below the solidus, increases from about 0.1% at 12% Cr to about 0.2% at 20 to 30% Cr.

In alloys containing more than about 35% Cr, the α solid solution is gradually converted to the hard and brittle σ phase by holding the alloys in the temperature range between 600 and 900 C for long periods.

For information about the constitution of chromium steels, see the article on page 458 in this Handbook.

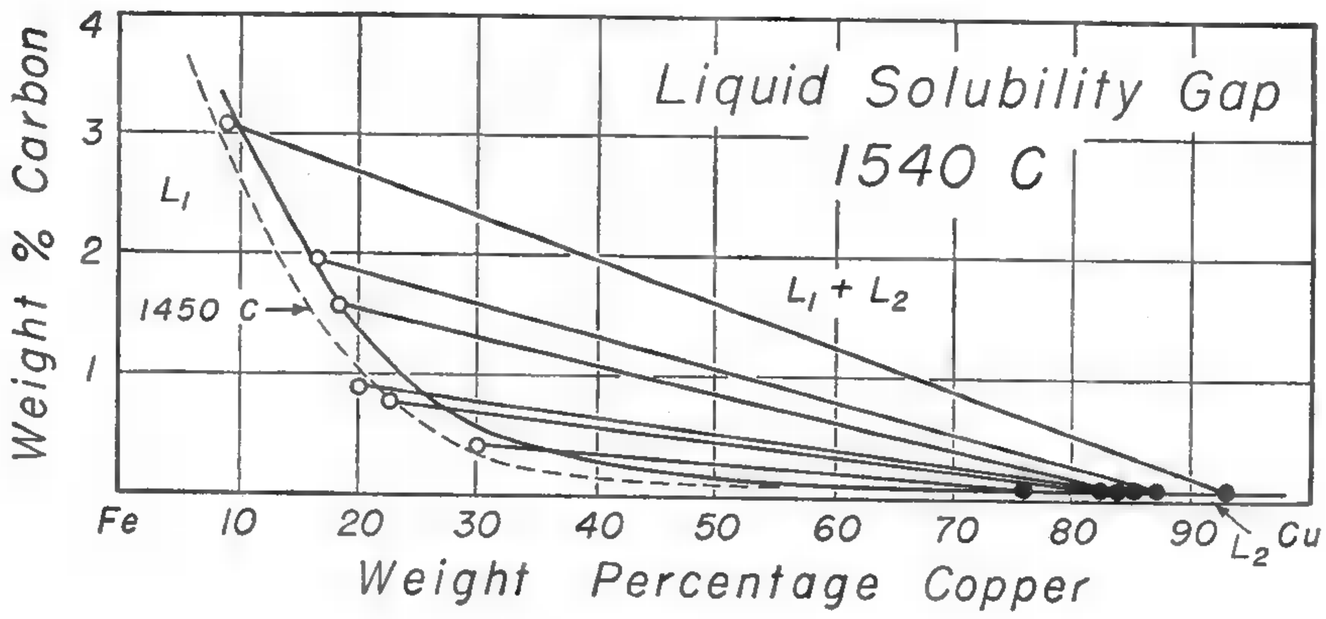
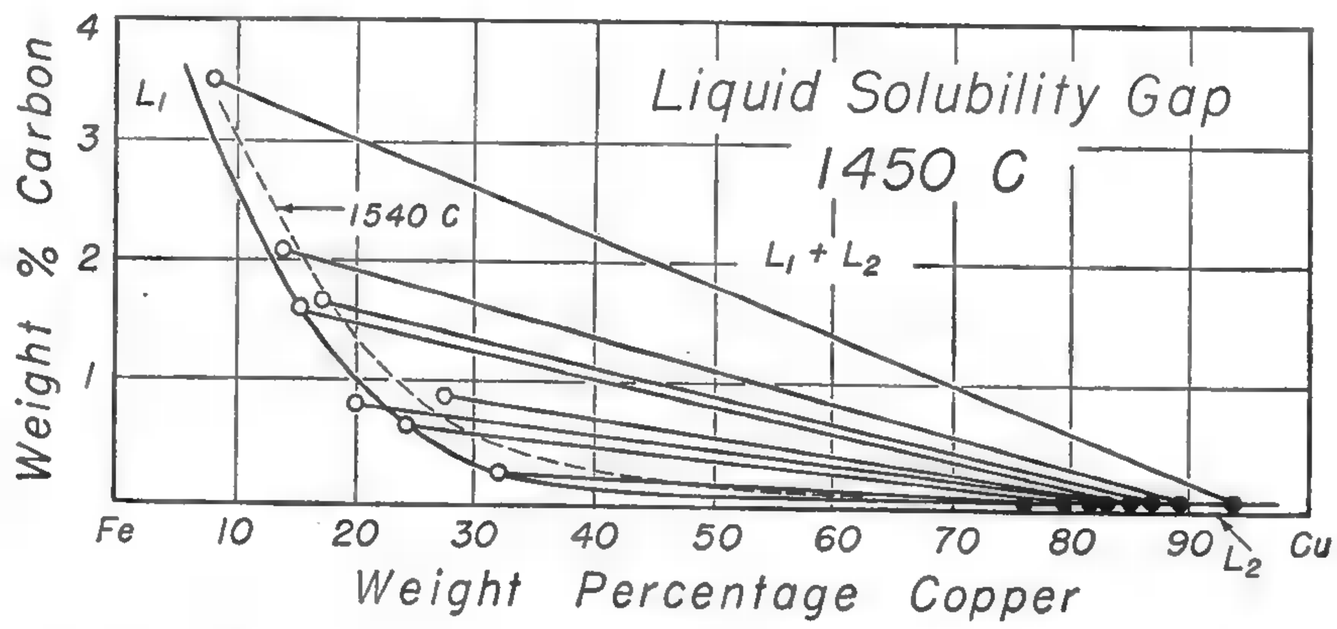
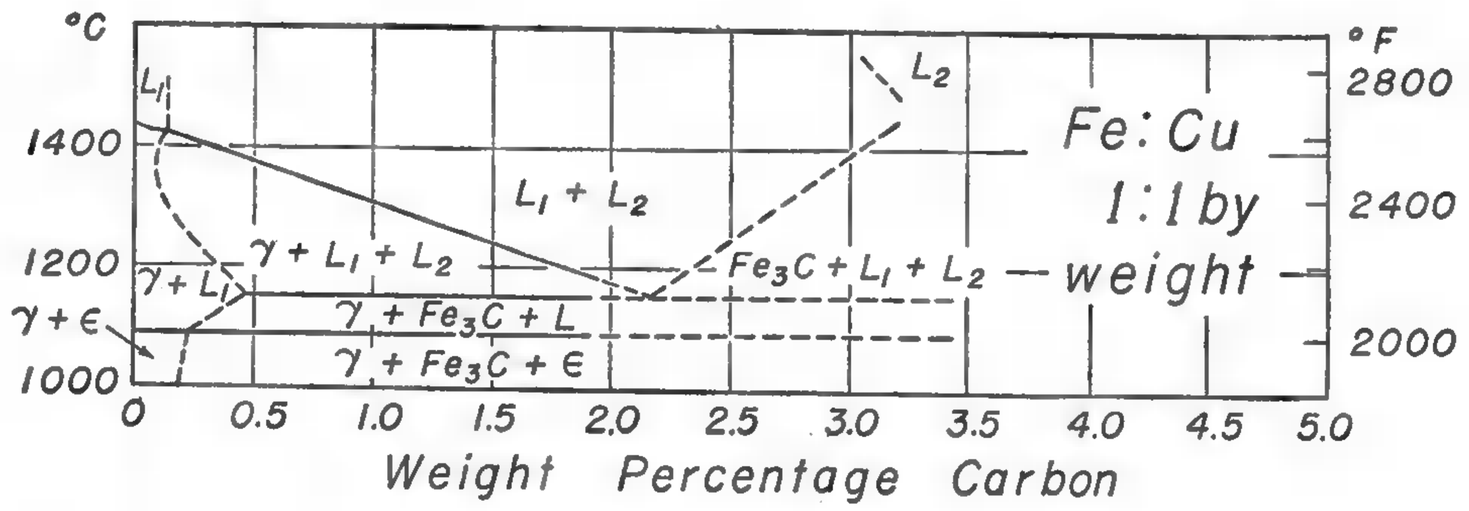
C-Cu-Fe Carbon-Copper-Iron

By B. N. Daniloff*







The following phases have been proved to exist in the system: L_1, iron-rich liquid; L_2, copper-rich liquid; α, γ, δ and ϵ solid solutions, and iron carbide. Evidence of graphite has also been reported[5] at higher concentrations of carbon and copper.

Maddocks and Claussen[3] determined the intersection of the two-liquid region with the liquidus surface. Their work shows that the liquid immiscibility line does not intersect the iron-copper temperature-concentration plane. This is confirmed by the work of Iwasé[2] whose isothermal sections at 1450 and 1540 C are shown. According to Iwasé, about 0.02% C is sufficient to introduce liquid immiscibility in alloys containing 50% Fe and 50% Cu. The mutual liquid solubility increases with temperature.

The vertical section through the 50% Fe – 50% Cu line, obtained by Maddocks,[3] shows that the monotectic and peritectic four-phase planes exist separately, the former at 1150 C and the latter at 1094 C. The iron-carbon eutectic temperature is raised to 1150 C by the addition of copper, and the monotectic four-phase point is at about 4.2% C and 2.5% Cu.

* San Francisco Naval Shipyard, San Francisco

The δ-γ transformation temperature of the iron-carbon system is raised by the addition of copper.[6]

The ϵ phase probably dissolves some carbon, although quantitative data are lacking.

The extent of the γ phase has not been accurately established. According to Ishiwara[1] the maximum extent of the γ solid solution is at 1.7% C and about 6% Cu. The γ region is limited below by the three surfaces representing primary separation of the α phase, ϵ phase and cementite. The ternary eutectoid point, according to Ishiwara, is at about 700 C and its composition about 0.9% C and 1.9% Cu.

It has been reported[4] that copper dissolves 0.0001% C at 1100 C and 0.003% C at 1700 C.

C-Fe-Mn Carbon-Iron-Manganese

By Cyril Wells*

In the ternary alloys, the α phase is a solid solution of carbon and manganese in α iron and the γ phase is a solid solution of carbon and manganese in γ iron. The phase designated C is a carbide of the form $(Fe,Mn)_3C$ in which as many as one-quarter of the iron atoms in the orthorhombic cementite crystal structure may be replaced by manganese.

Manganese atoms dissolved in α or γ replace some iron atoms. Carbon atoms dissolved in α or γ are present in interstices.

C-Fe-Mo Carbon-Iron-Molybdenum

By W. P. Sykes*

The complete diagram, as determined by Takei,[1] includes the iron-molybdenum side, and extends to Fe_3C and Mo_2C. The diagram is based on studies of 156 alloys. Some of the more important details included in the following paragraphs were taken from Marsh's review of Takei's data.[2]

Phase	Explanation
a	Solid solution of Mo and C in *a* Fe
γ	Solid solution of Mo and C in γ Fe
C	Fe_3C (capable of dissolving Mo, C, and Fe)
ω	Double carbide of Fe and Mo
ε	Fe_3Mo_2 dissolving Fe and C
η	FeMo dissolving Fe and C
θ	Mo_2C (capable of dissolving Fe and Mo)
δ	Solid solution of Fe and C in Mo

The double carbide, ω, is formed by peritectic reaction:

$$L + Mo_2C \rightleftarrows \omega$$

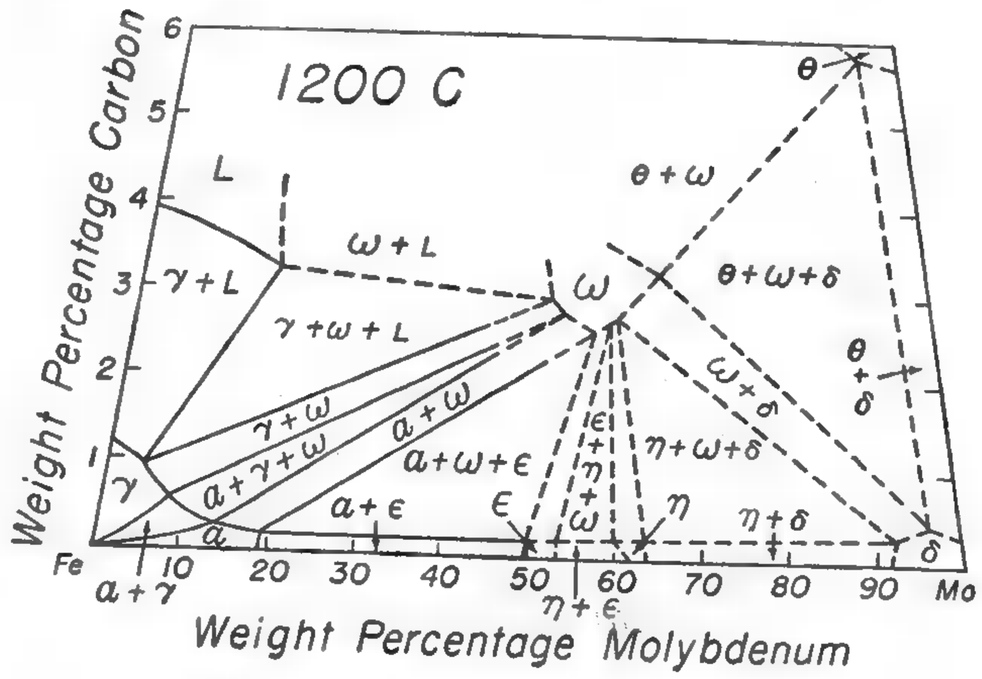
This phase forms eutectics with the binary phases.

The γ phase is decomposed by the peritecto-eutectoid reaction:

$$\gamma + \omega \rightleftarrows Fe_3C + a$$

The γ phase never coexists with the ε phase.

The η phase is decomposed by a eutectoid reaction as in the binary iron-molybdenum system.



* Lamp Department, General Electric Company, Cleveland

In the isothermal sections shown here the regions adjacent to the iron-molybdenum axis are not drawn to scale. This procedure shows clearly the shapes of these regions but gives an erroneous impression of magnitudes.

The sections at constant molybdenum contents, parallel to the carbon side, cannot be used to estimate relative proportions and compositions of the phases present, but these sections do show the identity of the phases.

Because of the existence of the ω phase the horizontal line corresponding to the iron-carbon eutectoid horizontal represents four-phase equilibrium $(\alpha + \gamma + \omega + C)$, which must be nonvariant in a system of three components. The three-phase field, corresponding to the "pearlite interval" in the iron-carbon-silicon system, is therefore eliminated in this system.

For information about the constitution of molybdenum steels, see Fig. 1 to 14 on pages 469 to 471.

C-Fe-Ni Carbon-Iron-Nickel

By C. M. Schwitter*

The uncertainty surrounding the true equilibrium system makes it inadvisable to present any diagram as authoritative. Reference may be made to the efforts of Marsh[1] to construct a diagram from available information. He concluded that "all possibility of arriving at a most probable iron-carbon-nickel diagram collapses because of . . . . inadequate experimental work on the ternary system."

A practical approach to a structural diagram is contained in the article entitled "Nickel in Steel", on page 473 of this Handbook. This is based on the work of Eash and Pilling[2] from a study of the microstructures developed in slowly cooled cast bars.

Although the equilibrium diagram is in doubt, certain effects of nickel on the iron-carbon system are fairly well known. Nickel is completely soluble in the liquid phase and remains in solid solution in both gamma and alpha iron. In the low-carbon hypoeutectic region of the iron-carbon system, the liquidus temperature appears to be lowered slightly by nickel, but the eutectic temperature is raised approximately 3 °C per 1% Ni over the range 0 to 50% Ni, and the carbon content of the eutectic is decreased about 0.03 to 0.06% for each 1% Ni over the same range. It also appears that the spread between the liquidus and solidus decreases slightly with nickel content over most of the range.

The effect of nickel up to 5 or 6% on the hypoeutectoid region of the iron-carbon system has been established by Scott[3] for commercial nickel steels. The A_3 transformation is lowered about 20 °C per 1% Ni. Each per cent of nickel lowers the A_1 or eutectoid temperature 10.6 °C, and reduces the carbon content of the eutectoid by 0.042%.

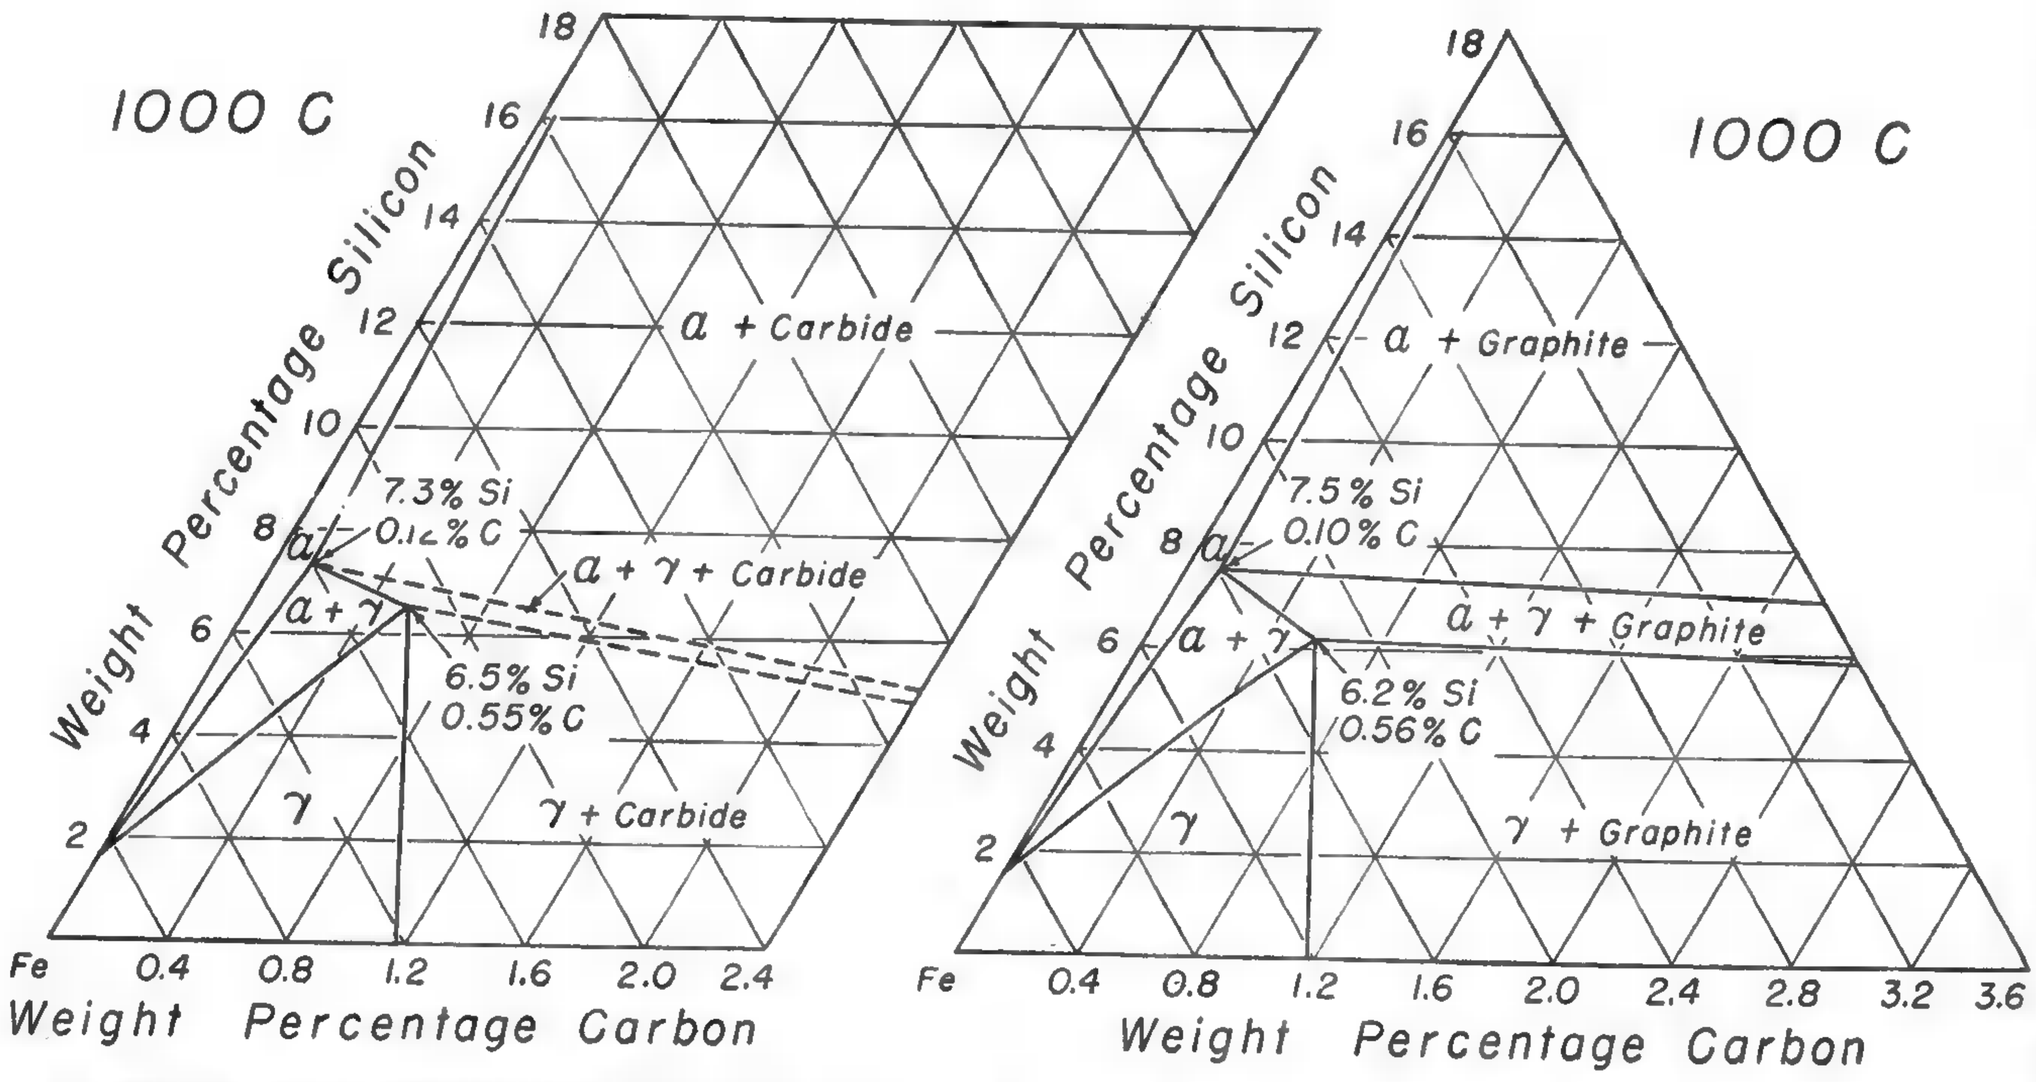
C-Fe-Si Carbon-Iron-Silicon

By Earl S. Greiner*



In view of the uncertainty concerning the stability of Fe_3C that has dissolved some silicon, two types of equilibrium for the iron-carbon-silicon alloys are considered:

(*a*) Fe-Si-(Fe,Si carbide)
(*b*) Fe-Si-C (as graphite)

An isothermal section of the iron-rich Fe-Si-(Fe,Si carbide) system at 1000 C, derived from data of Kriz and Poboril,[1] and a similar section at the same temperature for the Fe-Si-C(graphite) system are shown. At low temperature the isothermal section for the iron-rich alloys of the Fe-Si-(Fe,Si carbide) system will presumably consist of the α and α + (Fe,Si carbide) phase areas, and that for the Fe-Si-C(graphite) system will consist of the α and α + C(graphite) phase areas.

Additional data on the constitution of carbon-iron-silicon alloys can be obtained from the articles "Silicon in Steel", page 476, and "Cast Iron", page 505 in this Handbook.

C-Fe-Ti Carbon-Iron-Titanium

By M. F. Hawkes*

There is evidence for a pseudobinary eutectic system between TiC and Fe_3C. The solubilities of titanium in Fe_3C and of iron in TiC are apparently very small.

The value of 1350 C for the Fe-Fe_2Ti eutectic (instead of 1310 C as shown in the iron-titanium diagram in this Handbook) is used in order to preserve the relationships among the various quaternary equilibriums as developed by Tofaute and Büttinghaus.[1] Diffusion studies by Gaeff[2] lend support to this value, which is higher than most other investigators have reported.

The first intermediate phase in the iron-titanium system is designated here as Fe_2Ti. Tofaute and Büttinghaus had assumed, from the work of previous investigators, that this phase is Fe_3Ti, but there is reason to doubt the correctness of such an assumption. In the discussion of the iron-titanium system in this Handbook (*see* page 1219), references are cited which lead to the conclusion that Fe_2Ti represents the composition of this phase more accurately than Fe_3Ti.

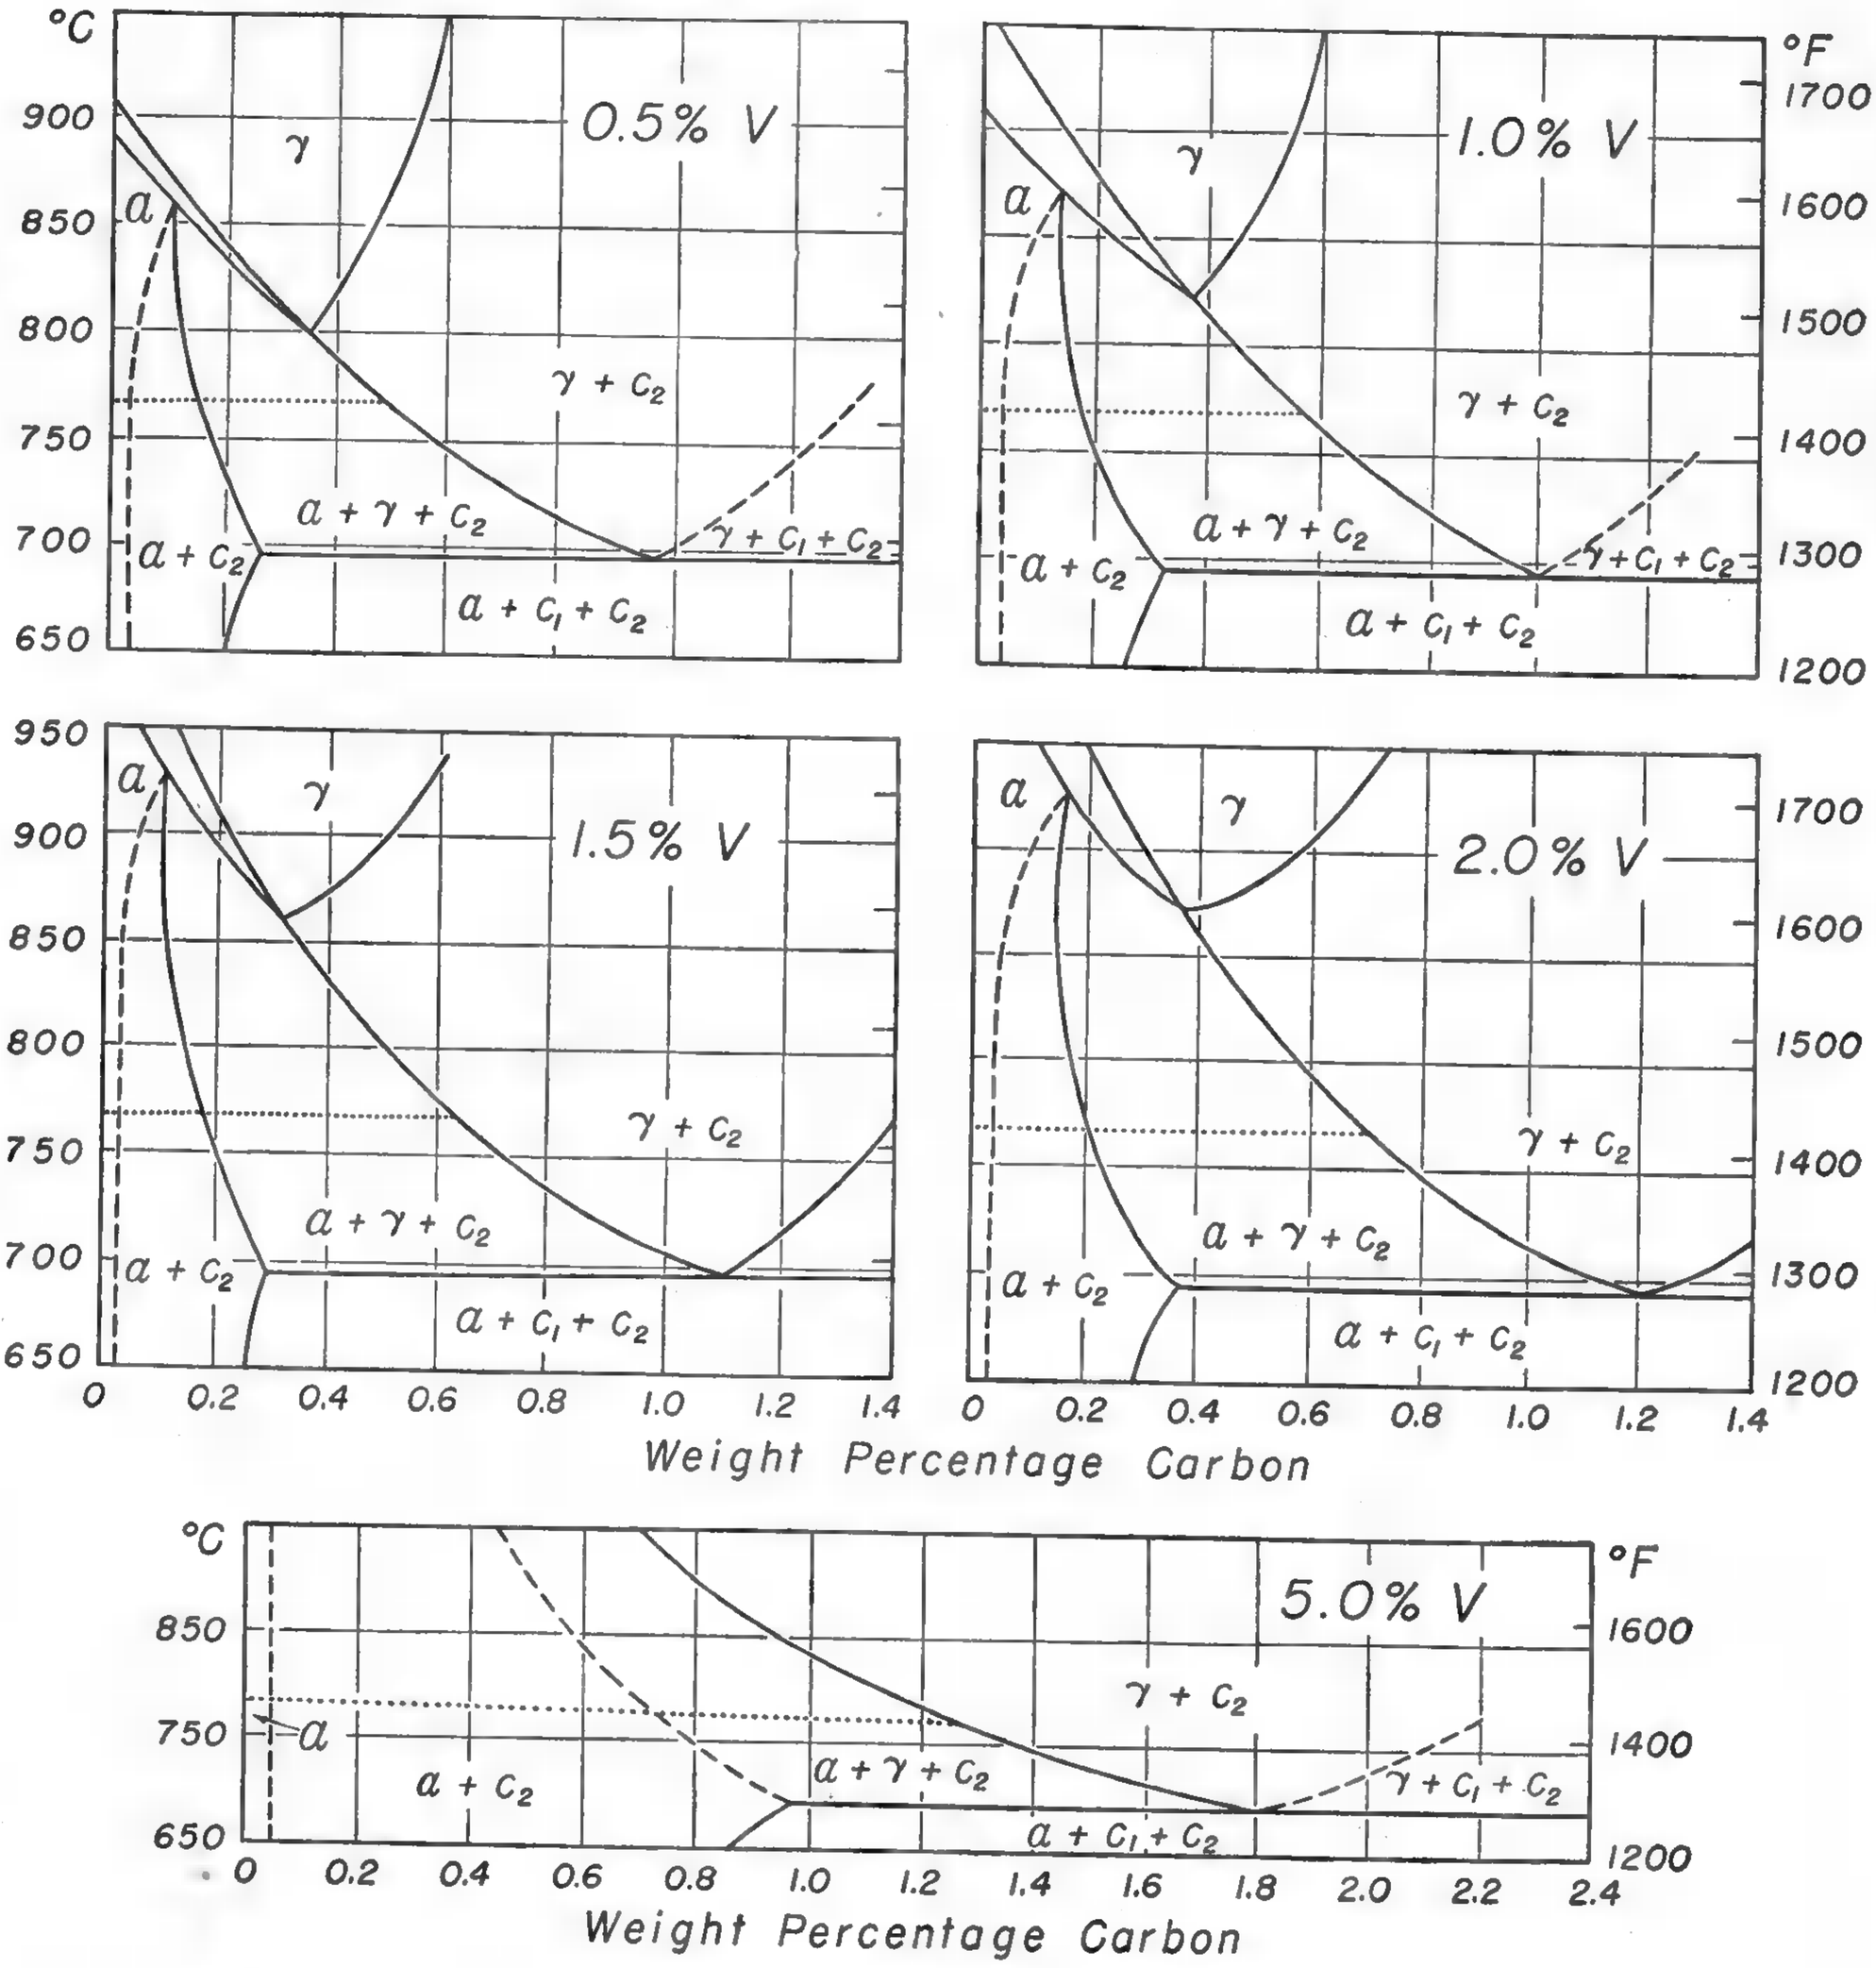
C-Fe-V Carbon-Iron-Vanadium

By Jerome Strauss* and Carl L. Shapiro*



The vertical sections presented by Wever, Rose and Eggers[1] are shown. The phases indicated by C_1 and C_2 here were designated Fe_3C and V_4C_3, respectively, in the original.[1]

The extension of the gamma field by carbon may be compensated by adding vanadium in approximately the ratio of vanadium to carbon in V_4C_3.[2] The solubility of carbon in γ is decreased by the addition of vanadium.[1,3]

Vanadium carbides not shown in the diagram may exist but no double carbide with iron is known.[4,5,6,7]

Vogel and Martin[8] claim that vanadium increases the solubility of carbon in ferrite.

C-Fe-W Carbon-Iron-Tungsten

By G. A. Roberts* and A. H. Grobe*

Takeda[1] postulates that $(Fe,W)_6C$ is metastable with respect to WC as Fe_3C is with respect to graphite. Therefore, the diagrams here represent metastable conditions.

According to many investigators, the stable carbides are WC and W_2C. However, as these carbides are seldom formed in ordinary heat treating operations, the more commonly observed, complex carbide has been shown in the ternary sections. The section of the diagram between tungsten and Fe_3C is a quasi-binary section.

Westgren and Phragmén[2] report $(Fe,W)_6C$ to be face-centered cubic with 112 atoms per unit cell and a lattice parameter of approximately 11.08 kX. The carbide probably varies in composition between Fe_3W_3C at 1.64% C and Fe_4W_2C at 1.99% C.

Both Fe_2W and Fe_3W_2 have been reported as stable phases in the iron-tungsten system. For this ternary diagram, only Fe_3W_2 (labeled epsilon) has been shown.

Cd-Sb-Sn Cadmium-Antimony-Tin

By W. T. Pell-Walpole*

The alloys of industrial interest in this system are confined to the tin-rich region, and detailed investigation has been limited to alloys containing up to 14% Sb and 45% Cd.

The constitution is depicted by (*a*) contour maps of the liquidus, the solidus, the surfaces of secondary separation, and the invariant reactions; (*b*) the isothermal sections for four temperatures; (*c*) two vertical sections of the most important group of alloys; and (*d*) a contour map showing the ternary limits of the α phase.

The phase nomenclature has been selected to be consistent with that used for the binary cadmium-tin system; that is, α, β, γ designate the phases originating in that binary system; the compound phases are referred to by δ and ϵ, or by their approximate chemical formulas, SbSn and CdSb respectively.

The five areas of the liquidus surface correspond to the primary separation of the phases, as follow:

Area *ABCDE* — α
DEFG — β
BCKL — SbSn
FGIH — γ
CDGIJK — CdSb

The surfaces of secondary separation are:

Area *ABCD* $\alpha + L \rightarrow \beta$
EFGHI SbSn $+ L \rightarrow \alpha$
JK'LM, *MLNO* $L \rightarrow \beta + \gamma$
GHP, *GPQ* $L \rightarrow$ CdSb + SbSn
BCGF, *CGQR* $L \rightarrow \alpha +$ CdSb
CRTL, *KK'LC* $L \rightarrow \beta +$ CdSb
TLU, *NLU* $L \rightarrow \gamma +$ CdSb

The solidus map has ten areas representing the solidification of single phases or phase combinations, as follow:

Area *ABCDE* Solidification of α from *L*
BCFG Lower surface of the reaction SbSn $+ L \rightarrow \alpha$
CFH Simultaneous solidification of α + CdSb + SbSn at 227 C
DCHI Solidification of α + CdSb from *L*
DEJK Lower surface of reaction $\alpha + L \rightarrow \beta$
JKNM Solidification of β from *L*
DKLI Simultaneous solidification of $\alpha + \beta$ + CdSb at 209 C
MNQR Lower surface of eutectic $L \rightarrow \gamma + \beta$
NOPQ Simultaneous separation of $\beta + \gamma$ + CdSb at 180 C

The area *OPRS*, shown in the same diagram as the invariant reactions, represents the inclined plane along which the eutectoid decomposition $\beta \rightarrow \alpha + \gamma$ occurs.

The ternary peritectic reactions that occur in equilibrium at 227 and 209 C are readily suppressed with normal rates of cooling; hence metastable phase combinations are common in as-cast alloys.

The β phase may be retained at room temperature by quenching, but gradually decomposes on standing. The eutectoid decomposition temperature is subject to marked undercooling and superheating.

Crystal Structures and Composition Limits of Solid Phases

Phase	Structure	Maximum Solubility Limits
α	Tetragonal	9 % Sb, 1.5% Cd at 227 C 5.5% Sb, 2.4% Cd at 209 C
β	Undetermined	5.1% Sb, 5.5% Cd at 209 C 2.0% Sb, 7.0% Cd at 180 C
γ	Close-packed hexagonal	Undetermined
SbSn	NaCl type	Undetermined
CdSb	Rhombic	Undetermined

Four invariant reactions occur, as shown in the section labeled Ternary Reaction Planes:

Area *ABCD:* SbSn + *L* (10% Cd, 8.2% Sb) $\rightleftarrows$ CdSb + α (1.5% Cd, 9% Sb) at 227 C
Area *EFGHI:* α (2.4% Cd, 5.5% Sb) + *L* (15.4% Cd, 4.3% Sb) $\rightleftarrows$ CdSb + β (5.5% Cd, 5.1% Sb) at 209 C
Area *JLMN:* *L* (33% Sb, 1% Cd) + CdSb $\rightleftarrows$ β (7% Cd, 2% Sb) + γ (cadmium-rich) at 180 C
Area *PQMR:* β (5.3% Cd, 0.8% Sb) $\rightleftarrows$ α (0.7% Cd, 1.0% Sb) + CdSb + γ (cadmium-rich) at 145 C

Cr-Fe-Ni Chromium-Iron-Nickel

By E. C. Bain* and R. H. Aborn*

The principal feature of this ternary system is its characteristic phase shifts caused by the allotropy of iron.

The maximum separation of liquidus and solidus in ternary alloys that contain up to 50% Cr reaches 100 °C in a 30% Fe, 48% Cr, 22% Ni alloy, but in iron-rich alloys of the stainless steel type this separation does not exceed 40 °C.[1]

The α and γ solid solutions in the iron-rich region of the diagram are generally termed "ferrite" and "austenite" respectively.

The alpha (ferrite) stabilizing influence of chromium (*see* Fe-Cr system) is predominant at very high and low temperatures, whereas the gamma (austenite) stabilizing influence of nickel (*see* Fe-Ni system) is predominant at intermediate temperatures. The outstanding feature, however, is the pronounced reluctance of metastable austenite to transform when once established at higher temperature. The temperature range in which the stable gamma (austenite) region is broadest[2] lies between 900 and 1300 C but the range for any one alloy is often considerably narrower and will vary with composition.

The addition of nickel appears to raise the upper temperature limit of stability of sigma, the brittle iron-chromium compound (*see* Fe-Cr system), to about 920 C and in so doing as much as 8% Ni may be dissolved.[3] Although sigma is shown in equilibrium with gamma (austenite) within certain composition limits, sigma forms more usually from alpha (ferrite). The sluggishness of sigma formation in Cr-Fe-Ni alloys is even greater than in Fe-Cr alloys, so the constitution of the ternary alloys with respect to sigma is uncertain below about 650 C.

Since many commercial alloys, particularly those of the stainless steel type, contain about 0.1% C, the structural constituents present in such alloys (up to 50% Cr or 50% Ni) after rapid cooling from temperatures of maximum austenite formation, are shown also.

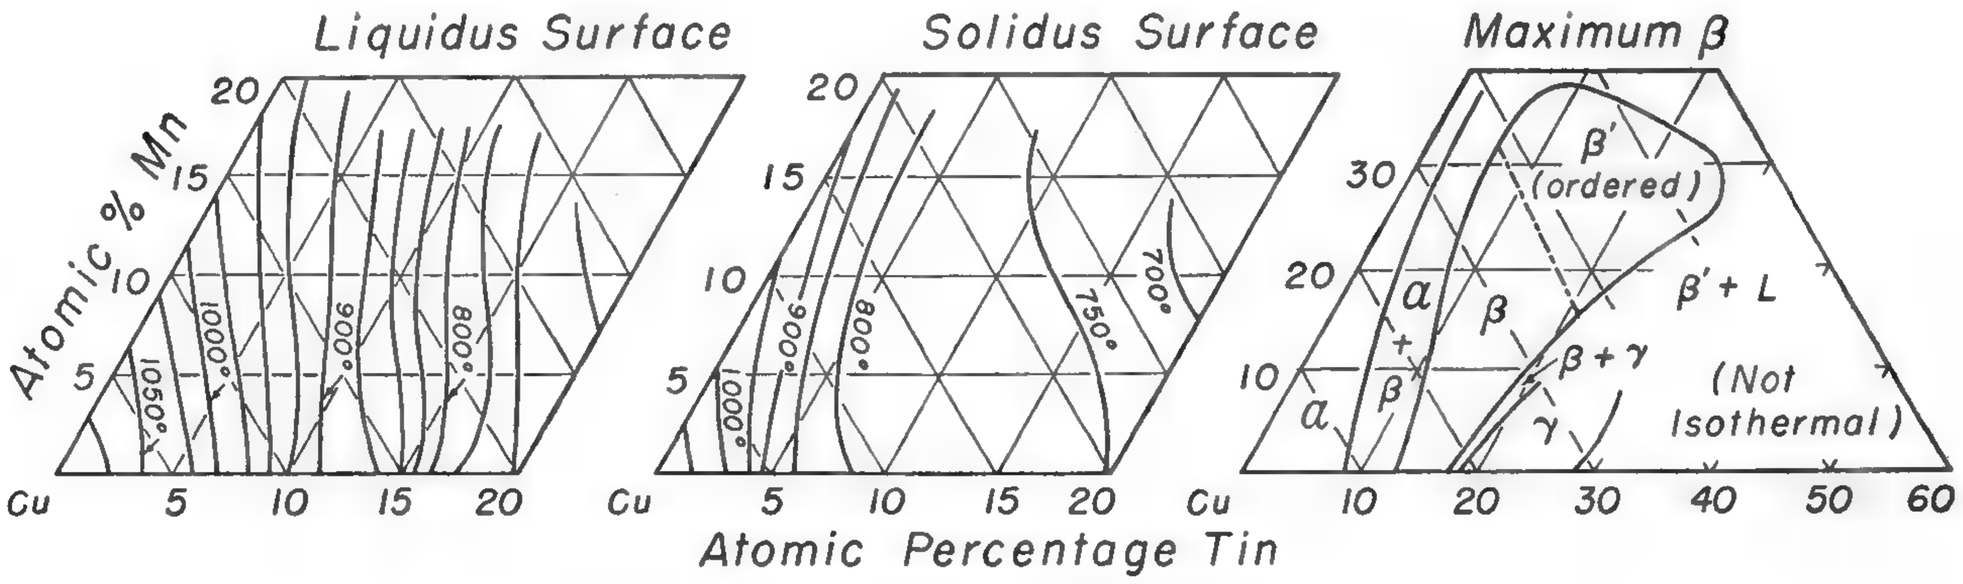
Cu-Mn-Sn Copper-Manganese-Tin

By Louis A. Carapella*



(Text and references are on the next page.)

* Senior Industrial Fellow, Mellon Institute of Industrial Research, Pittsburgh

The contours of both the liquidus and solidus isotherms for the copper-rich portion of the system are illustrated.[1] The same phases that exist in the binary bronze system appear to persist up to 15% Mn, along with the "*X* constituent", which might be Cu_5MnSn_2.[2] The β phase was reported[1] to have a narrow range of homogeneity—a deduction later contradicted by X-ray, microscopic and magnetometric examination of alloys containing up to 40% Mn.[3]

The maximum range of the β phase is outlined in the last figure.[3] At higher manganese and tin contents, β becomes ordered, even at high temperatures. Both β and β' are unstable below 600 C, but they may be retained at room temperature by drastic quenching.

The ordered β' phase is ferromagnetic; the maximum effect occurs at the composition Cu_2MnSn, which has a magnetic saturation moment exceeding that of pure nickel.

Cu-Ni-Sn Copper-Nickel-Tin

By J. T. Eash*

The liquidus contours of the copper-rich alloys and isothermal sections at 780, 700 and 300 C are shown. The solid phases are isometric in structure with the exception of η, which is probably derived from the hexagonal phase of the copper-tin system.

Cu-Ni-Zn Copper-Nickel-Zinc

By T. E. Kihlgren*

The diagrams presented are those of J. Schramm,[6] reorientated so that the base line will represent the binary copper-zinc alloys, since the commercially important nickel silvers are essentially brasses containing up to 25% Ni. The η phase domain of the ternary system is extremely small; the solubility at 100 C of nickel in zinc is of the order of 0.02% and of copper in zinc about 0.3%.

Crystal Structure of Phases

α—Face-centered cubic
β—Body-centered cubic
β'—Body-centered cubic with superstructure (corresponds to low-temperature phase of Cu-Zn system)
β_1—Body-centered tetragonal, AuCu type (corresponds to the low-temperature phase of the Ni-Zn system)
γ—Cubic, low symmetry, 52 atoms per unit cell
δ—Hexagonal
ϵ—Close-packed hexagonal
η—Close-packed hexagonal

Cu-Sb-Sn Copper-Antimony-Tin

By J. M. Blalock, Jr.*

Although the tin-rich alloys of tin, copper and antimony are very important commercially, and have been the subject of considerable study, there is insufficient published information concerning the constitution of the entire system. By metallographic means, Ellis and Karelitz[1] correlated the physical properties with the microstructures of the tin-rich alloys. The only study of the entire system is that of Tasaki,[2] and the accompanying data are based entirely on his work. It is significant, however, that there is good agreement between the two investigations in the area included in both.

Because Tasaki's work is based mostly on the results of thermal analysis, it is probable that the contours of the liquidus surface are correct. Because of the sluggishness with which these alloys approach equilibrium in the solid state, it is likely that the second diagram indicates the phases to be expected in cast alloys, rather than true equilibrium at room temperature.

Tasaki identified one ternary compound metallographically ($Cu_{12}Sn_7Sb_3$ at 38.9% Cu, 42.3% Sn, 18.8% Sb). With the help of the accompanying tabulations the reactions at the liquidus surface may be easily followed. The cusps in the isotherms lying between points *H* and *E* seem to indicate that there is a reaction along a line joining these cusps, but Tasaki was unable to find any other evidence of such a reaction and concluded that there is none.

Because of the complexity of the three binary systems involved, it is logical to expect phase relationships in the solid ternary alloys to be complicated also, and phase boundaries have not been definitely established. By designating most of the phases in the second diagram with "primes", Tasaki indicated that these phases probably undergo changes in the solid state. The κ phase is the only phase which Tasaki identified as being a product of a transformation taking place below the solidus; it seems likely that ζ is one of the phases participating in this transformation. It was definitely established that the solubility of antimony in Cu_6Sn_5 decreases with temperature; therefore these alloys may be susceptible to age hardening.

Cu-Sn-Zn Copper-Tin-Zinc

By Cyril Stanley Smith*

There is no detailed information on the alloys containing less than 50% Cu. The liquidus is based on reference 1, smoothed into the results from reference 2, near the copper-zinc side. The constitution at 500 C, mainly from reference 2, is given in the isothermal section. The α and β phases extend continuously between the two binary fields. β (or the related γ) in the binary copper-tin system decomposes eutectoidally to $\alpha + \delta$ at 520 C, and the eutectoid extends nearly to the copper-zinc side, decreasing in temperature as the zinc content increases. The phase marked γ probably represents a continuous series of solid solutions between γ(Cu-Zn) and δ(Cu-Sn), which have the same structure.

The decrease in solubility at 300 C shown by the dotted line of the isothermal section, occurs only after extremely long annealing of heavily cold worked samples, and for most industrial purposes the 500 C line represents the effective solubility.

Fe-Mn-O Iron-Manganese-Oxygen

Andrew, Maddocks and Howat [J Iron Steel Inst, 124, 283 (1931)] investigated the section between the compositions FeO and MnO. The liquidus and solidus are slightly curved lines, about 20 C apart, joining the melting temperatures of wüstite and MnO (1410 and 1585 C respectively). It is known that FeO does not exist as a pure substance. Assuming that the "FeO" of these investigators was wüstite containing about 25% O, the thermal effect observed at about 1170 C might have been caused by precipitation of Fe_3O_4 from wüstite (*see* Fe-O system, page 1212).

Fe-Mn-S Iron-Manganese-Sulfur

Vogel and Hotop [Arch Eisenhüttenw, 11, 41 (1937)] investigated the system up to the line joining FeS and MnS. In the manganese-sulfur system, the liquid miscibility gap extends from 0.3 to 33.5% S at 1580 C; MnS melts at 1600 ± 10 C; and there is a eutectic at 1230 C near the manganese side. A ternary eutectic point at 1000 C nearly coincides with the binary eutectic point of the iron-sulfur system (*see* page 1215). There are two maximums of three-phase equilibrium, which largely determine the conditions of solidification.

Fe-Mn-Si Iron-Manganese-Silicon

By Louis A. Carapella*

The thermal and microscopic investigations of Vogel and Bedarff[1] show a ternary system with seven surfaces of primary solidification in which, with decreasing temperature, the following phases are in equilibrium with the melt: the ternary solid solutions of delta manganese, gamma manganese, gamma iron, and alpha iron, the compound FeSi, and the solid solutions of FeSi-MnSi and Mn_5Si_3-$Fe_{12}Si_{11}Mn_5$ respectively. There are also four surfaces of secondary separation, at 1160, 1120, 1020 and 1010 C, and two invariant reactions in the solid state, at 1000 and 720 C.

There are three quasi-binary systems: FeSi – MnSi, Mn_5Si_3 – $Fe_{12}Si_{11}Mn_5$ and FeSi – $Fe_{12}Si_{11}Mn_5$. The last-named system is simple eutectiferous with a eutectic near the ternary compound and at about 1210 C. The other two quasi-binary systems have narrow ranges of solidification and continuous series of solid solutions. Both Vogel and Bedarff[1] and Jänecke[2] have presented isothermal sections for 400 C. Neither of these sections is compatible with present knowledge of the binary Fe-Mn and Fe-Si systems at 400 C.

Fe-Mo-Ni Iron-Molybdenum-Nickel

Köster [Arch Eisenhüttenw, 8, 169 (1934)] investigated the ternary system by thermal and micrographic methods in the region iron-Fe_3Mo_2-MoNi-nickel. Fe_3Mo_2 and MoNi form a continuous series of solid solutions. The solubility of α and γ in this solid solution increases with increasing temperature, and precipitation hardening is possible in certain of these alloys. The magnetic transformation surface intersects the γ solid solution surface at 20 C at the points 60% Ni, 17% Mo, 23% Fe and 19% Ni, 10% Mo, and 71% Fe. For data on the mechanical properties of heat-resistant Ni-Mo-Fe castings, see pages 577 and 578 in this Handbook.

Fe-Ni-S Iron-Nickel-Sulfur

Vogel and Tonn[1] investigated the system iron-nickel-Ni_3S_2-FeS above 480 C, and determined the Curie points. Guertler and Savelsberg[2] reported the compounds $2FeS \cdot Ni_3S_2$ and $2FeS \cdot Ni_2S$, both of which decompose, on cooling, into a mixture of FeS and Ni_6S_5 with the liberation of a small amount of nickel. Hawley and co-workers[3] reported that pentlandite is a solid solution series varying from 55% NiS, 45% FeS to nearly 90% NiS, 10% FeS.

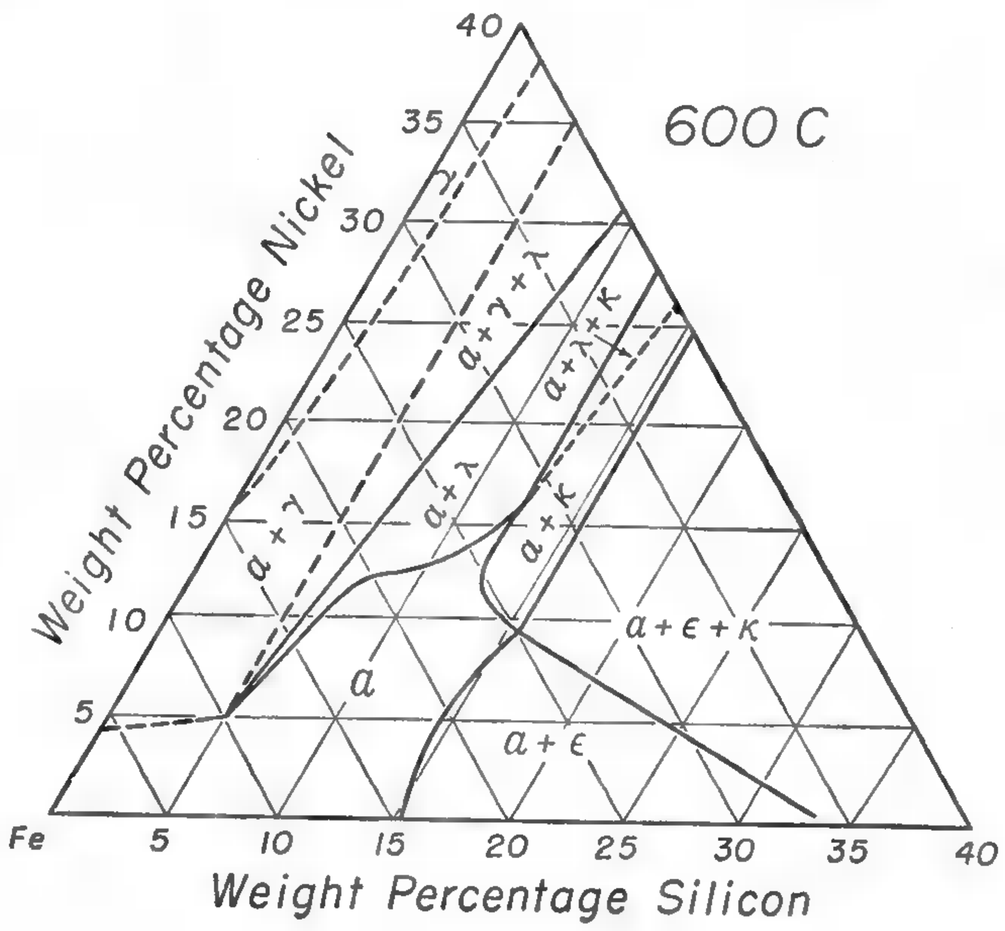
Fe-Ni-Si Iron-Nickel-Silicon

The constitution of the iron-rich iron-nickel-silicon alloys at 600 C was investigated by Greiner and Jette [Trans AIME, 152, 48 (1943)], using X-ray diffraction methods. Most of the alloys were annealed for either 28 or 56 days at 595 or 600 C.

The α, γ and ϵ phases have the same structures as corresponding phases in the binary iron-nickel and iron-silicon alloys.

The λ phase was reported as cubic with $a = 6.131$ kX. The κ phase was reported as tetragonal with $a = 8.308$ kX and $c = 9.012$ kX. Because the λ and κ phases were observed only in duplex alloys, these structures were presented as tentative.

The surface representing the lattice constants of the alpha phase alloys is not a plane.



The Ternary Limits of the Alpha Phase at 600 C

Fe-Ni-Ti Iron-Nickel-Titanium

By Louis A. Carapella*

There is a ternary eutectic at about 20% Ti, 42% Ni and 1105 C. Ni_3Ti and Fe_2Ti form a quasi-binary system, with a eutectic point at 25% Ti, 41% Ni and 1320 C. The maximum solid solubility of Fe_2Ti in Ni_3Ti is about 18%.

Mg-Mn-Zn Magnesium-Manganese-Zinc

By G. F. Sager† and B. J Nelson†

There is a ternary eutectic at 3.2% Mg, 0.07% Mn and 369 C.[1] The solubility of manganese in liquid magnesium containing 6% Zn is approximately 1% at 650 C, 1.7% at 720 C and 3% at 800 C.[2]

Fe-Ni-W Iron-Nickel-Tungsten

The diagram determined by Winkler and Vogel [Arch Eisenhüttenw, 6, 165 (1932)] has four surfaces of primary crystallization, denoting solidification of α, γ, Fe_3W_2, and a tungsten-rich solid solution, S. Two four-phase equilibriums occur: liquid + $\alpha \rightleftarrows \gamma + Fe_3W_2$ at 1465 C, and liquid + $Fe_3W_2 \rightleftarrows \gamma + S$ at 1455 C. There are three univariant solidification reactions. The ternary limits of the α and γ phases are wide at high temperature, but restricted at low temperature. The γ phase can exist in equilibrium with each of the following: Fe_3W_2, Ni_6W, and the tungsten-rich phase, S. Other transformations were noted.—Louis A. Carapella

Mo-Ni-Si Molybdenum-Nickel-Silicon

H. Pfautsch [Z Metallkunde, 17, 48 (1925)] investigated the effect of silicon on nickel-molybdenum alloys. He found evidence for two ternary phases, Ni_4MoSi_2 and Ni_3Mo_2Si, which melt between 2100 and 2200 C. Ni_4MoSi_2 transforms at about 850 C. Details are given concerning the resistance of the alloys to caustic soda, ammonia, sodium sulfide, hydrochloric acid, nitric acid, tartaric acid, and other liquids. It was reported that silicon increases the corrosion resistance of nickel-molybdenum alloys in hydrochloric acid. The hardness of the alloys is reported also. [This information is from an abstract in J Inst Metals, 35, 554 (1926).]

Pb-Sb-Sn Lead-Antimony-Tin

By R. I. Jaffee* and H. P. Nielsen*

For the liquidus surface, the lead corner has been drawn from Weaver's data,[2] and elsewhere the diagram is from the data of Iwasé and Aoki.[1] Using the nomenclature of these investigators, the following are the fields of primary crystallization: antimony-rich solution, α, in *APKE;* SbSn solution, β, in *PRSMX;* tin-rich solution, γ, in *RCWS;* and lead-rich solution, δ, in *EXMSWB*. There are two invariant points in the system: a ternary eutectic at *X*, where α, β, and δ crystallize simultaneously at 239 C, and a peritectic point at *S* where β reacts with liquid to form $\gamma + \delta$. Along *PX* the peritectic reaction of α with liquid to form β takes place. Another peritectic reaction takes place along the line *RS*, where β reacts with liquid to form γ. Eutectic separation of δ and α takes place along *EX*, of δ and β along *XMS*, and of δ and γ along *SW*. There is a maximum in *XS*, the eutectic line of δ and β, at *M*, which is coincident with the intersection of *XS* with the pseudobinary line from Pb to SbSn.

Summarizing, the reactions that take place at the invariant points and along the boundary lines are:

X	:	$L_X \rightleftarrows \alpha + \beta + \delta$	(239 C)
S	:	$L_S + \beta \rightleftarrows \delta + \gamma$	(189 C)
PX	:	$L + \alpha \rightleftarrows \beta$	
RS	:	$L + \beta \rightleftarrows \gamma$	
EX	:	$L \rightleftarrows \alpha + \delta$	
XS	:	$L \rightleftarrows \delta + \beta$	
SW	:	$L \rightleftarrows \delta + \gamma$	

The locations of the invariant points *X* and *S*, and the point *M*, as found by the various investigators, are:

Point	Investigator	Percentage Tin	Percentage Antimony	Percentage Lead	Temperature, deg Cent
Eutectic, *X*	Iwasé and Aoki[1]	3.5	11.5	85	240
	Weaver[2]	4	12	84	239
Peritectic, *S*	Loebe[3]	60.5	3.0	36.5	191
	Campbell and Elder[4]	57.5	2.5	40.0	189
	Campbell[5]	57.5	2.5	40.0	189
	Heyn and Bauer[6]	53.5	4.0	42.5	184
	Iwasé and Aoki[1]	57.5	2.5	40.0	189
Pseudobinary Eutectic, *M*	Iwasé and Aoki[1]	10	10	80	245
	Weaver[2]	10	10	80	246.5

Concerning the eutectic in the pseudobinary system, Pb-SbSn, Loebe,[3] Campbell,[5] and the early investigators took it to be a peritectic point and reported its composition as 10% Sn, 10% Sb, 80% Pb. Iwasé and Aoki first noticed the maximum in *XS* at this composition, and Weaver, who checked their observation, pointed out the significance of the maximum, and constructed a diagram of the pseudobinary system from thermal data. The early investigators may have missed the ternary eutectic because of inadequate etching methods. Weaver used an electrolytic etch in 10% hydrochloric acid, which clearly distinguished between the α and β phases.

Solid solubilities of the four phases at the temperatures of the invariant points were determined microscopically by Iwasé and Aoki, and they reported the locations of the two-phase and three-phase fields at these temperatures. Their determinations are for alloys annealed 10 days or more, and would not apply to alloys in the cast condition. Weaver has given data on the phase fields in the lead corner for cast alloys. For cast alloys, the boundary between the $\alpha + \beta + \delta$ field and the $\beta + \delta$ field is closer to the pseudobinary line than it is for annealed alloys.

Lead-base lead-antimony-tin alloys are used extensively for bearings and for type metal, because of the low melting points, good casting characteristics, and the relatively high hardness of the alloys. Compositions and properties are given elsewhere in this Handbook (*see especially* "Bearing Materials", page 745; "Type Metals", page 957; and the data sheets for lead-base babbitts, page 965). The structure of these commercial alloys usually consists of hard particles of antimony (α) or SbSn (β) in a matrix of ternary eutectic.

Antimony is frequently added to lead-tin solders in amounts up to 6% of the tin content, for the purpose of increasing the shear strength of the soldered joints. The beneficial effect of antimony is found with solders containing appreciable amounts of tin. An excessive content of antimony causes the formation of SbSn (β), which is considered detrimental in solders.

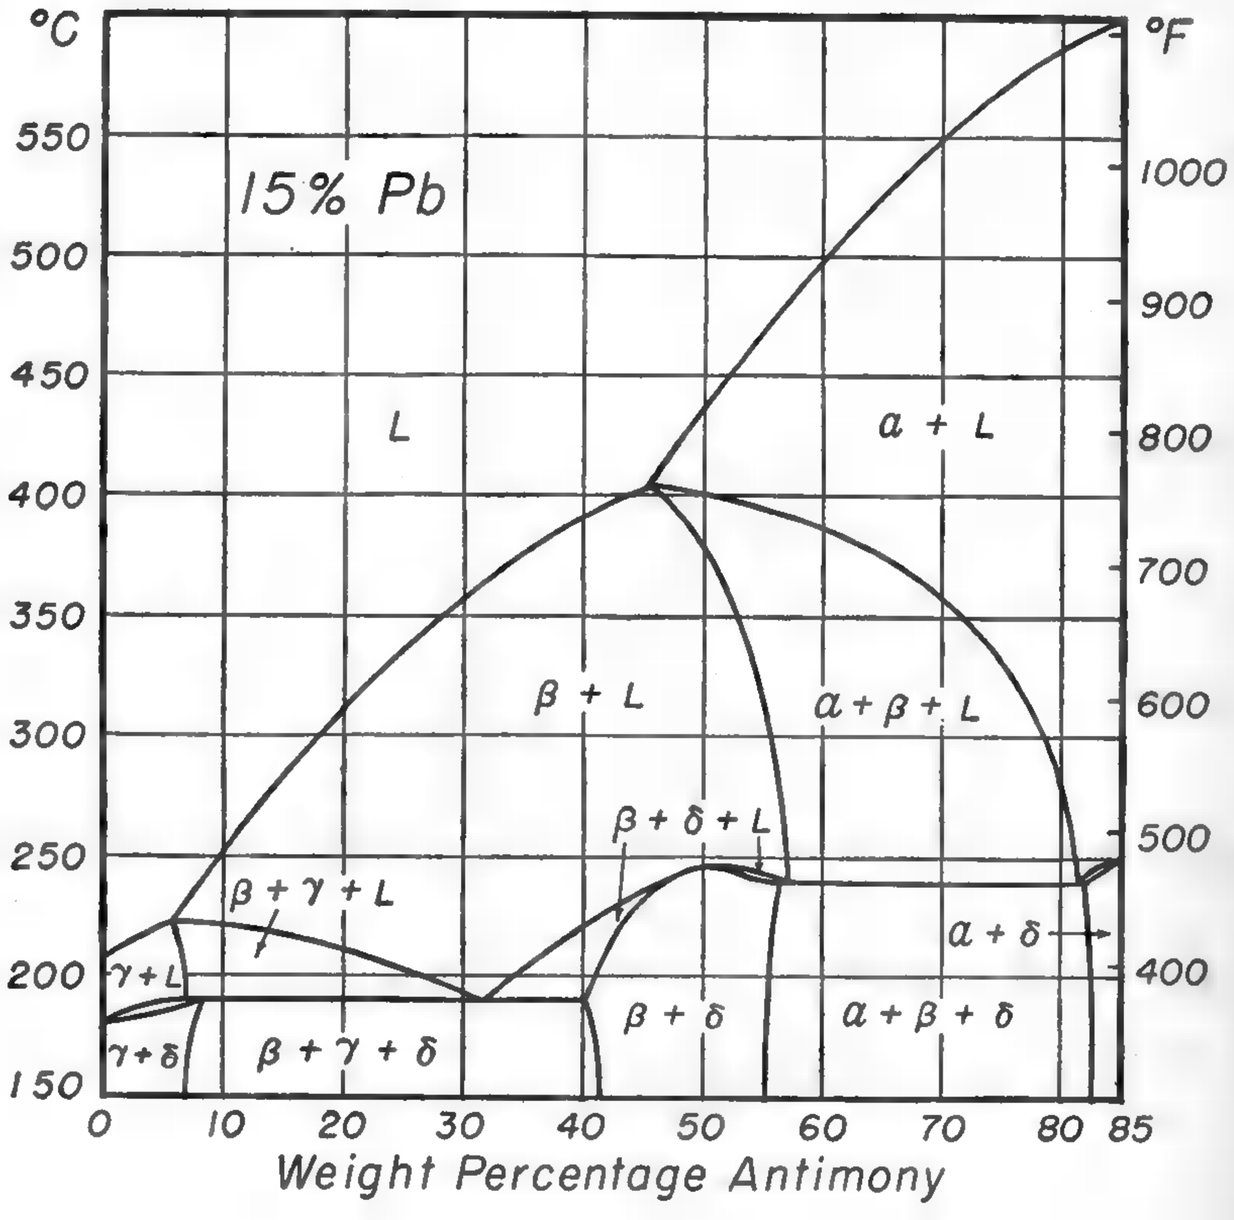
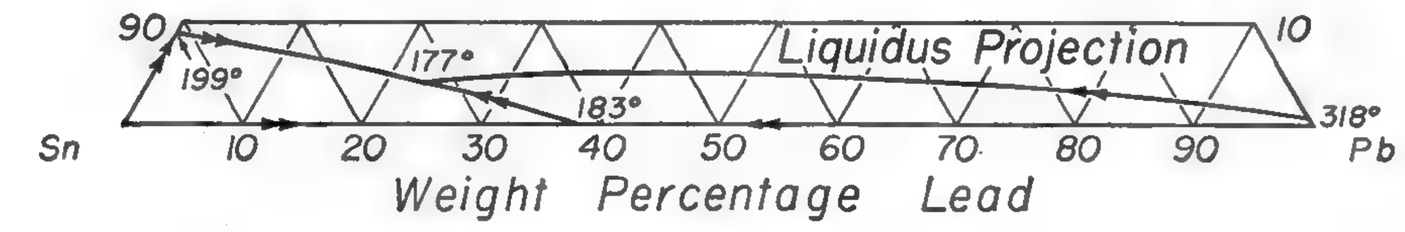
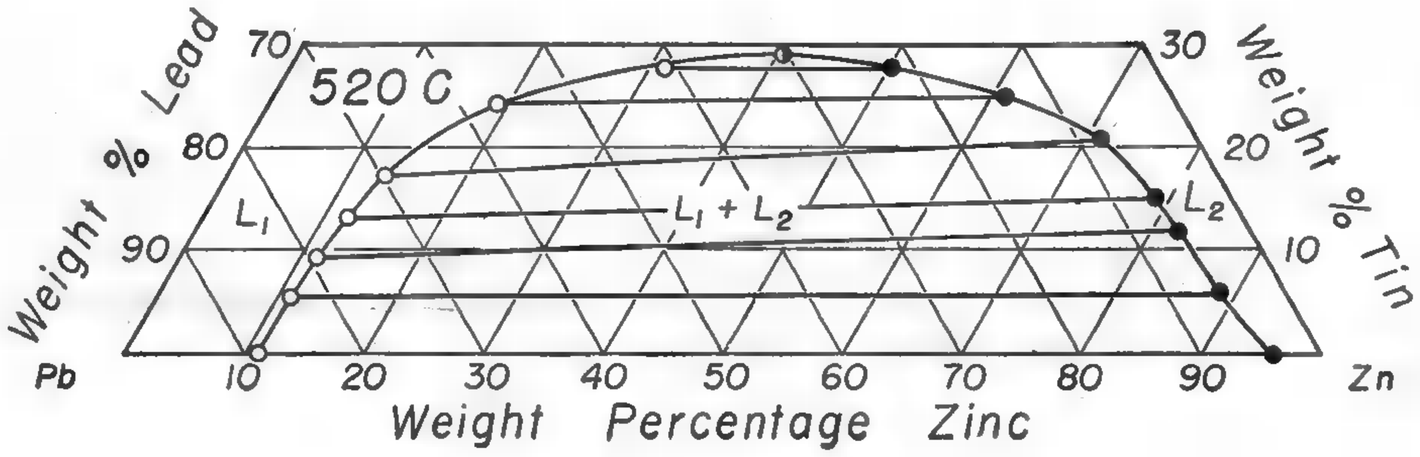
Liquidus Surface



Pb-Sn-Zn Lead-Tin-Zinc





The liquid miscibility gap of the lead-zinc system extends into the ternary system to a tin content of 29% at 520 C[1] (*see cut*). Isotherms have been determined also for higher[2] and for lower[3] temperatures. The miscibility gap lies entirely in the solidification field of zinc. The ternary eutectic point is at 24% Pb, 5% Zn, 71% Sn and 177 C[3] (*see cut*).

INDEX★

THIS INDEX contains three principal types of entry: materials (chiefly metals and alloys), processes, and properties.

Materials are indexed more completely than processes and properties. The various steels are listed separately, alphabetized according to adjectives; for example, *Austenitic manganese steel, Carbon steel, High-carbon high-chromium tool steel, Martensitic stainless steel,* etc. Nonferrous alloys are listed (1) under the common names, such as *Cartridge brass, White gold* and (2) under the names of the components, with the basis metal given first, as *Copper-zinc, Gold-nickel-copper-zinc.* Numerical trade designations are grouped under the name of the basis metal. For example, 4340 steel is listed under *Steel, SAE-AISI designations;* 17 S aluminum alloy is listed under *Aluminum alloys, trade designations.* Designations of government specifications for nonferrous metals and alloys are indexed on the last page, 1332.

Specific information about the processing of a certain metal is indexed as subordinate entries under the name of the metal. For example, extrusion of tin alloys is indexed as *Tin alloys, extrusion.* Under the name of a process, general information is referred to, and specific information about processing a certain metal may be listed again, depending on the importance of the discussion. Processes such as cold heading, precision casting and press forging are indexed according to the adjective rather than the noun.

Properties of a specific material are listed as subordinate entries under the name of the material. General comparisons or tabulations of a property for a group of materials are indexed under the name of the property.

The letter (T) or (F) in parentheses after an index entry means that the information referred to is in a Table or Figure, respectively, on one of the pages mentioned.

equipment 36
illustrations (F) 38
multiple production (F) 38
operation 38
tool nomenclature (F) 37
Drop hammer, definition 5
Drop-hammer coining 42, 43
Drop-hammer forming of aluminum 774
Drop-hammers (forging),
board (F) 37
steam (F) 36
types 36, 37
Drop-hammer stamping dies 1082
Dross, definition 5
in lead cable sheath 949
in melting copper alloys 856, 857
Drums for wire rope (T) 539, 540
Dry cyaniding (carbonitriding) of steel .. 696
Dry sand mold, definition 5
Ductility, definition 5

Ductility at low temperatures,
alloy constructional steel (T) 208
aluminum alloys (T) 213
cast steel (T) 210
chromium-manganese-nickel steel (T) . 211
chromium-nickel steel (T) 211
copper alloys (T) 214
high-manganese steel (T) 212
iron-nickel alloys (T) 211
magnesium alloys (T) 214
nickel alloys (T) 215
nickel steel (T) 210
Ductility – bend testing of metals 90
Ductility in steel, effect of inclusions 450
secondary low 442
Ductility test machines 129
Ductility test of
sheet metals, types 90, 129
welded joint 139
wire 134
Dumet wire 601
Dummy, definition 5
Dummy block, definition 5
Duplexed parts, powder metallurgy 47
Duplexing
in grain growth in steel 401
in malleable iron 520
Duplex metal tube, impact extrusion 950
Duplex process of steelmaking 322
Duralumin, definition 5
Duralumin alloys,
macro-etchants (T) 798
properties 206, 803, 804
Durville process, definition 5
Dust explosions 52, 53
Dusting, definition 5
Dust-processing equipment 53
Dust removal from blast furnace gas 317
Dusts, industrial hazards from 755–760

Indirect extrusion, definition 7
Indium, physical properties (T) 20, 21
Indium-aluminum, phase diagram 1162
Indium in gold alloys 1097
Indium-lead, phase diagram 1223
Indium plating on lead bearings 222
Induction furnace for steel (F) 332, 333
Induction hardening,
- definition 7
- heating data (T) 281, 282
- service failures and 248
- steels for 282

Induction hardening of
- gray iron castings 519
- pearlitic malleable iron 522
- steel, case depth measurement 666
- 1045 steel (T) 283
- steel gears 641

Induction heating,
- advantages 281, 282
- applications 280–283
- definition 7
- efficiency – frequency – bar diameter (F) 281
- equipment for various processes (T) . 280, 282
- frequency selection 280, 281
- high initial cost 281
- power source and frequency (T) 280, 282

Induction heating for
- brazing 80, 282, 283
- cladding 1106
- forging 281
- hardening 280-282
- hot coining 281
- selective hardening 280
- shrink fitting 282, 283
- sintering 282, 283
- soldering 83, 282, 283
- stress relieving 281, 282
- tempering 281, 282

Induction heating for (continued)
- upsetting 281
- various processes (E) 282
- welding 282, 283

Induction heating of steel,
- frequency – bar diameter (F) 281, 283

Induction melting of
- aluminum 767, 768
- copper 846, 847
- Inconel 1028
- precious metals 1097, 1098
- steel 332–334
  - charging the furnace 333
  - melting procedure 333
  - operating principles 333
  - pouring 334

Induction relationships of permanent magnet alloys (F) 596
Induflux, Waugh 153
Industrial poisoning by metals 755–760
Ingot, definition 7
Ingot iron,
- B-H curves (F) 429, 430, 588, 594
- cold worked,
  - high-temperature properties (F) 437
  - properties with reduction 437
  - work hardening coefficient 437
- composition (T) 424
- creep strength (F) (T) 433
- definition 7
- density (T) 312
- density – reduction (F) 424
- hardness – reduction curve (F) 1051
- hardness – temperature (F) 433
- high-temperature properties (T) 432, 433, 504
- hysteresis curve (F) 429, 430, 588, 594
- low-temperature properties (T) 207
- magnetization curve (B-H) (F) 429, 430, 588, 594
- properties (T) 423–434
- properties – reduction (F) 437
- residual induction – coercive force (F) .. 430
- stress-strain curve – reduction (F) 437
- tensile strength at high temperature (T) 432
- work hardening capacity (F) 437

Ingot molds of gray cast iron, composition (T) 507
Ingot pattern in tool steel (F) 415
Ingots,
- pouring practice 334–337
- types for aluminum alloys 768, 769

Inhibitor, definition 7
Inhibitors in
- aluminum alloys, stress corrosion and .. 230
- green sand mold for magnesium 968
- macro-etching of steel 393
- pickling steel, ... 727, 728
  - advantages and disadvantages 728
  - nature and composition 727
  - testing 728
  - theory and mechanism of 727

Inhibitors to
- corrosion of magnesium in aqueous systems 998
- dezincification of copper alloys 896
- grain growth in steel 400
- rust 734–736
  - See also *Rust-preventive compounds*
- transformation in tin 1071

Initial creep, definition 7
Initial tension in steel springs 646
Inoculants in cast iron 515
Inoculated irons (cast), definition 515
Inoculation, definition 7
Inserts, definition 8
Inserts in
- composite steel (F) 543, 545
- machine forging 32
- magnesium,
  - interferences for press fit and shrink fit (T) 1005
  - types 1004, 1005

Insoluble, anode, definition 8
Inspection, electric 155
Inspection by high frequency 154
Inspection by magnetic analysis 151–153
Inspection of
- bolts, nuts, screws, studs, pins 140
- coatings on bolts, etc 140
- plaster mold castings (copper) 855
- rolled steel sheet and strip 346
- semifinished steel 346
- sling chain 341, 342
- steel castings 524

Instruments for
- calibration 91–93
- dilatometry 168–174
- pyrometry 174–187
- testing,
  - See articles on Mechanical testing.
  - See also *Brinell meter, Pyrometer. Sonigage*, etc.

K

Kahlbaum iron, composition (T) 424
Kalling's reagent for steel (T) 395
Kanner's special tin plate 710
Kanthal alloys 606
Keller's etch 798, 800
Kerf, definition 378
Keyhole specimen, definition 8
Killed steel, definition 8, 324
  for rolled sheet and strip 356
Killing (or deoxidation) in
  acid electric-arc process 331
  basic electric-arc process 328
Kiln, definition 8
King Brinell machine, portable 96
Kink test for wire 135
Kip, definition 8
"K" Monel 1030, 1032–1034, 1051–1053
Knives and cutters of composite steel. 543, 545
Knives, butcher, tempering temperatures. 661
Knives, woodworking, tool steel for 662
Knockout, definition 8
Knoop hardness, definition 8
Knoop hardness numbers 102
Knoop indenter for Tukon tester 96
Knurling,
  definition 8
  dies and tools for 45
  machines for 45
  of copper alloys 887
  with automatic screw machines 45
Kovar 604, 1108
Krause rolling mill, definition 8
"KR" Monel 1032, 1052
Krypton, properties (T) 20, 21
Krypton-iron, constitution 1209
Kure Beach, N.C., field station,
  corrosion resistance of alloys 899
  corrosion testing of magnesium 995
KX or kX, definition 19
Kyanite, properties (T) 28

L

Lacquers, methods of application 893
Ladles in blast furnace process (iron) .317, 318
Ladles in steelmaking,
  carburization and deoxidation in 335
  operation 335–337
  types (F) 335
Lamagal, furnace lining 1028
Lamb waves in supersonic testing 58
Laminations,
  definition 8
  supersonic testing of 157
Lance cutting 383, 384
Lancing in gas or flame cutting 383, 384
Lanthanum, properties (T) 20, 21
Lap, definition 8
  forging, microstructure (F) 246
  in semifinished steel 348
Lap braze (F) 79
Lap joint by brazing (F) 79
Lapping precious metals 1109
Lapping stages for cemented carbides 61
Lap shear test of spot welds 139
Lap weld, definition 8
Latent heat, definition 8
Latent heat of fusion,
  See *Heat of fusion.*
Latent heat of transformation,
  See *Heat of transformation.*
Latent heat of vaporization,
  See *Heat of vaporization.*
Lathe knurling 44, 45
Lattice, cubic or hexagonal
  See *Cubic lattice, Hexagonal lattice*

for reclamation of worn parts 721
porosity (T) 720
processes 721
scratch hardness (T) 721
Spray quenching, definition 14
Spray tower coolers in quenching of steel 625
Spring-back, definition 14
Springing, definition 14
Springs, nonferrous,
copper-alloy, production 870
nickel-alloy,
stress-equalizing annealing 1032, 1033
small flat and helical 644, 646
Springs, steel,
coil, stresses for peened and nonpeened (T) 250
coiling strains 646
composition of steels for 644–647
decarburized, fatigue strength 248
fatigue strength with prestressing 250
fatigue strength with shot peening 249
flat 644–646
heat treatment 644–647
helical 645–647
helical, shot-peened, fatigue strength – treatment (F) 250
high-duty, steel wire for 646
initial tension 646
large flat and leaf,
heat treatment (T) 645
steels for 644
large helical,
heat treatment 647
shot peening 647
steels for 646
leaf, fatigue failure in decarburized (F) 249
shot blasting or peening 646
shot peened, final stress – initial stress (F) 250
small flat, heat treatment 646
small helical (T) 645
steels for (T) 644–646
stress relieving 646
Sprues, definition 14
Squeeze riveter 779, 985
Squeeze riveting of
aluminum alloy rivets 779
magnesium alloy assemblies 985
Squeezing of wrought iron 504
Stabilization of
alloy steel 265
austenite in steel 265, 612
austenitic stainless steel 558
corrosion-resistant castings 550
magnesium alloy castings 971
zinc alloys, die-cast 1079
Stabilizing anneal, definition 14
Stabilizing treatment, definition 14
Stack flame cutting 383
Stainless chromium irons,
thermal expansion (T) 311
Stainless clad steels (F) 545, 546
applications 546
properties 546
strength of bond 545
Stainless iron,
definition 377

ADDENDA (*April 15, 1948*)

Chromium

IN A RECENT publication on electrodeposited chromium [A. Brenner, P. Burkhead and C. Jennings, J Research Nat Bur Standards, **40**, 31 (1948)] the following values are reported for some properties of the annealed metal. Hardness, 200 Knoop; modulus of elasticity, 36,000,000 psi; tensile strength, 70,000 psi; electrical resistivity, 13.0 microhm-cm at 28 C; melting point, 1890 ± 10 C. The effects of heat treatment and oxygen content on most of these properties were studied. These data were published after the compilation on pages 1135 and 1136 of this Handbook had been printed.

Selenium

RECENT publications indicate that the electrical resistivity of annealed selenium at room temperature, in the dark, is of the order of 100,000 ohm-cm, a value considerably higher than that given on page 1140 in this Handbook. The electrical resistivity of selenium is affected by light and other factors. Data are given in the following publications. F. de Boer, Philips Res Rep, **2**, 352 (1947); B. D. Cullity, Metals Tech, **15**, TP 2313 (Jan 1948); and W. E. Blackburn, J Applied Phys, **19**, 51 (1948). None of these articles was available when the compilation of properties on page 1140 of this Handbook was printed.

Trade Names

ALTHOUGH this Handbook contains many trade names, it is not a general source for the identification of proprietary designations. The most complete list of alloy trade names is "Engineering Alloys", revised edition, by N. E. Woldman and R. J. Metzlar, American Society for Metals, 1945. Trade names of 1700 tool materials are listed in "A Directory of Tool, Metal-Cutting, and Die Steels, and Sintered Carbides", 19th edition, by T. W. Lippert, Iron Age, 1947. For trade names of processes and equipment, as well as alloys, the reader may refer to "10,000 Trade Names", by T. W. Lippert, Iron Age, 1947.

INDEX OF GOVERNMENT SPECIFICATION NUMBERS FOR NONFERROUS METALS AND ALLOYS

INDEXED BELOW are designating numbers for the following government specifications: Army-Navy Aeronautical, Federal, Navy, Army, and Air Force. The pages referred to are those on which the nonferrous data sheets are given. In each entry, the common name or trade designation of the alloy is included parenthetically for identification.

Joint Army-Navy specifications and specifications of the Navy Bureau of Ordnance and Bureau of Aeronautics are not indexed below, although a few of these are listed under item A4 in the nonferrous data sheets.

Items that are indicated with a star (★) have been added by the indexer, and are not mentioned in the text.

GUIDE TO THE USE OF THE NONFERROUS DATA SHEETS

In this edition of the Metals Handbook, nearly all the specific data for nonferrous metals and alloys have been presented according to a new, semitabular arrangement. This data sheet form has been used so that the reader can easily find information of the same kind for various alloys by following key numbers, which are the same throughout the Nonferrous Section. General information concerning melting, shaping, treating, metallography, and corrosion is included in articles that deal collectively with groups of similar alloys; only specific information is presented in the nonferrous data sheets.

The outline for the data sheet form was made inclusive enough so that there would be a place for every type of information that might be important for some metal or alloy. Only about half the key numbers have been used frequently in the Nonferrous Section, and the most important of these items are listed below. Other key numbers are given in the index; for example, see Supraconductivity *in the index.*

A Designations
- *1* Common name
- *2* Trade name
- *3* ASTM number
- *4* Government number
- *5* Other designations
- *6* Foreign equivalents

B Applications
- *1* Typical uses
- *2* Precautions in use

C Mass
- *1* Density
- *2* Density vs temperature
- *3* Compressibility
- *4* Density vs deformation
- *5* Solidification shrinkage

D Thermal Properties
- *1* Liquidus temperature
- *2* Solidus temperature
- *6* Thermal expansion
- *11* Specific heat
- *13* Heat of fusion
- *16* Thermal conductivity
- *19* Recrystallization temperature

E Electrical Properties
- *1* Volume conductivity (% of standard copper)
- *2* Electrical resistivity
- *5* Temperature coefficient of electrical resistivity

F Optical Properties
- *1* Reflectivity
- *4* Color
- *5* Emissivity

G Magnetic Properties
- *1* Influence of treatments
- *2* Magnetic susceptibility
- *3* Magnetic permeability

H Velocity of Sound

I Chemical Properties
- *1* General corrosion
- *2* Resistance to specific chemical agents

J Structure
- *1* Crystal structure
- *2* Slip plane
- *3* Twinning plane

K Mechanical Properties

Various tabular and graphical arrangements have been used for presenting typical values of the most important mechanical properties. Unless otherwise stated, the numbers given are average values and should not be used for purposes of specification.

- *4* Machinability index
- *9* Damping capacity

L Testing
- *1* Metallography (included only for metals not dealt with in an article on metallography)
- *2* Radiography
- *3* Corrosion tests
- *4* Mechanical tests (included only when some special method of testing is involved)

M Composition Limits
- *1* Quotations from commercial specifications
- *2* Consequences of exceeding impurity limits

N Working Data
- *1* Melting temperature
- *2* Casting temperature
- *3* Alloying practice
- *4* Preferred deoxidizers
- *5* Type of flux
- *6* Precautions in melting
- *7* Hot working temperature
- *8* Shortness temperature
- *9* Annealing temperature
- *10* Maximum reduction between anneals
- *11* Suitable forming methods
- *12* Precautions in forming
- *15* Heat treatment
- *17* Suitable joining methods

The data sheets for the several groups of nonferrous alloys begin on the following pages:

Aluminum 810
Wrought Alloys 811
Casting Alloys 824
Copper 903
Wrought Alloys 909
Casting Alloys 935
Lead and Lead Alloys 960
Magnesium and Magnesium Alloys 1013
Nickel and Nickel Alloys 1046
Tin and Tin Alloys 1070
Zinc and Zinc Alloys 1086
Precious Metals 1110
Silver and Silver Alloys 1110
Gold and Gold Alloys 1116
Platinum and Platinum Alloys 1121
Palladium and Palladium Alloys 1126
Other Precious Metals 1130
Miscellaneous Metals 1133

METALS HANDBOOK

1948 EDITION

AMERICAN SOCIETY FOR METALS
